If the above hypothesis be correct then it should be possible to show that there is a signif- cant cross reaction between antibodies to unfolded γ-globulin of species A with simil unfolded γ-globulins of species B, C, D, &c. Fig. 2 shows diagrammatically how the commo grouping might become exposed when, for example, agglutinating antibody from fo different species reacts with rabbit red cells. To test the hypothesis, rabbits were immunized b intravenous injections of rabbit red cells suspended in saline after agglutination by the natural occurring antibodies in sheep, human, horse and guinea-pig sera respectively. The exte to which the antibodies so produced cross-react when brought into contact with antibod combined with its specific antigen was tested by using each of these sera as a Coombs seru to agglutinate human O Rh D +ve cells pre-treated with incomplete anti-D. The result are shown in Table III. Since such a degree of cross-reactivity could not be expected to occu

with free globulin the results must be interpreted as showing the exposure of common non-specific groupings when the antibody reacted with its antigen, in this case the anti-D globulin with the D groupings, on the red cells.

The appearance in the serum of rheumatoid arthritics of a factor with properties similar to those induced in the rabbit sera in the above experiments suggests that it, too, is an antibody to the non-specific groups of immune γ-globulin. It is, therefore, to be regarded as a form of auto-antibody; not to a normal body constituent but to one already modified by a form of denaturation.

TABLE III.—REACTION OF RABBIT ANTISERA TO GLOBULINS OF DIFFERENT SPECIES WITH HUMAN RED CELLS SENSITIZED WITH INCOMPLETE ANTI-D SERUM

No.	Rabbit antisera to	Agglutination titre with human red cells

Professor D. H. Collins (Sheffield): I agree with Dr. Tegner that the diagnosis of rheumatoid arthritis can sometimes be made from nodule biopsy; once, in my own experience, even a few months in advance of clinically manifest arthritis. The lesion of granuloma annulare, though usually more superficial, is the one common source of confusion. The synovial lesion of rheumatoid arthritis, fulfilling the criteria previously enunciated (Collins, D. H., 1949, *Proc. R. Soc. Med.*, **42**, 731) is really very characteristic, but I prefer to use the words "rheumatoid type of synovitis" in the biopsy report, leaving the clinician the right to his own convictions about what is or is not rheumatoid arthritis.

The symposium has shown some of the ways in which we are learning more about the nature and mechanism of a mysterious disease. Unfortunately we are still far from having any information about its cause or causes. Much intellectual effort can be wasted talking about hypothetical "collagen diseases" and mutually comparing rheumatoid arthritis, disseminated lupus, systemic sclerosis, polyarteritis and so forth, because one can only

compare an unknown with other unknowns. The methods of morbid anatomy and histology have probably never revealed the cause of any disease without the pathologist considering collateral evidence or being able to compare the unknown with something that is known.

Dr. Brian Lacey (The John Burford Carlill Pathological Laboratories, Westminster School of Medicine):

Knudsen and Thomas (1957) recorded raised red cell potassium levels in rheumatoid arthritis. Besides its intrinsic interest for those studying pathogenesis, this finding seems likely to prove of great help, complementary to that given by serological and histological examinations, in sorting out these conditions.

KNUDSEN, E. T., and THOMAS, M. J. (1957) *Lancet*, i, 251.

Dr. John H. Glyn (The Arthur Stanley Institute): One speaker has stated that the presence of L.E. cells in a patient's blood is conclusive evidence that the patient is suffering from systemic lupus erythematosus. As clinicians, I think we are entitled to challenge this conception since we are all familiar with cases of chronic and typical rheumatoid arthritis where this phenomenon is found coincidentally. In such cases it has not seemed to bear sinister prognostic implications so far. A recent study of this test by Kievits *et al.* (1956) arrived at a similar conclusion in relation to individual cases.

We have indeed been studying one very interesting patient who attended out-patients for a check-up following a short period of vague rheumatic symptoms. She was concerned about these symptoms because her sister had recently died of systemic lupus erythematosus. In the last year L.E. cells have been found in this girl's peripheral blood on four separate occasions and during this period she has been devoid of symptoms or physical signs. We are naturally watching this patient very carefully.

Dr. H. J. Gibson (Bath): It was interesting to note that Dr. Cruickshank found focal lesions in muscle to be among the most frequent extra-articular abnormalities in his post-mortem series. It is nearly ten years since I put forward evidence that rheumatoid myositis was part of the disease in a high proportion of cases. Many workers since then have regarded the lymphorrhages as "non-specific". Does Dr. Cruickshank consider the focal lymphocytic lesions in muscle to be as much a part of rheumatoid disease as the lymphocytic foci of the synovial membrane?

Dr. L. E. Glynn has put forward evidence that the antigenic quality of an antibody is modified by attachment to its antigen and that the Rose-Waaler factor may be an auto-antibody. How does he explain the many examples which have been found of antibodies which do not act as sensitizers for the Rose-Waaler system?

Dr. D. A. Brewerton (King's College Hospital) stressed the importance of muscle involvement. In a recent clinical survey of hand deformities, 13% of 300 patients had contractures of the intrinsic muscles of the hand. One of these patients had presented with muscle contractures before there was clinical or radiological evidence of joint involvement. In the same series 64% of the patients had clinically demonstrable tendon lesions in the hands.

Still's Disease with Pseudoxanthoma Elasticum.—Stephen C. Gold, M.D.

S. O., aged 9 years and 10 months, developed Still's disease at the age of 14 months, starting with pain in the right knee, fever, lymphadenopathy and rash. There was also some swelling of the feet and hands. There was a further period of activity at the age of 3½ years, with abdominal pain (laparotomy was performed, with negative findings) and with the later development of pericarditis, fever, polyarthritis and anæmia (hæmoglobin 58%). She made a satisfactory response to cortisone therapy.

She was first admitted to the Special Unit at Taplow under the care of Dr. E. G. L. Bywaters in 1952, with an acute relapse of the arthritis and fever. There was also lymphadenopathy, a typical Still's rash, high erythrocyte sedimentation rate and an iron refractory anæmia. She was discharged symptom free, taking cortisone 37·5 mg. daily with aspirin. The cortisone had to be reduced following a wedge fracture affecting the eighth thoracic vertebra in November 1954, and finally it was stopped following a hæmatemesis in January 1955. In May 1955 the patient went into a remission following an attack of measles.

She was readmitted in July 1956 with pericarditis, acute arthritis, a Still's rash, fever, leucocytosis and a severe anæmia. The erythrocyte sedimentation rate was 110 mm. in the first hour (Westergren). Butazolidin treatment produced no improvement, and in October she was put back on to hydrocortisone systemically, on which she made a rapid improvement. At the present time she is virtually symptom free, despite continued activity of the disease. At the moment she is taking 40 mg. of hydrocortisone daily and is having active physiotherapy. The joints which are involved are the cervical spine, temporo-mandibular, elbows, wrists, hips, knees, ankles and feet. The hæmoglobin is now 87%, and her erythrocyte sedimentation rate 80 mm. in the hour.

Pseudoxanthoma elasticum.—On July 19, 1956, at a time when the Still's disease was very active, her lips and face swelled up, followed by apparent whealing at the sides of her neck and bends of her elbows. These erythematous lesions itched severely, and persisted for a few days before a well-defined area with serpiginous edges became apparent; there was a surrounding erythema. Within a week the central area became moist and raw, and a few other lesions developed on both forearms. There was a serosanguineous discharge from the centre of these lesions, which, when they started to heal, became less irritable and appeared scaly. When first seen by me (S. C. G.) the areas involved showed a yellowish discoloration, with some superficial scarring at the sites that had previously discharged. The surface resembled chamois leather, and the distribution and general appearance suggested a clinical diagnosis of pseudoxanthoma elasticum. In spite of a negative family history and absence of other signs confirmatory of this disease, a biopsy specimen of skin was taken, and revealed, histologically, changes compatible with pseudoxanthoma elasticum.

Comment.—So far as I have been able to ascertain no similar case has been recorded. It is an important point to realize that the apparent pseudoxanthoma elasticum developed when this patient's Still's disease was at its height and the skin process appeared to become less acute as the Still's disease was controlled by steroid therapy. It is unusual to see ulceration and discharge in pseudoxanthoma elasticum but this has been recorded and is generally in association with marked calcification of the dermis. To-day, the skin appearances are hardly characteristic of pseudoxanthoma elasticum. The yellowish colour is scarcely apparent, but signs of previous ulceration are still to be seen.

Dr. **H. Haber:** This is a very unusual case from the clinical point of view. Histologically, however, one has to accept the case as pseudoxanthoma elasticum. The corium exhibits marked cellularity due to inflammatory changes. Stain for elastica reveals the characteristic changes found only in this condition. The elastica shows fragmentation and curling of its fibres. Silver stain reveals the elastica to be heavily calcified.

The **President:** Pseudoxanthoma elasticum may have a systemic distribution with subsequent sclerosis affecting the heart and blood vessels of the limbs and the viscera. As far as I know, the connective tissue of the joints has not been involved.

It has been suggested that the altered fibres in pseudoxanthoma elasticum are in reality degenerated collagen which takes up the elastic fibre stain (Hannay, P. W., 1951, *Brit. J. Derm.*, **63**, 92).

If this were so in this case, it would indicate a relationship to the collagen changes in Still's disease.

Dr. F. F. Hellier: I do not think that this condition is a true pseudoxanthoma elasticum but that it is some other abnormality of the elastic tissue which gives a similar histological appearance.

Dr. P. J. Hare: I wonder whether there is any evidence that this is a fatty degeneration of elastic tissue which would readily calcify and whether it could act as a cause of the inflammatory reaction which is so striking in the section.

Xeroderma Pigmentosum.—STEPHEN C. GOLD, M.D.

This young woman of 24 recently arrived from Cyprus. Her parents were aware of abnormal freckling of her skin on the areas exposed to bright light since early childhood, and at various periods as she grew up, nodules appeared which have been destroyed by various local means. There is no family history of such a condition, and there is no consanguinity of her parents.

When she attended St. John's Hospital for Diseases of the Skin in December 1956 she presented a classical appearance of xeroderma pigmentosum on the face, neck, dorsal surfaces of her hands, and forearms. There was marked freckling, patchy atrophy and some telangiectasia throughout these areas, while scattered, particularly on the face, were small, crusty lesions suggestive of keratomata, rodent ulcers; there was one larger lesion under the left eye, elevated and dark, apparently increasing in size more rapidly than any other, which clinically suggested the diagnosis of malignant melanoma. There has also been some recent tendency of this lesion to bleed on trauma.

Several biopsies have been performed, and the large lesion has been completely excised. Histologically, the clinical diagnosis of the various tumours was confirmed. The large one proved to be a malignant melanoma, and in the same biopsy specimen there was evidence of a rodent ulcer at the edge of this malignant melanoma. There were many keratomata, as well as small rodent ulcers. Most of these have been removed, but there are one or two still awaiting attention.

This case is presented because it is so typical and also to stimulate discussion on the future handling and on any recommendations which should be made in order to discourage further tumour formation.

Dr. H. Haber: Xeroderma pigmentosum is a condition due to extreme intolerance of the skin to sunlight. White people living in tropical countries show similar changes when their skin breaks down after a prolonged exposure. But even in these cases one has to postulate individual tolerance to light as shown by different degrees of damage produced by people living under similar conditions in the tropics.

The changes produced consist of atrophy, hyperkeratosis and disturbance of pigmentation. Malignant changes in form of keratomas, basal cell epitheliomas and squamous cell epitheliomas are features of the condition. Pigmentary changes lead to freckles, the formation of lentigines, malignant lentigines and malignant melanomas.

Sections of this case show ample evidence of the outlined changes.

Dr. F. F. Hellier: I would like to refer to an interesting case under Dr. J. T. Ingram's care which is somewhat similar to this. It is a young girl who shows multiple appalling tumours on her face but this girl is a complete albino so that her face is quite white. Section of one of the tumours has shown it to be a basal cell carcinoma but it is probable that others are squamous epitheliomata. The condition seems to be a form of xeroderma pigmentosum without pigment. She is to have surgical treatment but this has been delayed because her hæmoglobin is only 19%.

Xeroderma Pigmentosum.—H. SCHWARTZ, M.D. (for HUGH GORDON, M.C., F.R.C.P.).

Miss G. T., aged 17.

This patient was first noted to have a generalized mottled pigmentation shortly after birth. Her brother, four years older, was also considerably freckled but the degree was much less and the onset later in life.

She first attended the Royal Marsden Hospital in 1946 for X-ray treatment of an epithelioma near the left angle of the upper lip (Figs. 1 and 2). Further epitheliomata on the face were successfully treated also by X-rays in January 1948, September 1948, and August 1951. A lesion on the left calf was excised in 1951 and another from the right shin in 1953.

A recurrent and occasionally painful inflammation of the conjunctivæ has existed since 1951 and has been resistant to treatment.

Since 1948 (Figs. 3 and 4) she has been wearing a cosmetic light screening cream compounded by Dr. D. W. Smithers and Mr. J. H. Wood (Chief Pharmacist at the Royal Marsden Hospital):

	%
Titanium dioxide ..	25
Magnesium stearate ..	12·5
Butyl stearate	12·5
Menthyl salicylate ..	20
Pigment base	2
Vanishing cream ..	28

FIG. 1.—November 1946, aged 6.

FIG. 2.—November 1946, aged 6.

FIG. 3.—June 1949, aged 9.

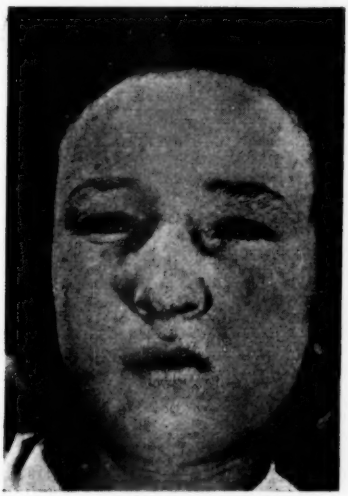

FIG. 4.—July 1951, aged 11.

Figs. 2 and 4 are reproduced from Smithers and Wood (1952) by kind permission.

Comment.—This patient's maternal and paternal grandfathers were brothers and her mother and father therefore were first cousins. In 1952, Smithers and Wood published details of the case under the title "Xeroderma Pigmentosum. An attempt at cancer prophylaxis", and she is being shown to demonstrate the continued effectiveness of the cover cream compounded by them and now manufactured commercially. I believe the cream currently in use also contains 2% of iso-butyl-para-amino benzoate, but it is my opinion that its light screening efficacy is more related to the high powder content (titanium dioxide) acting as a mechanical barrier to light rather than to the alleged light absorbing properties of the other contained compounds.

Since she began using her cream only one epithelioma has developed on a cream-protected area, although two others occurred on parts of the body much less exposed to light.

REFERENCE.—SMITHERS, D. W., and WOOD, J. H. (1952) *Lancet*, , 945.

Dermatomyositis.—B. SCHWARTZ, M.D.

Mrs. I. N., aged 44.

In November 1956 this patient, who had no previous history of skin disease, was referred to Dr. Stephen Gold because of the development, following a tooth extraction two weeks previously, of an irritating skin rash over the arms, chest, thighs and hands and some puffiness of the face and pains in the legs.

Past medical history.—A left radical mastectomy with bilateral oophorectomy was performed in April 1956 and the sternal and axillary areas were subsequently subjected to deep X-ray therapy.

On initial examination.—She was afebrile and showed: (1) Pronounced erythema with some telangiectases symmetrically placed over the chest, thighs and arms with streaky lesions over the dorsum of the fingers and telangiectases around the nail folds. (2) Swelling of the periorbital tissues. (3) Marked muscular weakness of the limbs and back.

A diagnosis of dermatomyositis was made and she was admitted to hospital for further observation.

Investigations.—Urine: No abnormality. Blood pressure 125/95.

Blood count: Hb 96% (14·2 grams per 100 ml.); W.B.C. 5,800; P. 63, L. 31, M. 5, B. 1%. No L. E. cells were seen in the peripheral blood.

Blood urea: 22 mg. per 100 ml.

Total serum proteins: 7·6 mg. per 100 ml.; albumin 3·3 mg. per 100 ml. Globulin 4·3 mg. per 100 ml.

A muscle biopsy from the right deltoid area showed no significant abnormality.

Treatment with prednisone 40 mg. daily resulted in rapid improvement in appearance and muscular power but there has been some recurrence since the drug was inadvertently discontinued.

Comment.—This adds further to the already growing number of cases where the occurrence of dermatomyositis has been associated with malignant disease, the initial lesion here being a spheroidal cell carcinoma of the breast.

Dr. S. Gold: This patient presented a very characteristic picture of an œdematous and red face, with linear erythema on the backs of her hands and muscle weakness of her trunk and thighs. Her breast was first removed some months ago, followed by a bilateral oophorectomy. Subsequently, following some dental treatment, the dermatomyositis developed dramatically. The question of the administration of steroids is an interesting one. The use of prednisone has certainly suppressed this patient's symptoms of dermatomyositis in the most satisfactory manner; I understand that there is nothing to suggest that the use of steroids would encourage secondary metastases.

Dr. F. F. Hellier: I should like to ask whether anyone has had experience of *transaminase*. This is an enzyme which occurs in the blood-stream when muscles are damaged and has been estimated in cardiac infarction. It gives some indication of the amount of damage to muscle in the heart and it is being used at the Mayo Clinic to estimate the activity of the disease process in dermatomyositis. It is important to know when this condition is active and when it is burnt out, if one is using steroids, as obviously one does not want to go on with them for an unnecessarily long time.

The following cases were also shown:

Acro-keratosis Verruciformis.—Dr. ARTHUR ROOK and Dr. DANILO STEVANOVIC.

? Neuro-fibroma.—Dr. PATRICK HALL-SMITH.

(1) Necrobiosis Lipoidica, (2) Leuconychia Congenita, (3) Nævus of Ota, (4) Porokeratosis (Mibelli).—Dr. STEPHEN GOLD.

Benign Mucous Membrane Pemphigoid.—Dr. LOUIS FORMAN.

Section of Experimental Medicine and Therapeutics

President—Professor C. A. KEELE, M.D., F.R.C.P.

[*February* 12, 1957]

Chemical Causes of Pain and Itch

PRESIDENT'S ADDRESS

By Professor C. A. KEELE, M.D., F.R.C.P.

PAIN and itch are unpleasant sensations which are readily distinguished from other cutaneous sensations such as touch and temperature, and can usually be distinguished from each other, particularly because cutaneous pain leads to reflex withdrawal, and itching provokes the desire to scratch.

Both sensations can be elicited by physical and chemical stimuli and several investigators, e.g. Rothman (1941, 1954) and Bishop (1946, 1948), have pointed to numerous factors which pain and itch have in common. After leaving the skin the nerve pathway mediating itch runs to the spinal cord and accompanies the fibres subserving pain in ascending the antero-lateral tracts. Bickford (1937–38) showed that cordotomy abolished both pain and itch, but not touch, and he observed similar sensory dissociation in patients with syringomyelia. Critchley (1956) has reported that in persons with congenital indifference to painful stimuli itching is also absent.

There is also much evidence, from common experience and from experimental studies, showing a close functional relation between pain and itch. Many stimuli to the skin can produce itch when the intensity is low and pain when the intensity is high. Bishop (1946) applied electrical stimuli to a single pain spot and reported that passage of a weak constant current, or repeated weak shocks, produced itch, whereas a stronger stimulus produced pain. Hardy *et al.* (1950) found that prolonged application of heat at an intensity below threshold for pain, produced itching. It has therefore been suggested that itch is, in fact, subthreshold pain.

Lewis *et al.* (1927–29) attributed the itching produced by such physical stimuli to the release of histamine or H-substance. However, it is by no means clear that the production of itch by low intensity physical stimulation is always chemically mediated, and where such stimuli produce itch without obvious vascular changes in the skin it is difficult to exclude a direct action on the appropriate nerve receptors.

Other points of resemblance have been made by Hardy *et al.* (1952). They have gone farther than Lewis in ascribing two qualities to superficial pain, namely pricking and burning, and have reported that pricking pain is abolished by ischæmia before burning pain. They have also distinguished pricking and burning types of itch, and suggest that *pricking* pain and itch are conveyed by fast-conducting nerve fibres and *burning* pain and itch by slow-conducting fibres.

A most important factor influencing the occurrence of pain is *hyperalgesia.* When tissues are damaged the sensitivity of pain nerve endings increases and normally subthreshold stimuli become painful. Hardy *et al.* (1950) have distinguished between the *primary* hyperalgesia of the actually damaged tissues, in which pain threshold is lowered, and the surrounding *secondary* hyperalgesia in which pain threshold is normal but the response to a painful stimulus is exaggerated. The secondary hyperalgesia corresponds to the spreading nociensor tenderness of Lewis, but Wolff attributes it to changes within the spinal cord induced by stimuli from the damaged area. Bickford noted that when itching was induced in the skin by a gnat bite or by histamine, the area of *spontaneous* itching was surrounded by a much larger area of *itchy* skin in which itching was very readily set up by light friction. The itchy skin corresponds to the secondary hyperalgesia just referred to and is likewise attributed to activity in the spinal cord.

Now although pain and itch have much in common they are in many ways mutually exclusive. When pain occurs spontaneous itching is depressed or abolished, provided the

pain stimulus is applied within the area of itchy skin. This is the rationale of scratching. Further, in an area of primary or secondary hyperalgesia neither spontaneous itch nor itchy skin can be established.

In certain respects pain and itch are quite distinct from each other. (1) Each has its own peculiar quality, and has a wide range of intensity from the just perceptible to the completely intolerable, and as Lewis pointed out both may be experienced simultaneously. (2) Superficial pain leads to reflex and voluntary evasive movements and itching to scratching movements. (3) Lewis noted that immersion of skin in water at 40–41° C. alleviated itching but aggravated burning pain. (4) Morphine, while relieving pain can actually make itching worse, whereas the converse is true of the barbiturates. (5) Itch cannot be elicited from skin after removal of the epidermis.

Lewis (1942) was not only convinced that itch and pain are separate phenomena, but also wondered whether superficial and deep pain should not be regarded as different sensations. I shall return later to the relation between depth of receptors and type of sensation, in the light of our own work on pain-production by chemical agents.

Chemical Factors in the Production of Pain

The production of pain by chemical factors has been little studied experimentally because it is difficult to make repeated applications of the substances under investigation, and to obtain accurate measurements of the results. We know of course that surface application of strong irritants such as chloroform, acids and alkalis, produces severe and painful damage in the skin and mucous membranes, and that injected solutions of certain drugs, such as organic arsenicals and mercurials, and of hypo- or hypertonic solutions will produce pain in both skin and deeper structures. Other examples of *extrinsic* pain-producing materials are nettle stings and certain venoms, such as wasp venom, which I shall mention later.

It is, however, more important to consider the possibility of pain-production by *intrinsic* chemicals, substances derived from living body fluids and tissues. Consider, for example, the pain of *peptic ulcer*. It is natural to suspect that pain in this condition is due to the action of the acid gastric juice on the ulcerated surface, and the relief of this pain by administration of antacids supports this view. Moreover, Palmer (1926), and Bonney and Pickering (1946–48) have reported that administration of HCl at pH of 1–2 produces pain in many patients with ulcer, and that when spontaneous ulcer pain occurs the pH of the gastric contents is markedly acid.

To take another illustration—the pain and tenderness in *ischæmic muscle*. MacWilliam and Webster (1923) suggested that the pain which develops when muscles are worked under ischæmic conditions might be due to metabolic products of activity. Lewis *et al.* (1931) developed this view and postulated a "factor P" as the stimulus to pain. Factor P is presumed to arise from metabolic activities in muscle fibres and to diffuse thence to the extracellular space where stimulation of pain nerve endings takes place. The steady increase of pain during ischæmic muscular work is attributed to accumulation of factor P in the tissue spaces, and the very rapid relief which follows restoration of the circulation to the speedy dispersal of this substance. Lewis did not identify factor P and suggestions by others that it is lactic acid or potassium have never been confirmed.

The chief interest in this type of pain lies in the explanation which it offers for the pain which accompanies activity in skeletal and cardiac muscle in the presence of obstructive arterial disease. The pain of intermittent claudication in the limbs, and of angina pectoris, are both typically provoked by exertion and relieved by rest. With sudden complete occlusion of an artery, as in coronary thrombosis, the onset of pain is similarly produced but it cannot, of course, be relieved by rest.

Inflammation is another state in which it has been postulated that pain is provoked by chemical agents. Dolor was one of the cardinal features of inflammation mentioned by Celsus, the others being rubor, calor and tumor. Whilst much work has been done on the factors which may account for the vasodilatation and increased permeability of the inflammatory response, much less attention has been paid to the processes by which pain arises in this state, though it is commonly said that the pain is due to increased tension in the inflamed tissues. Now whilst there may certainly be an increased tension in an inflamed area this factor cannot directly provide more than a partial explanation since the outstanding feature of an inflammatory process is the marked *hyperalgesia* which it induces. In inflamed tissues the pain threshold is much reduced and stimuli which are not painful in normal tissues may be very painful in the affected region. The hyperalgesic state may be such that even arterial pulsation can produce a severe throbbing pain with each heart beat.

Sometimes an inflamed area is spontaneously painful, that is pain is present without application of an external stimulus, or when the inflamed part is completely at rest. Lewis (1942) suggested that in such cases the chemical agents which produce hyperalgesia have reached a sufficiently high concentration to stimulate the pain nerve endings on their own.

One of the examples which Lewis gave to support the idea of chemically induced pain was the delayed pain which follows a heat burn. After the intense physical stimulus of the heat the sharp peak of pain often subsides to zero, and then after 15–60 seconds pain returns, builds up to a moderate intensity within a few minutes, and then slowly subsides again. After this there is no more spontaneous pain but there is frequently hyperalgesia. The subsequent hyperalgesia resembles that produced by other forms of injury such as occurs after excessive cooling (−15° C.), exposure to ultraviolet light, scratching and infective and allergic inflammatory processes.

Lewis showed that when there was cutaneous hyperalgesia following injury spontaneous pain could be aroused either by warming the skin to 30–35° C. or by occluding the circulation to the affected part. He suggested that in both these cases the spontaneous pain was produced by an increased local concentration of metabolites, the raised temperature increasing their production and the ischæmia preventing their removal. However, as pointed out by Nathan (1953) occlusion might act by increasing the sensitivity of the pain nerve fibres, so that pain could occur without any increase in concentration of pain-producing metabolites.

So far there have been no suggestions as to what these metabolites are. Lewis merely said that he did not think histamine was concerned. He found that aqueous extracts of skin caused pain on intradermal injection but did not identify the active principle.

Experimental Work on Pain-producing Substances.

At the Middlesex Hospital Medical School, with my colleagues Miss Desirée Armstrong, Dr. J. B. Jepson and Dr. J. W. Stewart, we have been investigating the possible role of intrinsic chemical factors in the production of cutaneous pain with particular reference to substances which develop in blood (Armstrong *et al.*, 1957).

In conjunction with Drs. Dry and Markham (Armstrong *et al.*, 1953) we first studied various methods for producing pain by chemical agents. Lewis had administered histamine and other substances by *pricking through a drop of solution* placed on the skin, but we soon found that this mode of application was unsatisfactory since pain was not produced by substances which were very active when given in other ways. We also tried *intradermal injection* which was certainly effective with most substances which we tested. However, we sometimes observed irregular responses, such that isotonic saline might occasionally be painful and normally painful solutions ineffective. Of course, with sufficiently numerous injections such irregularities could be taken account of, but our subjects (I was one of them!) did not seem to enjoy receiving the large number of injections needed to give statistically significant results. Further, it was obviously dangerous to inject inflammatory exudates which might be contaminated with bacteria or foreign materials to which the subjects might become sensitized. So we developed what was for our purposes a better method, in which the substances to be tested are applied to the exposed base of a blister produced by cantharidin.

Blister area.—Cantharidin plaster, 0·3% and about 1 cm. in diameter, is applied to the skin of the forearm for four to six hours in the evening. By the next morning a blister has usually developed. The fluid (about 0·2 ml.) is aspirated, the raised epidermis is removed and the base of the blister is then available for testing. Dr. J. Boss has shown that all but the basal epidermal cells are removed and that the cells of this layer tend to be separated from each other though still attached to the basement membrane. The nerve fibres which end in the epidermis will be ruptured during blister formation but deeper nerve terminals will remain intact.

The area is bathed in Locke's solution which does not produce pain. This solution is removed at intervals (usually ten minutes) to allow application of the test materials. We have found this technique to be very reliable and sensitive, and the effect of a given solution is reproducible during an experimental session lasting one and a half to two hours. The subject of course does not know the nature of the applied materials and on some occasions the experimenter has also been kept in ignorance.

We are aware that the blister base is not a normal tissue and that it might be hypersensitive to certain agents, but since pain often occurs in already damaged tissues the conditions of our tests are reasonably relevant. The constancy of response to a given concentration of a standard agent is of great value in assessing the rise and fall in activity of labile pain-producing fluids such as inflammatory exudates and plasma. Solutions need not be sterilized as they are rapidly removed, but we have naturally avoided heavily contaminated materials.

We have obtained much useful information from the blister area which has most of the advantages of an isolated organ preparation combined with the very unusual property of remaining attached to the rest of the body.

I will now describe the effects of various pain-producing agents as tested on the blister area.

Acetylcholine (ACh).—When different amounts (in Locke's solution) are applied to the blister area pain is produced with concentrations from 10^{-5} g./ml. upwards. The pain is commonly immediate in onset, smarting or stinging in character, rapidly reaches a peak and then subsides to zero within 30–60 seconds. The effects of different doses are graded.

Potassium chloride.—Solutions, from 0·1 to 1%, produce pain rather similar to that seen with ACh but the effect comes on a little more slowly and lasts rather longer.

Tonicity.—Marked deviations from physiologically normal osmotic pressure also produce pain. With decreasing concentrations of NaCl pain occurs at about 0·3% NaCl and with increasing concentrations at about 3% NaCl.

Acidity.—When acid solutions are applied to the blister area pain is not produced until the pH falls to about 3–3·5.

Histamine.—The part played by histamine in tissue reactions, and claims by Rosenthal that it is the mediator of cutaneous pain led us to test this substance on the blister area.

Briefly, we have found that in concentrations of 10^{-5} g./ml. or higher it can produce transient pain (which is sometimes severe with 10^{-3} g./ml. concentration) the pain being followed by itching. Itching alone occurred with concentrations from 10^{-5} to 10^{-7} g./ml. Whenever there were sensory effects weal and flare were also seen.

It is difficult to know whether histamine release in skin or other tissues ever produces concentrations high enough to cause pain. Certainly, the classical instance of *in vivo* release of histamine, namely the urticarial weal, is accompanied not by pain but by itching. However, one cannot exclude the possibility that with more severe tissue damage, high, pain-producing concentrations of histamine might be released at first, but in these circumstances other pain-producing agents might also be present.

Substance in Inflammatory Exudates

In the course of our earlier work we collected the fluid from the blister into a glass tuberculin syringe and in some experiments we reapplied this fluid to the exposed blister base, at first regarding this as a control application. However, we were surprised to find that on many occasions the blister fluid produced marked and prolonged pain after a latent period of 15–45 seconds. On other occasions blister fluid did not produce pain and eventually we found that when the application was made within one hour of aspiration the fluid was almost invariably painful whereas after one hour it was not. Thus the pain was produced by an unstable constituent of blister fluid.

At first we thought this substance might be 5-hydroxytryptamine (serotonin, 5-HT). We therefore tested blood serum which was known to contain 5-hydroxytryptamine and found that this produced pain similar to that evoked by blister fluid, plasma being negative in these experiments. Platelet extracts also produced pain. By this time we had obtained synthetic 5-HT which produced the same type of pain as blister fluid and serum, 5-HT being effective in concentrations of 10^{-6} to 10^{-7} g./ml. and occasionally at 10^{-8} g./ml.

Now since 5-HT is known to be very active in causing contraction of the isolated rat uterus we applied blister fluid to this preparation and observed uterine contractions. However, we soon found several respects in which the active substance in blister fluid differs from 5-HT. For example, the substance in blister fluid is unstable, but 5-HT is stable in this fluid; the action of 5-HT on the rat uterus is antagonized by dihydroergotamine and lysergic acid diethylamide, that of blister fluid is not; and acetone which extracts 5-HT from protein-rich fluids precipitates the activity of blister fluid with the proteins.

Thus we had found that both serum and blister fluid contained pain-producing agents, that in serum being a stable compound of known structure, namely 5-HT, that in blister fluid being an unstable substance of unknown composition. We then found that the activity of blister fluid could be preserved by deep-freezing which meant that we could keep such fluids until it was convenient to test them.

We still had to consider the question—why is a blister not painful?—for such is the case. To study this point we tested fluid immediately after withdrawal from a blister and found that it did not cause either pain or uterine contraction but that after a short while it did both. Thus the pain-producing, uterus-stimulating activity developed only after collection of the blister fluid into the glass syringe. Blister fluid was inactive *in situ*, and was activated after a few minutes in a glass syringe, the activity reaching a peak after 5–10 minutes and then declining.

We soon found that other *inflammatory exudates* such as a pleural effusion and joint fluid from patients with rheumatoid arthritis behaved just like blister fluid (Argent *et al.*, 1954). Finally we found (Armstrong *et al.*, 1957) that blood plasma responded in the same way. (Our original negative responses to plasma were due to testing more than one hour after collection of the blood, when the pain-producing substance had come and gone.)

Thus it seems likely that the pain-producing activity of inflammatory exudates is due

to their derivation from plasma in which the fundamental process of activation by glass can be much more conveniently studied. Heparin does not affect this activation of plasma. When blood is collected into a siliconed syringe, transferred to polythene centrifuge tubes containing heparin, and spun at 4,000 rev./minute for 15–20 minutes, the upper half of the plasma contains no red cells or leucocytes and very few platelets. Such plasma does not cause pain or contract the rat uterus (we call it "preactive" plasma), but when transferred to glass it is activated exactly as described for the exudates. Thus virtually cell-free plasma can form a powerful pain-producing substance when brought into contact with glass.

And now for the nature of this substance. Using ultrafiltrates, and aqueous and alcoholic extracts of active plasma, we have found that from its physical, chemical and biological properties the pain-producing substance (PPS for short) appears to be a polypeptide, closely resembling the substance "bradykinin" described by Rocha e Silva *et al.* (1949). Bradykinin is made by the action of trypsin or proteolytic snake venom on plasma α_2-globulins. Plasma PPS resembles bradykinin in that it, or something very similar, can be formed by the addition of trypsin to preactive plasma; the proteolytic enzyme of plasma, called plasmin or fibrinolysin, acts in the same way. Activation of plasma by contact with glass or by addition of trypsin or plasmin, is inhibited by the soya bean trypsin inhibitor.

All these findings suggest that the fundamental process in the formation of PPS is activation of a proteolytic enzyme in plasma. The rapid decay of the substance is presumably due to the presence of a peptidase in plasma (Armstrong *et al.*, 1957).

Mediators of Pathological Pain

Next, I shall consider how far these various chemicals can account for pathological pain. It seems to me unlikely that there is a single chemical mediator for all types of pain, and comparisons with the role of ACh or noradrenaline as transmitters, or of histamine in anaphylactic shock, are over-simplifications.

Nettle stings.—Emmelin and Feldberg (1947) showed that nettle stings contain high concentrations of ACh and histamine which could certainly produce the initial stinging pain. The itching and triple response would of course be due to the histamine. Recently, Collier and Chesher (1956) have shown that nettle stings also contain 5-HT in amounts which could produce pain of longer duration. It is also intriguing to hear that Brittain and Collier (1957) have found an antagonist to 5-HT in dock leaves!

But even with three pain-producing agents it is still difficult to explain why the pain following nettle stings may last for some hours. It seems possible that a proteolytic enzyme called solanain, which occurs in nettle stings, might contribute to the picture by forming pain-producing polypeptides from plasma and tissue proteins.

Wasp venom.—Jaques and Schachter (1954) have shown that wasp venom contains, in addition to high concentrations of histamine and 5-HT, a pain-producing polypeptide named kinin. There is no difficulty here in accounting for both pain and local tissue reactions in terms of these substances.

Among other venoms, *bee* venom contains much histamine, but no 5-HT, and *scorpion* venom contains enough 5-HT to produce pain (Adam and Weiss, 1956).

The possible role of the intrinsic pain-producing factors.—This is necessarily speculative as there are no technical means of measuring local release of these substances while pain is occurring. To me it seems most likely that pain resulting from tissue damage could be due to histamine (in high concentration), 5-HT and the plasma PPS, though in the special case of peptic ulcer HCl can play a part, and it would be difficult to exclude the contribution of released potassium from damaged cells.

Histamine would be liberated from damaged mast cells, and perhaps 5-*HT* as well, but release of the latter could arise in another way. Trauma damages capillary endothelium which then becomes sticky. Leucocytes and platelets adhere to the damaged endothelium, the platelets disintegrate and release 5-HT in high local concentration. If blood escapes into the tissues release of 5-HT from platelets would also occur. The work of Beloff and Peters (1945) shows that tissue damage releases an active proteolytic enzyme in skin and if such an enzyme acted on plasma it could form the pain-producing polypeptide. Tissue cells also contain an activator of the proteolytic system of plasma.

It is interesting to note that histamine, 5-HT and the plasma PPS form a mixture almost identical with that found in wasp venom. It is as if such an unholy trinity had been evolved by Nature as the most reliable recipe for pain!

Apart from the production of actual pain by these chemical agents it is probable that all three can also produce hyperalgesia. Another factor which increases the sensitivity of the pain endings is ischæmia of the nerve fibres, so in an area of tissue damage with accompanying œdema there are several influences tending to cause pain.

The hyperalgesia of inflammation underlies the pain associated with many conditions.

The pain of peptic ulcer is determined not only by acid, but even more by the sensitivity of the inflamed ulcer (Kinsella, 1953; Smith, 1955); migraine is due to stimulation by distension of temporal periarterial nerve endings made hypersensitive by plasma PPS (Osterfeld *et al.*, 1955); toothache is due to increased tension in an inflamed pulp. Finally, I would like to suggest that the pain of coronary occlusion is due not only to Lewis' factor P but also to the 5-HT and PPS which will be liberated in the acute inflammatory process, and at the same time the pain nerve endings will be rendered hyperalgesic as the result of ischæmia of the nerves.

Chemical Production of Itch

The first substance one thinks of in this connexion is *histamine*. When Lewis and his colleagues were studying the cutaneous vascular actions of histamine they naturally noted the itching which it produces when pricked into the skin. When the release of histamine or H-substance was postulated as a feature of the response to mild tissue injury or to cutaneous allergic reactions of the urticarial type, the argument was supported by the occurrence of itching in these states. Lewis also noted the itching associated with the triple response provoked by introduction of morphine into the skin and itching has been recorded with other histamine liberators such as tubocurarine, compound 48/80, and certain diamidines used in the treatment of trypanosomiasis.

In *urticaria* itching is a regular occurrence, and it is significant that it is most marked before or during the early phase of development of the weal. This shows that the sensory effect is not due to mechanical distension of the skin. In *dermographia* histamine release is usually unaccompanied by itching. These differences have been attributed by Broadbent (1953, 1955) to differences in the site of liberation of histamine. In urticaria the release of histamine is just beneath or partly in the epidermis, which leads to itching, whereas in dermographia the release occurs deeper in the dermis away from the superficial itch receptors. The deeper nerve endings contain pain receptors which, as already described, are stimulated by high concentrations of histamine. In Lewis' experiments histamine was introduced by pricking through a drop of solution on the surface of the skin. This explains why he recorded itching only, without pain, whereas other investigators have reported that intradermal injection of histamine does produce pain. In our own studies on the blister base histamine probably produces itching by acting on the epidermal receptors in the intact skin surrounding the exposed area, whereas pain results from higher concentrations acting on the receptors in the dermis.

A well-known extrinsic source of itch is "itch powder" or cowhage which consists of the very fine sharp-pointed spicules or trichomes which cover the seed pods of the leguminous plant *Mucuna pruriens*. This plant was first brought to England by Hans Sloane when he returned from the West Indies in 1688, and in the eighteenth century cowhage, taken in honey or treacle, was used in the treatment of roundworms. When rubbed into the skin the powder produces marked itch, both burning and pricking in character and becoming painful at times. Itching can occur without much evidence of cutaneous vasodilatation, but often there is erythema and sometimes weal and flare. The itching is not a mechanical effect due to pricking since previously boiled spicules are not effective.

Broadbent (1953) showed that an extract of cowhage contained very little histamine, but experiments on the cat's blood pressure, the guinea-pig ileum and on human skin suggested that the active principle was a histamine liberator. Subsequently Bowden *et al.* (1954) found that cowhage also contained 5-HT in amounts which, from our experience, could account for the pain which sometimes accompanies its application.

However, more recent studies by Shelley and Arthur (1955) have shown that cowhage contains a proteolytic enzyme, which they call *mucunain*. When this was administered by intradermal injection it produced itching within 30 seconds. They have also used a simple technique for making what appears to be an intra-epidermal injection. By inserting a single cowhage spicule almost parallel to the skin surface they produced itching within 15–30 seconds without erythema or urticaria. The discovery of one pruritogenic proteinase naturally raised the question whether other proteolytic enzymes acted similarly. Arthur and Shelley (1955) have shown that intra-epidermal or intradermal administration of both plant proteinases, such as papain, and animal proteinases, such as trypsin, chymotrypsin and plasmin, can produce itching which from its speed of onset is not due to histamine release. Other types of enzymes were inactive.

This work suggests that within the body two main groups of substances could give rise to itching.

(1) *Histamine*, liberated by injury, drugs or an antigen-antibody reaction in the skin.

(2) *Proteolytic* enzymes, liberated as the result of cellular injury. It is not known whether these enzymes act directly on nerve endings or whether they liberate polypeptides in a manner similar to that described for the pain-producing substance of plasma. Proteolytic

enzymes can of course release histamine from tissues, but Shelley and Arthur's work seems to me to show that they probably cause itch in some other way. We have observed that in addition to their pruritogenic action when applied superficially to the skin, mucunain and trypsin also produce pain when applied to the deeper nerve endings exposed in the blister base.

Another aspect of chemical production of itch is the possibility of *central* itch. So far as I am aware the production of itch by the action of chemical agents on the central nervous system has not been clearly demonstrated in man, However, experiments on cats and dogs have shown that the application of certain drugs to the brain provokes marked scratching. Koenigstein (1948) showed that intracisternal injections of morphine, eserine, pilocarpine or ACh were very active in the cat, and Feldberg and Sherwood (1954) have found that intraventricular administration of diisopropylfluorophosphonate (DFP) and eserine produces signs of intense itching in the same species.

This experimental work in animals raises the possibility that certain types of itching in man might be of central origin, particularly in those instances where itching is widespread and where there are initially no abnormal manifestations in the skin. In the case of morphine, pruritus might be produced by histamine liberation in the skin or by a central action as suggested by the work of Koenigstein. However, it does not seem likely that histamine would be the cause of itching unless there was accompanying vasodilatation and wealing, since Arthur and Shelley (1955) found that after intra-epidermal administration of histamine itching never occurred without these other signs. The relief of itching by antihistamine drugs is, of course, no proof that the cause of itching is histamine release, since these drugs have well-recognized central nervous actions of a depressant nature.

The generalized pruritus of obstructive jaundice, Hodgkin's disease, chronic nephritis or diabetes cannot be explained in terms of any known chemical agent, nor indeed is it known whether the itching is due to a peripheral or a central nervous action. In the case of obstructive jaundice, the fact that bile salts are weak histamine releasers appears to be irrelevant, since Sherlock (1955) has shown that there is no constant relation between itching and the blood cholic acid level, and the itching is not aggravated by intravenous injection of bile salts. Some other, as yet unknown, factor must be involved.

With regard to the itching of skin diseases there is one condition for which one can confidently offer an explanation. I refer to urticaria, in which Lewis' original view that this was the typical lesion of histamine release has been amply confirmed by subsequent work. Antihistamines can prevent not only the itching, but the development of the flare and weal. It is more difficult to point to definite single factors to explain the itching of such conditions as eczema, atopic dermatitis and lichen planus. Histamine could, of course, be involved, so could proteolytic enzymes from the damaged cells, but there is no clear way of determining what part these (or other factors) play in any given case. It would certainly be worth while to study the effects of inhibitors of proteolytic enzymes, for example, the soya bean trypsin inhibitor, on the itching of superficial inflammatory conditions of the skin.

And now to return to the relation between pain and itch. First, something must be said about the histology of the nerve endings in the skin. Weddell and his colleagues at Oxford (Weddell *et al.*, 1955) have shown that nerve fibres end in naked axoplasmic filaments in the epidermis, and at various levels in the dermis. It was formerly thought that free, unencapsulated nerve endings were concerned only with pain, but Weddell's recent demonstrations that all forms of cutaneous sensation can be felt in skin which does not possess specialized encapsulated endings, shows that some of the free nerve endings must be involved in the perception of temperature and touch as well as pain.

Our own work on chemical production of pain and that of others on itch, can be readily linked with a distribution of free nerve endings in epidermis and different levels in the dermis. It seems to me very likely that the *intra-epidermal* nerve endings are concerned only with *itch* and the dermal endings only with *pain.*

The receptors for itch must therefore be situated on the axoplasmic filaments running between, but not into, the cells of the epidermis, penetrating as far as the stratum granulosum. These receptors can be stimulated by histamine and proteolytic enzymes, but not by other substances such as potassium or 5-HT. They can also be activated by mechanical, thermal and electrical stimuli at intensities below those which cause pain, though there may be chemical mediation in these cases. Light contact can certainly stimulate them in itchy skin. When the epidermis is removed itching can no longer be elicited, because the appropriate receptors have gone. Since the occurrence of itching is related to the so-called pain spots on the skin, and since nerve fibres conveying itch run up the anterolateral tracts of the spinal cord, it is assumed that the itch fibres, though independent of pain fibres, pursue the same anatomical pathway. The only differences are at the very periphery, and presumably also in the central nervous system where the pathways end.

With these assumptions it is easy to explain how itch can be felt at all intensities from the just detectable to the intolerable, without any element of pain. One can also explain how pain can be felt even at the lowest intensities without any trace of itch, and how it is quite possible to distinguish both sensations occurring simultaneously. These facts are much more difficult to explain on the assumption that itch is subthreshold pain (Bishop, 1948). It is, of course, true that a painful stimulus can abolish itching but this would seem to be due to a central suppression rather than a peripheral modification of nervous activity.

Lewis was tempted to regard superficial and deep pain as distinct sensations and our work shows that the quality of pain may differ even at different levels in the dermis. On the blister base the typical immediate smarting pain produced by ACh is different in character from the delayed duller pain of 5-HT and PPS. The difference in time of onset suggests that ACh acts on nerve endings right on the surface of the exposed base and that 5-HT and PPS act on deeper nerve endings to which they take time to penetrate. Incidentally, the action of KCl in producing a sensation of warmth shows that receptors other than itch and pain can be chemically activated.

We have not ourselves studied subcutaneous or deeper pain receptors but they probably also show selective sensitivity to chemical and physical stimuli and the pain produced is certainly of a different quality from that evoked in superficial structures.

SUMMARY

I suggest that there are at different depths in the skin, nerve endings which can be differentially stimulated by chemical and physical agents to give rise to different qualities of sensation. The most superficial, the intra-epidermal endings, are concerned with itch, some of the superficial dermal endings with smarting pain (the type of pain which most closely resembles itch in character), and some of the deeper dermal endings with a "duller" type of pain. The nerve fibres coming from the epidermis and different layers of the dermis are distinct from each other but they all run together in peripheral nerve and spinal cord to end presumably in anatomically distinct regions in the brain. This hypothesis suggests that a suitable anatomical substratum exists for the functional activities which I have discussed.

DISCUSSION ON THE MODERN OUTLOOK IN THE MANAGEMENT OF PULMONARY TUBERCULOSIS

Dr. K. Neville Irvine:

BCG Vaccination

From my angle the modern outlook in the management of any preventable disease is its prevention. We have all read of the ravages of smallpox before vaccination; in the twenty-four years that I have been in general practice I have myself seen diphtheria practically wiped out by APT; I hope that I may live to see pulmonary tuberculosis similarly reduced to a rare condition by preventive measures.

The ideal method of eradicating tuberculosis is to remove all sources of infection; this is the line taken by our veterinary colleagues in producing tuberculin-negative herds. Unfortunately this is a slow and difficult procedure if you cannot slaughter infectious cases. In the meantime much may be done by protective measures for the uninfected. Better standards of living, less overcrowding and education in hygiene are matters with which we general practitioners deal daily; there is little fresh to discuss here.

In 1949 a new preventive measure was introduced into this country. Under the control of the Ministry of Health, BCG vaccine was released to approved vaccinators for use on especially exposed persons—nurses, medical students, and the contacts of known cases of tuberculosis; it did not enter the realm of general practice. But in 1953 it was released for the mass vaccination of one age-group of the entire population—the 13-year-olds. To-day the family doctor is having rapidly to read up a subject about which he was never taught as a student, so that he can answer the searching questions of anxious parents. It is for this reason that I am confining myself to this one aspect of the prevention of tuberculosis.

When we consider that about every five-hundredth person we meet in a bus is an unknown infectious case of tuberculosis, it is clear that our chances of becoming infected are great. Ninety-nine times out of a hundred our first encounter with the tubercle bacillus results only in a subclinical infection—thanks to our natural resistance. This subclinical infection stimulates the body to produce an acquired resistance in addition to our natural resistance, so that we are better protected from future outside infection; we have, however, no guarantee that our own subclinical infection may not develop into clinical disease later. In short, the first invasion with the tubercle bacillus is a boon if it does not produce progressive primary disease or a later endogenous spread.

This is the whole object of deliberately giving a person a primary infection with BCG. BCG was a bovine tubercle bacillus fifty years ago, but it has long since been rendered non-pathogenic. Introduced as a live vaccine into the skin it multiplies for six weeks and then regresses. Being non-pathogenic, it does not produce progressive primary disease or a later endogenous spread—but it does produce acquired resistance to any subsequent virulent infection.

In BCG we have a valuable preventive weapon—if it is safe and effective. So far one case of lupus of the vaccination site, which rapidly responded to treatment, is the only misadventure reported in this country (Davies, 1955). In the world literature there are 4 cases that have died as the result of BCG vaccination (Irvine, 1957); this is deplorable, but it must be remembered that a total of about 145 million BCG vaccinations have now been carried out in the world, which gives a mortality rate of one in 36 million. Between 1941 and 1949 in England and Wales alone there were 43 deaths from smallpox vaccination (Registrar-General, 1949).

The First (Progress) Report of the Medical Research Council Trial of BCG (1956) gives the answer to the question of its efficacy; it shows that 4 out of 5 of the vaccinated were protected. This was in a group unexposed to known tuberculosis. In an epidemic of tuberculosis in a girls' school in Denmark where the exposure was heavy, 95% of the vaccinated were protected (Hyge, 1947).

If then we accept that BCG vaccine is reasonably safe and that the protection it produces—though not so complete as with smallpox vaccination or diphtheria inoculation—is worth while, why do we not advocate that everyone should be vaccinated? The reason is that, unlike antidiphtheria inoculation, you cannot give BCG to susceptible and immune alike. BCG vaccination in the uninfected person is like smallpox vaccination in slow motion; if BCG is given to someone who has already been infected, the result is very different. An angry reaction begins within a few hours and may reach its height in two days; the site of vaccination rapidly breaks down and the BCG is ejected by the body defences in a profuse purulent discharge. This is known as Koch's phenomenon.

It is wise therefore to differentiate between the infected and uninfected before giving BCG vaccine; fortunately there is a test which will do this—the tuberculin test. Anyone who has been infected with the tubercle bacillus becomes allergic to tuberculin, usually within six weeks. All that is necessary is to apply tuberculin to the skin; if no reaction occurs by the third day he may safely be vaccinated.

There are several methods of applying tuberculin. You may inject it diluted between the layers of the skin (the Mantoux test), scratch it into the skin (the Pirquet test), apply it to the skin under plaster (Moro and jelly tests), or prick it into the skin with needles (the Heaf multiple-puncture test). I shall confine myself to this last and newest test, because in this I think we have the most practical of all the tuberculin tests from the general practitioner's point of view. Let me say at the outset that its main disadvantage is the cost of the Heaf apparatus with which it is given.[1] This carries six needles drawn up behind an end-plate in which there are six holes; on firing the gun the needles stab through the holes in the end-plate to project a set distance. It is sterilized by dipping the end-plate into a shallow tray of spirit and igniting it.

The test is performed by cleaning the skin of the forearm with acetone and placing on it a drop of special tuberculin[2] (PPD 2 mg./ml. in 50% glycerol with 0·5% phenol); this solution is both stable and difficult to contaminate. The drop of tuberculin is spread by the end-plate of the Heaf apparatus into a half-inch circle: the skin of the forearm is drawn taut with the left hand: the end-plate is held firmly in the centre of the tuberculin and the gun fired. No skill is required as the apparatus is mechanically adjusted to perform the same six punctures to the same depth each time (Heaf, 1951).

The test should not be read before the third day and some workers claim that it is reliable even when read as late as the seventh (Townsend and Macdonald, 1955). As with all tuberculin tests, skill is required to read the weaker results. It should be remembered that in most negative reactions the six punctures will still be clearly visible; they may even be surrounded by a ring of erythema and bear a tiny crust in the centre. This should cause no confusion as the criterion of the minimal positive reaction is *palpable induration* around at least four of the punctures. Usually the positive reaction is more definite than this and the six punctures will have coalesced to form a ring or a plaque of induration. If in doubt, call the result negative and retest if possible.

I have discussed this test in some detail because, though it is too new to have reached most textbooks, it is rapidly becoming popular. As a result you may one day be asked to read the result of this test in a 13-year-old kept away from school by illness. Moreover for those of us who can afford this apparatus, a foolproof tuberculin test that is applicable both to the infant and the adult is of great interest.

If a general practitioner is prepared to do a tuberculin test on his patients, should he not be given access to BCG vaccine so that he can vaccinate the negative reactors in his practice? Before answering this question I think I should make it clear that BCG vaccination is nothing like as simple as antidiphtheria inoculation. To begin with it is a live vaccine which should not be used more than fourteen days after manufacture: it comes from Copenhagen and has to be ordered at least two weeks in advance: it deteriorates if not kept in a refrigerator, is damaged by heat and killed by exposure to sunlight; it can contain no preservative and so any ampoule must be used within a short time of opening. The dose is one-tenth of a millilitre, so for accuracy a special long syringe is generally used. The BCG issued by the Ministry has to be injected intracutaneously which requires a special quarter-inch needle with a short bevel and a skill in a technique that few of us were taught in our student days; if the injection is accidentally given subcutaneously, a local abscess the size of a cherry is likely to appear six weeks later. The healthy infant that would be the first care of every family doctor is the greatest BCG headache of all; not only is a baby's

[1]Obtainable from Messrs. Allen & Hanburys Ltd., Bethnal Green, London, E.2, or from Messrs. H. G. East & Co., 37a, Oxford Rd., Cowley, Oxford.

[2]Obtainable as "Protoderm" from Messrs. Allen & Hanburys Ltd., Bethnal Green, London, E.

skin extremely thin and tough, but it is in this age-group that glandular abscesses follow the most perfect vaccinations with distressing frequency.

I feel, therefore, that our generation of general practitioners would be wise to leave BCG vaccination at the moment to specially trained vaccinators. As the number of approved vaccinators is not great—they are mostly chest physicians or school medical officers—they cannot be expected to take on any great extension of BCG vaccination. This is limiting wider use of the vaccine. The solution which I would advocate is that no medical student should in future reach qualification without having had practical training in tuberculin testing and BCG vaccination. Those of our generation who are keen on preventive medicine could also be given practical training in a short postgraduate course. By this means it should soon become possible for the Ministry to release BCG vaccine to the family doctor for use alongside his other preventive inoculations.

Meanwhile we must be prepared to give advice to the mother of the 13-year-old. Before vaccination he will be given an initial tuberculin test: what is the significance of a positive reaction? In a healthy boy this probably only means that he has had a subclinical infection at some time, but this is only a probability; the best way to be sure is to take a chest X-ray. A marked positive reaction is a warning to keep an eye on the boy for some time; the M.R.C. found four times more cases of tuberculosis developing later in fierce reactors than in mild. The fierce reactions are uncomfortable; a dressing of antihistamine ointment is useful.

Next, the negative reactor will be vaccinated with BCG. If a reaction occurs at the site of vaccination in the first week, refer him back to the vaccinator. Little should normally be visible for two weeks when a painless papule appears; this increases to a maximum at six weeks. The average papule measures 10 mm. across; it should not normally exceed 20 mm. Three-quarters of these papules will break down to an ulcer and discharge pus. The average diameter of the ulcer is 5 mm.; it should not normally exceed 10 mm. If a dressing has to be applied to protect the clothing, it should allow as much air to the ulcer as possible; do not occlude it with a plaster dressing or smother it with penicillin ointment. If he wants to go swimming, there is a waterproof rubber sleeve on the market[1] that he can pull over the dressing. If instead of a papule, an abscess the size of a cherry develops, it should be aspirated—not incised; the best plan is to refer it back to the vaccinator.

After the sixth week the vaccination reaction should begin to regress and ulcers should be healed by the tenth week. Large or indolent ulcers may be helped by exposure to sunlight, dusting with PAS or dressing with a special "BCG Reaction Ointment".[2] A painless enlargement of the regional lymph glands normally occurs in 3% of all vaccinations about the sixth week and may last for several weeks; the mother should be reassured and no action taken. Sometimes, however, three to twelve months after vaccination the glands break down to form a cold abscess. This harmless but distressing complication occurs in about 0·5% of infants vaccinated; it is fortunately uncommon in school children. It should be treated by repeated aspiration and replacement of the pus with streptomycin—never by simple incision, or a troublesome sinus may result. There is evidence to suggest that any injection given in the same arm within six months of BCG may precipitate a glandular abscess; for this reason it is wise always to give BCG in the right arm thus leaving the traditional left arm free for other inoculations.

With the possible exception of the very rare complication of lupus, all complications of BCG always heal in the end—even if they have been wrongly treated. You may with complete confidence continue to reassure both yourself and the anxious mother.

Some six to twelve weeks after vaccination the tuberculin test is repeated; this time it should be positive, showing that infection with BCG has taken place and the vaccination has been effective. This change from negative to positive is called "conversion" and this post-vaccination test is called the "conversion test". For school children in the Oxford Region, the conversion rate to a Heaf test is 99·2%; similar findings have been reported in other parts of the country and there is much discussion about whether conversion testing will be necessary in the future.

At intervals vaccinated persons may be followed up with further tuberculin tests to see that the vaccination is still effective; if the tuberculin test returns again to negative—a process known as "reversion"—the person should be revaccinated. It is impracticable to go to these lengths with unexposed school children, but it is important that the full procedure should be carried out on those who are in continual contact with tuberculosis.

Made by Messrs. Kleinerts, 91, New Bond Street, London, W.1.

Glaxo Laboratories make a BCG Reaction Ointment (L.C.C. formula) containing in each gram hydrocortisone acetate 10 mg. dihydro-streptomycin 5,000 units and isonicotinic acid hydrazide 50 mg.

It has been my part to discuss the most modern addition to the methods of preventing pulmonary tuberculosis—BCG vaccination; I am anxious that I should not give the impression that I consider it to be the whole answer to the problem. It is but one more weapon in our armament against tuberculosis—though, I submit, a most effective one. I would offer just one word of caution when discussing our "new" vaccine with European colleagues; Scandinavia has been using it for thirty years and France for thirty-six.

Sir Geoffrey Marshall:

Chemotherapy

This is a good time for us as clinicians to take stock of our methods of dealing with patients suffering from tuberculosis. The situation has been changing fundamentally as a result of the introduction of effective chemotherapy. Many more patients are being treated in their own homes, and beds in sanatoria are standing empty; whereas only a few years ago there were long lists of patients awaiting admission. The number of new cases notified annually in England and Wales has fallen only slightly, from 50,000 before the war to about 40,000 now; but the death-rate is only one-third of what it was in 1938. This is heartening, but 8,000 deaths per annum from tuberculosis, most of them preventible, should not give us an excuse for complacence. The pattern of mortality has changed. Prior to the war the highest mortality was in young women; now the bulk of the deaths are in elderly men—those in the sixties and seventies, many of whom have been hit hard by the social changes of the Welfare State.

The fall of the gross mortality must be attributed largely to earlier diagnosis by the widespread use of radiography and to more effective treatment, in the form of chemotherapy which followed the advent of streptomycin in 1948.

Now let us consider how we should deal with various types of case, remembering that management of the patient, his dependants and contacts can never be satisfactory unless a large measure of the responsibility is kept in the hands of the general practitioner. Early diagnosis has been achieved in a great many cases by Mass Radiography. It is a procedure we should encourage, not least for men over 50 years of age. We can reassure the public who have been unduly alarmed by propaganda on the dangers of excessive radiation. There is no assessable risk to the subjects of chest radiography.

The Minimal Lesion

When X-ray films show normal lung fields apart from the presence of one or two discrete rounded opacities of not more than one centimetre in diameter, these are commonly called minimal lesions, and not infrequently these cases are kept under observation by periodical radiography, without treatment. Usually there is no sputum and no indication of toxæmia. The X-ray appearance may improve or it may remain unaltered for a year or more. But at any time you may find a sudden change for the worse. Moreover if swabs from the larynx or juice from the stomach are taken when the lesions are first seen, and if these materials are cultured for ten weeks, tubercle bacilli will be found in about one-fifth of the cases. I believe that we should treat all these patients by chemotherapy as soon as the lesions are found. The drugs penetrate the lesion and eliminate the tubercle bacilli most effectively when the lesions are only a few weeks old. Moreover early treatment would prevent the development of bronchial stenosis, with permanent structural damage to the lungs.

Pleural Effusion

The contemporary treatment for this is chemotherapy and early and thorough aspiration. If fluid recurs it is usual to inject streptomycin into the pleural cavity after each aspiration. Chemotherapy should be continued for twelve months at least in cases of minimal lesion and pleural effusion. Regular review with radiography should be maintained for several years.

In more advanced cases the main lesions are likely to be considerable areas of infiltration in the lungs, together with segmental atelectasis which is characterized by wedge-shaped or linear shadows in the lung fields. The presence of tuberculous cavities may be detectable only by tomography.

In all cases chemotherapy is an essential part of the treatment, and rest is necessary for a variable period of weeks or months. Whether treatment is to be carried out at home or in an institution will depend on individual circumstances. In all cases chemotherapy should be begun at home while awaiting admission to hospital. If the sputum is positive and there are children in the house, the patient should go to hospital. If the presence of a pleural effusion, or of cavitation in the lungs calls for constant observation or strict bed rest, hospital is the place for it. The mother and housewife will never rest with an easy mind in her own home, and she should go away until active disease has been arrested. Other patients may do very well at home, but precautions must be taken against spreading infection. There must be no visits by those susceptible to infection, and effective steps must be taken to sterilize sheets, pillow-cases and handkerchiefs.

With regard to the chemotherapy we have three effective drugs, any two of which may be given simultaneously. These drugs are streptomycin, PAS and Isoniazid. There are others, but they are too toxic for consideration here. It is usual to begin treatment with streptomycin by injection and one of the other two drugs by mouth. We must not give one drug by itself as this leads to the development of resistant strains of tubercle bacilli, with consequent danger to the patient and to the public. On the other hand there is little to be said for the administration of all three drugs at the same time. Give two at a time and give them in effective doses. For an adult we give intramuscular injections of streptomycin sulphate, 1 gram once a day on five to seven days a week. PAS is given by mouth on six days a week, 14 to 20 grams daily in divided doses; and Isoniazid is given by mouth in tablets of 100 mg. two or three times a day on six days a week.

As intramuscular injections are inconvenient when a patient resumes active life, we usually continue treatment with PAS and Isoniazid at that stage, and maintain chemotherapy for twelve months in the first instance, with shorter repeat courses at intervals thereafter.

In patients who are acutely ill, and in those who are intolerant of the drugs, great benefit is to be derived—as has been shown by Dr. L. E. Houghton—from giving preparations of the cortisone group together with the anti-tuberculous drugs.

Sir Clement Price Thomas:

Modern Surgical Treatment

I shall deal with my subject mainly from the point of view of the general principles guiding the form of treatment to be advised, and to indicate, by a consideration of cases treated, the reasons for such decisions.

Surgically speaking, after the beneficial general effects of drug therapy are accepted, the most important factor is the effect of the drugs on the bronchial disease; the healing of the disease in the bronchi produces one of two results, either the opening of the bronchi by the decrease in the thickness of the diseased bronchial mucosa leading to a decrease in the size of the cavity, and in favourable cases, its closure, or it leads to stenosis of the bronchi; this latter resulting from the fibrosis following up the healing of the disease, and the subsequent contraction of the fibrous tissue. Stenosis will only occur when the tuberculous process has involved the musculofibrous wall of the bronchus. These processes I believe to be the main factors in either the healing or blocking of tuberculous cavities. When stenosis affects the larger bronchi such as the lobar or main bronchi, mechanical problems ensue which are not strictly related to the tuberculous disease. One other factor resulting from the healing of tuberculous bronchial disease is that resection of the lung becomes a safer procedure in that the line of section of the bronchus will then be through healthy tissue.

There is a tendency to consider resection and relaxation operations as competitive procedures, instead of considering them as being complementary. As I shall show later, as a broad differentiation, resection should be reserved for tuberculous lesions which are either non-cavitated or have been converted from open lesions to closed lesions or, at least, into lesions which have ceased shedding tubercle bacilli, as judged by direct smears or cultures; on the other hand, open cavitated lesions, with a positive sputum, still are

best treated by thoracoplasty, if the cavity be in such a position that closure can be anticipated.

The practical politics of the issue are as have been indicated by my colleagues. All patients, after a satisfactory diagnosis has been made on all three grounds, clinical, radiological and bacteriological (including the sensitivity of the organisms to the available drugs), should be started on chemotherapy, using always two of the available drugs, never one, in order to prevent the emergency of insensitive strains of bacilli. It is usual to use streptomycin as one of them at the outset. The length of treatment will depend on many factors: the extent and severity of the disease, the persistence or otherwise of a positive sputum, the closure or blocking of the cavities; but, generally speaking, treatment should be continued for as long as there is steady even progress, on clinical, radiological and bacteriological grounds. No patient, who has a positive sputum at the outset of the disease, should be submitted to resection before he has had at least three months' medical treatment, and in those with cavitation, a minimum of six months' pre-operative treatment is safer.

Admittedly other factors arise which may modify the above course, but it should be quite fully realized that to modify such a curriculum is to increase the potential risk to the patient.

The tables list a series of cases submitted to resection for pulmonary tuberculosis and personally operated upon.

TABLE I

Total No. of cases	366
Total deaths	28 (7·65%)
Early	18 (4·9%)
Late	10 (2·7%)

TABLE II

		Deaths	
Cavitation I	53	8	early 6 (11·3%) late 2
Cavitation II	93	3	early 0 late 3
Solid	131	2	early 0 late 2
Cav. Sol.	22	0	

Cavitation I means that open cavitation was present at the time of operation.

Cavitation II indicates that a cavity was present when the patient first came under observation, but was closed at the time of operation.

Solid is self-explanatory.

Cav. sol. indicates a solid lesion showing evidence of cavitation.

Table I shows the number of cases with the early and late mortality. It is noteworthy that there has been only one early death in the last three years and that from coronary thrombosis.

From Tables II and III, it will be seen that all of the 18 early deaths, with the one exception already referred to who had a solid lesion, occurred in patients who had open cavitated disease at the time of operation. By early death is meant those patients who died whilst in hospital, who were, in fact, never fit enough to leave. Some died quite some time post-operatively from some complication of the operation, most commonly bronchial fistula with a complicating empyema and spread of the disease.

As would be expected, the highest mortality accompanies the more complicated forms of the disease, empyema and stenosis with underlying open cavitated disease. Interestingly enough, destroyed lungs have a lower operative mortality than the former two, and this I believe to be due to the fact that in quite an appreciable number of this latter group the tuberculous disease has burnt itself out. In other words, the patient has conquered the tuberculous infection at the expense of gross anatomical destruction.

If the whole group of patients with cavitated disease be alone considered, 85 in all, 17 patients died in hospital, a mortality rate of 20%.

This high mortality rate was, without doubt, due to operating on patients with open cavitated disease and a positive sputum at a time when the necessity for prolonged pre-operative chemotherapy in such cases was not properly appreciated. I believe that the time-duration of such treatment, with adequate daily dosage, is of more significance than the total quantitative dosage. There can be no question that the whole success of surgical intervention, especially resection, depends on adequate and effective pre-operative treatment.

TABLE III

		Deaths
Stenosis Total No.	22	4 (18·18%)
Without cav.	15	0
With cav.	7	4 { early 4 (57·1%) late 0

Cavitation II	2	0
Solid	2	0
Cav. sol.	2	0
Empyema	11	5 { early 4 (36·3%) late 1
Stenosis	15	3 { early 3 (20%) late 0
Destroyed	17	4 { early 3 (17·6%) late 1

In a certain number of patients, cavity closure and sputum conversion do not occur even with prolonged treatment, due commonly to drug resistance of the organisms; then again adequate treatment cannot be given owing to the patient's sensitivity to the drugs—in one case, the patient developed agranulocytosis. In any case, whatever the cause of failure, in such cases, if there is a reasonable chance of cavity closure, thoracoplasty is far and away the safer procedure. If the cavity, however, is in such a place as to preclude reasonable expectation of closure, for example in the basic segments of the lower lobe or in the middle lobe, then the risk may have to be undertaken but the risk should be clearly recognized.

It will be agreed that the aim in view is the cure of the patient's disease with as little risk as possible, and the choice of treatment lies in the accurate assessment of these two factors.

Tables IV, V and VI list the types of operative intervention and demonstrate the same points relative to open cavitated disease, and that the mortality is greater in proportion to the extent of the intervention.

The end-results of resection cannot yet be accurately assessed. It will be seen that there are 10 late deaths, this giving a mortality of 2·8% in the 348 who survive after leaving hospital, and of these, about two-thirds die of a disease other than tuberculosis. The end-results are difficult to report owing to the short time available since resection became general (with four exceptions, the longest survival is eight years); and also to the inadequate follow-up at the time of reporting. At the time of writing, however, of those followed up about 3% are classified as being poor, about 84% as good, and about 13% as fair. I feel reasonably certain that in the latter two groups, the majority of those considered fair, in due course, will eventually merge into those considered to be good.

I suggest that the conclusions to be drawn from the foregoing experience are that resection of the lung for tuberculosis can be rendered a safer procedure, provided adequate and effective chemotherapy is carried out before operation is undertaken, and that more than probably it will be attended by good long-term results.

DISCUSSION ON ANURIA IN MEDICAL CONDITIONS

Dr. M. D. Milne:

Anuria, which is strictly defined as *complete* failure of urine formation, is rare. Complete anuria is much more likely in surgical conditions associated with obstruction of both ureters or of the ureter of a single kidney. The term "anuria" is, however, often inaccurately applied to conditions associated with severe oliguria in which the daily urine volume is insufficient to maintain normal kidney function and preserve biochemical homeostasis. A better and more accurate term is "acute oliguric renal failure".

The daily urinary volume (v) is related to the mean urinary concentration and the total amount of solute excreted daily. Urinary concentration is dependent on the fluid intake and on the amount of water loss by extra-renal channels, e.g. the stools, sweat, and expired air. Solute excretion is mainly influenced by the diet, being high with a salty and high-protein diet and low with a diet containing little salt and protein. Normally, the following mathematical relationship holds (Fig. 1):

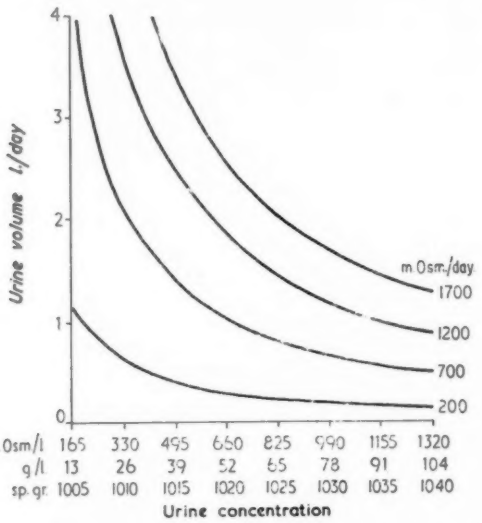

FIG. 1.—Relationship between urinary concentration and urine volume for (*a*) electrolyte-free and protein-free diet (200 m.osmoles/day). (*b*) Low protein diet (700 m.osmoles/day). (*c*) Good normal diet (1,200 m.osmoles/day). (*d*) High protein diet (1,700 m.osmoles/day). The urine volume is dependent on the amount of solute excretion as well as on the concentration of the urine. With low solute excretion satisfactory renal function is compatible with moderate oliguria. Urinary concentration is best expressed in m.osmoles/l., but may also be expressed in grams/l. and as urinary specific gravity. Equivalents between these values are only approximate.

$$c \times v = s$$

where c is the mean urinary concentration in m.osmoles/ml., v is the urine volume in ml./day, and s is the solute required to be excreted in m.osmoles/day. In clinical practice urinary concentration is measured by determination of specific gravity rather than the more accurate but more difficult method of estimation of urinary osmolarity. Approximate equivalent values are given in the abscissa of Fig. 1.

If a patient is receiving a protein and electrolyte free diet, e.g. in parenteral feeding with 5% glucose, the amount of solute excreted is entirely derived from the metabolic breakdown of body protein and may be less than 300 m.osmoles/day. Should the patient be dehydrated from vomiting or diarrhœa, a concentrated urine of an osmolarity greater than 1 m.osmole/ml. may be excreted. In such circumstances the daily urine volume would be only 300 ml./day, but there would be no renal failure and no increase of blood urea or non-protein nitrogen. This type of oliguria is physiological and obviously should not be classed as acute renal failure.

Acute oliguric renal failure is always associated with uræmia which steadily deteriorates unless diuresis occurs or the patient is treated by dialysis methods, e.g. the artificial kidney. In contrast, in chronic renal failure with polyuria, the degree of uræmia may remain unchanged for many months or even years. Acute renal failure may occur in patients with previously normal kidneys or in patients with preceding renal disease. The prognosis is obviously worse in the latter group, since at best, renal function can only be restored to its original impaired state. Differential diagnosis in patients seen for the first time in acute renal failure may be difficult. The single most useful feature is that the patients with an acute exacerbation of previous chronic uræmia have a normochromic anæmia due to long-standing renal disease. The two most important causes of oliguria in chronic uræmia are salt depletion or an acute exacerbation of chronic pyelonephritis. Severe salt depletion is particularly liable to occur in uræmic patients from vomiting or diarrhœa. If salt depletion occurs in normal subjects the kidneys will compensate by secretion of a salt-free urine due to increased aldosterone production. This cannot occur in uræmic patients as the renal tubules can no longer retain sodium efficiently, and continued salt loss occurs both in gastro-intestinal fluids and in the urine. Recognition of these two causes is of great importance since effective therapy by saline infusions or by antibiotics may lead to rapid improvement. If, however, these two factors can be excluded, the prognosis of an acute exacerbation of chronic uræmia is extremely grave since it is usually due to almost complete destruction of existing glomerular function by the previous renal disease.

The most important cause of acute renal failure in previously healthy patients is renal ischæmia. Classification is best based on the anatomical site of underlying disease:

(*a*) Obstruction of the main renal arteries.
(*b*) Obstruction of renal veins.
(*c*) Obstruction of smaller renal arteries or of the afferent glomerular arterioles.
(*d*) Glomerular lesions.
(*e*) Acute renal circulatory failure.
(*f*) Acute tubular necrosis.
(*g*) Renal cortical necrosis.
(*h*) Proximal tubular necrosis.
(*i*) Renal papillary necrosis.
(*j*) Obstructive lesions of the ureters.

Obstruction of the main renal arteries.—This may occur as a result of embolus, thrombosis, or a dissecting aneurysm of the abdominal aorta involving the origins of the renal arteries, and is obviously more liable to occur in a patient with a single kidney. The commonest cause of pathology at this site is, however, diagnostic aortography. This is a potentially dangerous investigation and should only be performed if the information obtained will be of direct value to the patient. Anuria may result from renal artery thrombosis, intimal stripping by injection of contrast media directly into the aortic wall (Gaylis and Laws, 1956), or from acute tubular necrosis from local high concentration of diodone. Miller *et al.* (1954) report 4 cases all of whom recovered, and Alwall *et al.* (1955) describe 8 cases with 2 deaths. I have recently seen 3 cases of which 1 died. The use of the Seldinger technique (1953) avoids the danger of intimal stripping but anuria may still occur from the other two causes. The technique is especially dangerous if only a single kidney is present.

Obstruction of the main renal veins.—This will cause anuria if the obstruction is complete. Renal vein thrombosis may or may not be associated with thrombosis of the inferior vena cava (Harrison *et al.*, 1956). Primary renal vein thrombosis is especially liable to occur

as a complication of acute gastro-enteritis in the first few months of life. Renal vein thrombosis in adults is more usually secondary to chronic renal disease with gross reduction of renal blood flow and is especially likely to occur in cases of secondary renal amyloidosis (Vilk, 1940; Harrison *et al.*, 1956). This type of anuria is also more liable to occur in patients with only a single kidney.

Obstruction of the smaller renal arteries.—The smaller renal arteries may be involved in polyarteritis nodosa, the kidneys being the organs most commonly affected. The uræmia usually terminates in an oliguric phase. Polyarteritis should be suspected if there is evidence of arteritis elsewhere and if there is rapid deterioration of renal function in patients in whom the blood pressure is normal or only slightly increased. Usually chronic renal failure without rise of blood pressure is only slowly progressive but cases of polyarteritis are exceptional, and there is rapid renal functional and structural damage. In

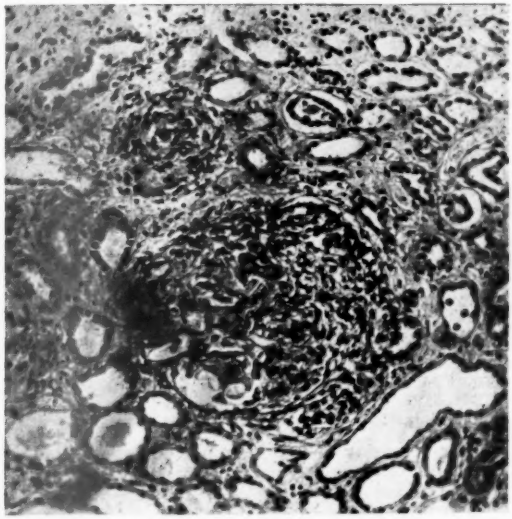

FIG. 2.—Section of glomerulus in a case of polyarteritis nodosa with severe and fatal oliguria. There is widespread necrotizing arteriolitis of the afferent glomerular arterioles. Hæmalum and eosin. ×142.

some cases the afferent glomerular arterioles are especially involved (Fig. 2), but necrotizing arteriolitis in this location may also occur in other types of renal disease, e.g. acute glomerulonephritis or malignant hypertension. Treatment with cortisone will often prevent further activity elsewhere, but unfortunately has little if any beneficial effect on the renal lesion. An accurate post-mortem diagnosis is often more difficult after cortisone therapy.

Glomerular lesions.—In a small proportion of cases of acute glomerular nephritis the oliguria may be severe enough to cause acute renal failure. Many cases show complete anuria and the prognosis is worse than in the more common acute tubular necrosis. The diagnosis is made by finding other signs of acute nephritis such as œdema and hypertension. Severe oliguria and rapidly progressive uræmia may occur in the subacute stage of glomerulonephritis, and is not uncommon in the nephropathy of Henoch-Schönlein purpura.

Acute renal circulatory failure and acute tubular necrosis.—This type of oliguria is secondary to conditions involving hæmorrhage and shock and is therefore more common in obstetric or surgical practice than in medical cases. In acute renal circulatory failure diuresis occurs when the circulatory insufficiency is effectively treated, but in acute tubular necrosis oliguria persists for a varying period up to two or three weeks. Since there is no permanent glomerular change the prognosis is good and there are no sequelæ if the patient survives. In purely medical practice, common causes are coronary thrombosis, gastro-intestinal hæmorrhage, incompatible blood transfusion, acute hæmolysis as in blackwater fever, and circulatory collapse from overdosage with ganglionic blocking drugs.

Renal cortical necrosis affects both glomeruli and tubules. About 80% of cases of renal cortical necrosis occur in association with concealed accidental hæmorrhage of pregnancy.

The remaining cases may occur either in children or adults and have usually been associated with episodes of severe vomiting or diarrhœa or with septicæmia or bacteræmia. Complete cortical necrosis is obviously inevitably fatal, but in less severe cases with only partial necrosis the patient may recover. There is, however, some permanent reduction of renal function owing to patchy destruction of glomeruli.

Proximal tubular necrosis follows ingestion of nephrotoxic drugs and poisons, e.g. mercuric chloride, potassium bichromate, chlorates, carbon tetrachloride, and large doses of sulphonamide drugs. There is widespread necrosis of proximal tubular cells without rupture of the basal membrane. The course and prognosis is similar to that of acute tubular necrosis.

Renal papillary necrosis.—In this condition there is necrosis of some or all of the renal papillæ (Fig. 3). About two-thirds of cases occur in diabetic patients with secondary

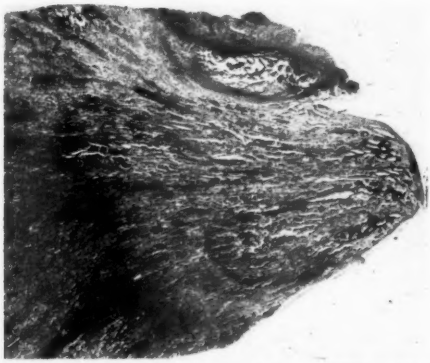

FIG. 3.—Section of renal papilla in a case of necrotizing papillitis with severe and fatal oliguria. There is complete necrosis of almost the whole papilla. A hæmorrhagic area separates the area of necrosis from living kidney tissue. Hæmalum and eosin. ×6.

pyelonephritis. The oliguria usually follows an acute exacerbation of urinary infection with severe dysuria, pyrexia and hæmaturia. There may be renal colic due to fragments of necrosed papillæ being passed down the ureters.

Ureteric obstruction.—This is a surgical variety of acute uræmia but may closely simulate the medical conditions already described. Anuria is usually complete and is obviously more likely to occur if there is a single kidney.

Conservative management by a protein and electrolyte-free but high caloric diet together with fluid restriction is the basis of treatment in all cases of acute renal failure. Blood urea, and serum potassium and bicarbonate should be determined each day. Treatment should be supplemented by dialysis, preferably by the artificial kidney, if any of the following signs of failure of conservative measures are found:

(*a*) Serum potassium above 8 mEq./1.
(*b*) Serum bicarbonate below 10 mEq./1.
(*c*) Electrocardiographic evidence of progressive hyperkalæmia, acidotic breathing, deepening stupor, or uræmic twitching or hyperexcitability.

Dr. A. M. Joekes:

The importance of the recognition of the presence or onset of acute renal failure was stressed. The recognition is made both earlier and more certainly by observing the volume and quality of the urine passed than from biochemical changes in the blood. Oliguria was defined as a urine volume less than 700 ml./twenty-four hours. In the presence of severe renal failure the specific gravity will lie between 1008 and 1014. With good renal function a twenty-four-hour urine volume of 700 ml. or less will result in a specific gravity

of 1018 or higher. In the absence of glycosuria or heavy proteinuria a specific gravity exceeding 1018 can be accepted as evidence of good renal function. Spurious low specific gravity oliguria may be met with under circumstances in which a low nitrogen intake is maintained and sodium chloride retention by the kidney is occurring. As a working rule it may be taken that the urine in a low specific gravity oliguria with severe renal damage will always contain considerable amounts of sodium and chloride and that their absence implies a physiological response by the kidney.

Among several illustrative cases of acute tubular necrosis complicating medical conditions, were included four occurring during the course of non-fatal hepatic disturbances in which no surgical intervention had occurred in the immediate past; in all 4 patients the acute renal failure ran the typical course of an acute tubular necrosis with recovery.

The only illustrative case which is here recorded is that of a young man of 21 in whom an acute tubular necrosis followed a severe hypotensive episode after a large pulmonary embolus.

History.—Male, aged 21.

Admitted to hospital 18.8.56 with a short history of cold, some pain in the left lower chest and blood-flecked sputum. On admission, an afebrile, healthy-looking boy. B.P. 110/65 with the only physical signs being some diminished movement of the left chest.

The following day he became febrile and the next day a small left-sided pleural effusion was discovered which contained a straw-coloured fluid. Mantoux 1/10,000 positive, W.B.C. 9,000, E.S.R. 86 mm. in the first hour. 21.8.56: Episode of pain in the right chest. 22.8.56: Small R pleural effusion.

Presumptive diagnosis—pulmonary tuberculosis and treatment started with streptomycin and isoniazid.

1.9.56: After swinging legs over the side of the bed suddenly collapsed and was found pulseless and unconscious at 7 a.m. Some two hours later intravenous infusion containing noradrenaline was started with rapid improvement in the general condition. B.P. which had previously slowly risen to 75/55 rose to 104/75. Noradrenaline drip was maintained for the following twenty-four hours, the B.P. at times still dropping as low as 85/60.

From the time of the sudden collapse, the patient was severely oliguric for four days. On the fifth, the urine volume started to increase and the urine volume reached one litre in the twenty-four hours on the seventh day. The blood urea, urine volume and body-weight are shown in Fig. 1. The course of the renal failure was typical of an acute tubular necrosis.

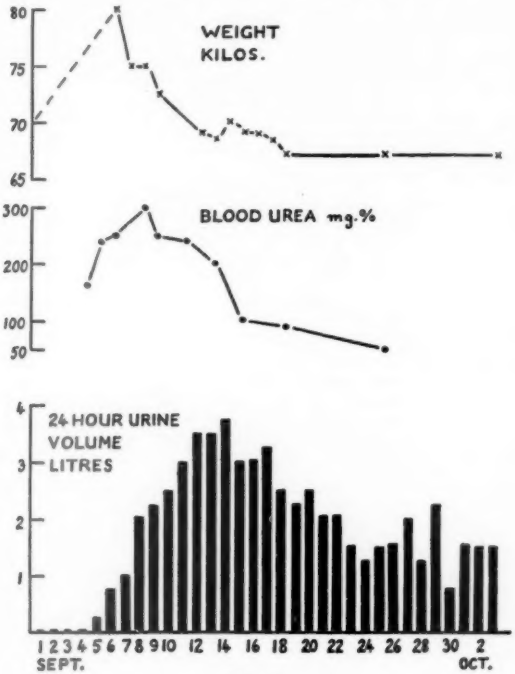

FIG. 1.

The pulmonary condition prior to the hypotensive episode was, in retrospect, typical of multiple pulmonary emboli, with a massive one occurring on 1.9.56. The radiological appearances of the lungs were characteristic and slight œdema of the ankle and calf tenderness were present on 7.9.56. ECG showed very severe acute right ventricular strain at this time.

During the first three days after the massive pulmonary embolus on 1.9.56, the patient was fairly severely overhydrated and on 4.9.56 the patient weighed 10 kg. more than his normal weight. At this time, he was overbreathing quite out of proportion to his chemical acidosis; this was assumed to be consistent with the hyperpnœa typically seen with pulmonary embolus. In view of the severe overhydration and the absence of a marked rise in serum potassium, the patient was left without any fluid administration for twenty-four hours in the hope that he would lose water via the lungs. This was most strikingly successful, the weight falling from 80 to 75 kg. in thirty-six hours, with marked improvement in his general condition. From then he was managed on intravenous alimentation, with 40% glucose and insulin (1 unit to 4 grams glucose) added to the drip. During the early diuretic phase, sodium and potassium loss in the urine was replaced intravenously.

The recovery was complicated by a severe penicillin skin rash, but renal function steadily improved, and he returned to full work three months after the initial illness.

Dr. E. M. Darmady:

The Renal Changes in Anuria Following Medical Conditions

Anuria follows a very large number of ætiological factors, but more frequently shock, disturbances of the electrolyte water balance, intravascular hæmolysis or combinations of all these factors. It is fortunate that the pathological changes in the kidney are similar, even to the extent that it is not possible to determine from the microscopical examinations the nature of the ætiological agent. This syndrome is known as acute tubular necrosis, and I propose to confine my remarks entirely to this condition.

This report is based on the examination of 53 kidneys obtained from post-mortem, and sent to us by many colleagues to whom we are grateful. In addition, we have examined five that have followed a specific nephrotoxin. Oliver, MacDowell and Tracey (1951) and Dible (1953) have already shown that the pathological changes differ from those seen in acute tubular necrosis, but as we have examined so few cases following nephrotoxins we do not propose to discuss them here.

All the kidneys have been examined both by microdissection and histological means. We have arranged them according to the duration and stage of their illness, and in order that the pathological changes can be correlated with the urinary output. Four phases are usually recognized: (1) Onset; (2) Anuric or oliguric; (3) Diuretic; (4) Late diuretic; and we propose to describe our findings in each phase:

(1) *Onset phase.*—In the onset phase, there is no anatomical defect in the nephron, although the glomerulus is often engorged with blood. Histological preparations using standard staining methods seldom suggest there are changes in the tubules, but by microdissection many nephrons show focal areas of epithelial disorganization, and loss of translucency. This is by no means widespread, and may be localized to a specific nephron. Staining for alkaline phosphatase confirms the early changes in the proximal tubules, for in many areas alkaline phosphatase is absent. At this stage the proximal tubules are most affected, although many nephrons may show little or no change. This is of importance, and will be referred to later.

(2) *Anuric and oliguric phase.*—The changes of the onset phase gradually merge into the findings of this stage. Transparent casts start to appear in the lower end of the proximal tubule, and later in the loops of Henle. By microdissection the focal epithelial changes in the proximal tubule become more marked, and there is shrinkage of the epithelium so that the lumen is now apparent. Once again many nephrons may be considered normal, although the volume of urine passed in life may be small. The epithelium soon starts to regenerate, and heaping of the cells may be observed. In some areas, necrosis of the cells may be apparent, and the lower part of the nephron may be dilated even though casts are not present.

About the fourth to sixth day after onset, the distal tubule begins to show widespread epithelial degeneration, while casts of all types start to appear in the lower part of the nephron affecting the loops of Henle, and the distal and collecting tubules. The lumen is dilated since the epithelium is shrunken and flattened. At the same time, rupture in the wall of the tubule appear and are found in all parts of the nephron. These probably correspond to tubulo-venous and tubulo-interstitial ruptures described by Dunn, Gillespie and Niven (1941), and Bywaters and Dible (1942).

The ruptures in the interstitial tissue are accompanied by a brisk lymphocytic reaction, particularly where the protein-like material had leaked into the tissues. The appearance of casts seen by microdissection are interesting in that they often affect the same nephron.

The casts seem to take up the shape of the lumen and epithelium arrangement, and are frequently multiple. At the same time the tubule is not dilated either at the site of the cast or above the cast, unless the tubule wall has ruptured. The presence of casts and the outstanding damage to the distal tubules at this stage of the disease has given rise to the misnomer "lower nephron nephrosis". As it is at this stage the untreated case usually dies early pathologists were obviously impressed by the extent of the lesion of the lower nephron (Lucke, 1946).

(3) *Diuretic phase.*—No hard and fast rules can be laid down as to the changes found in the early diuretic phase, for the histologist cannot from histological grounds alone predict whether at the time of death or biopsy, the patient was in anuria or diuresis. However, in general, evidence of regeneration is apparent in all parts of the nephron. The epithelium of the proximal tubule is usually shrunken and flattened, and by histological standards now begins to show a more regular pattern, whilst nuclei show mitotic divisions. As the period of time after the onset lengthens, so the repair of the nephron continues, starting from the proximal tubule downwards. Indeed, not only does the epithelium recover, but the casts, particularly in the collecting tubules show polymorphic nuclear leucocytic and macrophage infiltration.

Discussion

Although the sequence of renal changes is well recognized, there are these points in the understanding of the syndrome that require further elucidation. First, interstitial œdema that may be found particularly in the early anuric phase, or in the early diuretic phase. Second, the random distribution of the lesions, and third, the mechanism of the anuria.

As regards the first, Dible (1953) has suggested that the interstitial œdema which is often found in the boundary zone may result in "relative functional bar" to the passage of the filtrate, and this may maintain the anuria or oliguria, and at the same time it has often been suggested that there is a rise in intra-renal pressure. From microdissection studies, there is no evidence to confirm this, for the tubules show no evidence of collapse or dilatation higher in the nephron which would result from such an obstruction. Indeed, de Wardener (1955), who measured the intra-renal pressure following experimental acute tubular necrosis, found that the pressure was unaltered. For this reason, together with the fact that the interstitial œdema is not found constantly, we suggest that this view is untenable.

With regard to the second point, both histological and microdissection studies confirm the random distribution of the lesions. Indeed many nephrons may show little or no damage, whilst others are so damaged by rupture of the wall and cast formation that it is unlikely that they could have ever recovered function. Conversely, the lesions, even though not seriously disturbing the epithelium pattern, do not appear sufficient to prevent complete urinary function. In other renal conditions, epithelium disarrangement of the same severity has not been associated in life with oliguria. Furthermore, it is clear that in the early stages of the disease the tubular damage is not sufficient to prevent the passage of the filtrate. This makes us believe that the cause of the anuria cannot be directly attributed to the lesions of the tubules, but rather to the function of the glomerulus.

On the third point, it is possible that the findings following the anuria of the homotransplanted kidney may shed light on the mechanism of the anuria in this syndrome. Following homotransplantation of the kidney in dogs, urine is usually secreted for about four to six days after transplantation. At about this time there is an abrupt cessation of urine flow. Examination of the nephron at this time shows the glomerular neck to be narrowed and devoid of epithelium, but as these changes are also found before the cessation of urine flow, it is clearly not directly responsible for the anuria (Darmady, Dempster and Straack, 1955). Injection of indian ink in the renal circulation at the time of the anuria shows the glomeruli to be engorged with blood. Furthermore, cortisone treatment assists in preventing the changes in the glomerular neck, but it does not prevent the onset of anuria, and kidneys examined at this stage show a similar overfilling of the glomeruli. This suggests to us that the blood flow through the glomerulus is stagnant or sluggish, and that the tone of the glomerular tuft has been lost. The congestion of the glomerulus in the onset phase of acute tubular necrosis has led us to believe that the mechanism of the anuria is similar, and that the cause should be sought in the glomerulus.

Finally, it is often noted in the recovery or diuretic phase, there may be considerable excess urinary potassium. In primary aldosteronism, of which we have had the opportunity of examining 5 cases, vacuolation of the epthelium, particularly of the proximal tubule, is seen. Similar changes can also be found in some cases in the diuretic phase, which suggests that the potassium depletion may be a significant factor.

SUMMARY

(1) The renal changes in acute tubular necrosis in cases have been traced through the natural history of the syndrome, by both microdissection and histological preparations.

(2) The random distribution of the lesions is stressed.

(3) The role of glomerulus in producing anuria is discussed.

(4) The presence of vacuolation in the tubular epithelium of patients dying in the diuretic phase is analogous to the changes found in 5 cases of primary aldosteronism.

My thanks are due to Miss F. Stranack who has painstakingly prepared so many tissues for examination, and to the Medical Research Council for an expenses grant, which has made this work possible. I am also grateful to my many colleagues, who have provided the material on which these observations have been based.

DISCUSSION ON THE PHARMACOLOGICAL AND MEDICAL ASPECTS OF SMOKING

Professor J. H. Burn (Department of Pharmacology, Oxford University): *The Pharmacology of Smoking*

Amounts of nicotine received in smoking.—The observation that nicotine stimulates sympathetic ganglia is now an old one, and most people remember that the stimulant action passes over to a paralysing action when nicotine is applied. In the amounts which normally reach man, however, it is a ganglionic stimulant. I would like to begin my remarks with a consideration of this very point. How much nicotine does a man smoking a cigarette take in? There have been some surprising estimates, which seem to me too high. Thus Haag and Larson (1944) have concluded that cigarette smokers who inhale retain about 3 mg. nicotine from each cigarette, while those who do not inhale retain 0·35 mg. Now observations made in my own department by Ling and Wynn Parry (1949) suggested that the amounts were much smaller. They set up a long glass U-tube each arm of which was 50 cm. long and of internal diameter 1 cm. The U-tube was immersed in running cold water. To one side of the U-tube a holder was attached in which a cigarette could be fixed, and the other side was attached to a 50 ml. flask which was in turn attached to a filter pump which applied weak suction. A T-piece near the pump could be opened or closed so as to allow suction to draw air through the cigarette at intervals similar to those used by a smoker in smoking a cigarette. Usually 5 cigarettes were "smoked" in succession, and the nicotine condensed in the U-tube and in the flask was then collected and estimated. The deposit was dissolved in weak acid, made alkaline and extracted with ether. The ether extract was allowed to dry and the nicotine was taken up in 1% tartaric acid. It was then estimated on the blood pressure of a spinal cat. Results were obtained by Ling in 1935 and by Wynn Parry in 1948. They showed that the amount of nicotine entering the mouth during the smoking of one cigarette, which contains 1 gram tobacco, is between 0·6 mg. and 1·0 mg. The cigarettes used were the brands commonly smoked in Britain, including Players, Gold Flake and State Express.

This result gains confirmation from observations published by Burn *et al.* (1945) on the antidiuretic action of nicotine. Thus one subject who drank 1 litre of warm water and measured its rate of excretion by emptying his bladder at 15 min. intervals, smoked one cigarette, inhaling deeply, 45 min. after drinking the water. This caused inhibition of the diuresis for over one hour, the interval between the maximum rate of excretion before and after smoking being 105 min. On another occasion he repeated the experiment, but instead of smoking a cigarette, he received an injection of 1 mg. nicotine acid tartrate, corresponding to 0·33 mg. nicotine calculated as base. This produced a longer

inhibition of diuresis, the interval between the maximum rate of excretion before and after receiving the injection being 150 min. This, and a similar result in a second subject, suggested that the amount of nicotine reaching the blood when a subject inhales deeply is about 0·3 mg. per cigarette, and probably only one-third of the amount entering the mouth. Thus the figures given for the amounts of nicotine in the smoke of cigarettes by Haag and Larson (1944) and by Wolman (1953) do not apply to cigarettes obtained in Britain. Our lower results may be due to the use of the biological method for estimating nicotine, which ignores related substances which are without physiological action.

Heart-rate and blood pressure.—That smoking raises the heart-rate and the blood pressure is generally agreed. The rise in heart-rate is to be expected from the stimulation of the stellate ganglia by the nicotine. This would lead to a discharge of impulses along the cardio-accelerator nerves. The rise in blood pressure is also to be expected from the stimulation of the sympathetic ganglia, and, like the rise in heart-rate it may also be due in part to a release of adrenaline and noradrenaline from the adrenal medulla. In normal subjects the rise of blood pressure was found by Roth *et al.* (1944) to be about 10 to 20 mm., but it was found to be greater in patients with hypertension (Roth, 1954). In 16 patients whose average blood pressure was 170/117, the average increase caused was 38 mm. systolic and 23 mm. diastolic; 2 cigarettes were smoked in both series.

Peripheral vasoconstriction.—The rise of blood pressure is due, in the main, to vasoconstriction and the vasoconstriction is prominent in the vessels of the skin. Lampson (1935) used a plethysmographic method of measuring the rate of blood flow through the hand, and observed a striking fall in the blood flow when the subject smoked and inhaled a cigarette. The hand was in water at 32° C., and the flow per 100 ml. of hand fell from 19 to 4 ml. per min.

Other observers have recorded changes in skin temperature. Among these have been Barker (1931), Wright (1933), Wright and Moffatt (1934), Maddock *et al.* (1936) and Roth (1951). An example of the observations made showed a fall in the surface temperature at the finger tips from 32·5° C. to 25·8° C., the temperature returning to 32·4° C. about 35 min. after the end of smoking.

The explanation of these effects which would naturally be put forward is that the nicotine stimulated the ganglia of the sympathetic chain and so caused the vasoconstriction. It is, however, not certain that the action of the nicotine is only or mainly on the sympathetic chain. In the first place, observations on the perfused vessels of an isolated organ indicate that nicotine has a peripheral constrictor action in addition to its ordinary ganglionic action. This effect was first demonstrated with small doses (5 μg.) of nicotine by Haimovici and Pick (1946) in the perfused vessels of the frog. My colleague Kottegoda (1953*a*) observed a similar effect in the perfused rabbit ear and saw that it was abolished by hexamethonium. This seemed to indicate that nicotine was not acting directly on the vessels, but on some ganglion-like structure, though none was known in the tissues of the ear. Kottegoda also showed that the effect of nicotine was reversed when the vessels were perfused with a solution containing priscol. Now, in the presence of priscol, the constrictor action of adrenaline is reversed to a dilator action, and so it appeared that the constriction caused by nicotine might be due to the release of adrenaline, because the constrictor effect of nicotine was reversed in the presence of priscol. Finally, Ginzel and Kottegoda (1953) made observations on the isolated ears of rabbits in which the sympathetic fibres had degenerated. They removed the superior cervical ganglion and the stellate ganglion on one side, and three weeks later they tested such denervated ears. The action of nicotine was unaltered. In small amounts, e.g. 5 μg., it caused a vasoconstriction which was blocked by hexamethonium, and which was reversed to a vasodilator action in the presence of priscol.

The mechanism of the effect of nicotine is obscure. The effect is clearly independent of the postganglionic sympathetic fibres. Perhaps there is chromaffin tissue surrounding the small vessels of the ear; this tissue, which is present in various parts of the body, contains noradrenaline with a small amount of adrenaline. The action of nicotine may be to release these amines.

These observations may very well have an importance for human skin, particularly in diseases such as thrombo-angiitis obliterans and Raynaud's disease. It appears to be established that smoking may bring on the ulcers and the gangrene which is characteristic of thrombo-angiitis obliterans, and that the condition heals when smoking stops. McDevitt and Wright (1955) quote several cases where the disease was sufficiently severe that an amputation of a limb was required, and where a connexion with smoking was established by a recurrence of attacks when smoking was resumed. One was of a middle-aged

physician who had thrombo-angiitis for five years. He had three severe attacks, each associated with the resumption of smoking.

Another was a patient in the New York Hospital who first had active thrombo-angiitis in 1940. In 1941 he stopped smoking and his symptoms were arrested until 1949 when he started to smoke again. Within three months gangrene of three toes developed. Once more after abstinence from smoking and with other therapy the disease became quiescent. In the spring of 1954 he started to smoke cigarettes with a filter tip and this again made the disease active.

Evidence that in this disease the effect of nicotine is peripheral and independent of sympathetic innervation has been obtained by various observers (Silbert, 1935). Smoking aggravates the thrombo-angiitic process in limbs in which the sympathetic fibres have degenerated as a result of sympathectomy. The vasospasm of Raynaud's disease is also brought on in some patients as a result of smoking one or two cigarettes.

The coronary circulation.—Perhaps the most serious suspicion regarding nicotine concerns its effect on the coronary circulation. The direct action of nicotine on the vessels is to dilate them, but it has been shown beyond reasonable doubt that nicotine stimulates the supra-optic nucleus and causes a discharge of vasopressin from the posterior lobe of the pituitary gland. This discharge has been demonstrated by its antidiuretic action (Burn *et al.*, 1945). Now vasopressin causes constriction of the coronary vessels, and the question at issue is whether the amounts of vasopressin discharged during smoking are sufficient to reduce coronary flow. It has been shown that the coronary flow in the dog heart is reduced by about 14% when the amount of vasopressin in the blood is not more than 20 milli-units per litre.

There is no direct evidence yet available. However, Burn and Singh Grewal (1951) have recovered 95 milli-units vasopressin from the urine of one subject who smoked two cigarettes, and they also showed that when vasopressin is injected intravenously, about 5% appears in the urine. From this they calculated that their subject who smoked 2 cigarettes had 1,900 milli-units in his blood, which may be reckoned as 380 milli-units per litre. This concentration would certainly cause a severe reduction in the coronary flow. However, this subject was unusually sensitive to nicotine, and it is unlikely that smoking would normally produce such high concentrations of vasopressin in the blood as this.

The electrocardiogram.—ECG changes have been recorded after smoking. Graybiel *et al.* (1938) found that 20 out of 45 subjects showed a lowering of the T wave, and sometimes an inversion of it. As a result of our studies on atrial fibrillation in Oxford we are coming to the conclusion that this depression of the T wave may indicate a diminution of the active transport of potassium from the plasma into the cardiac muscle, and as the active transport is carried out by metabolic processes which require oxygen, a depression of the T wave may indicate a diminution of the blood flowing through the coronary circulation. Roth *et al.* (1944) also observed a lowering of the T wave. Evans and Stewart (1943) also described a lowering of the T wave.

The ballistocardiogram.—Smoking has been observed to produce changes in the ballistocardiogram (Dock *et al.*, 1951; Caccese and Schrager, 1951; Kelly *et al.*, 1954). The changes were rarely seen in young people, but were common in persons with coronary artery disease. This observation has been confirmed by Starr (1954) who considers that evidence of a change in the ballistocardiogram produced by smoking can be used as evidence of coronary disease.

Conclusion concerning the heart.—Thus the findings all point in the same direction that nicotine has an effect on the heart which, while harmless in the young and healthy person, is harmful in those who are older, and especially in those with coronary disease. This effect may be due to the release of vasopressin which reduces the coronary blood flow, or it may be due to the action of nicotine on chromaffin tissue in the heart causing the release of adrenaline and noradrenaline, which my colleague Kottegoda (1953*b*) has also demonstrated.

I would like to conclude with an expression of surprise that doctors seem often disinclined to tell their patients not to smoke. McDevitt and Wright (1955) speaking of patients with thrombo-angiitis obliterans say "We still encounter a number of patients who have never been told to stop smoking. They frequently submit to multiple sympathectomies, which are quite futile if they continue to smoke". To my mind this is also true in those with

some degree of coronary insufficiency. Such patients ought to be warned quite strictly not to smoke, for when they stop they sometimes improve very much.

Dr. Richard Doll (Statistical Research Unit, Medical Research Council) *Smoking and Lung Cancer*, said that the data relating smoking to lung cancer were now extensive. Twenty retrospective studies of patients with and without lung cancer in 7 countries had all led to similar conclusions. It seemed unlikely that any form of bias could have accounted for the results of some of the investigations—particularly since it now appeared that the association held only for squamous, oat cell and undifferentiated cancers and not at all for adenocarcinomas. The evidence had been appreciably strengthened by the results of two prospective studies carried out by a different method. In the British inquiry (Doll and Hill, 1956) doctors had been questioned in 1951 about their smoking habits and, in consequence of the replies, had been classified according to the amount they smoked, their method of smoking and whether or not they had stopped smoking. The death-rates subsequently observed in the various groups were very different; the rate for lung cancer was low in non-smokers and increased steadily with the amount smoked till it was more than twenty times higher among heavy smokers. A similar, but much less pronounced, trend was observed for chronic bronchitis and a slight trend was observed for coronary thrombosis. For other cancers and for all other diseases taken together there was no significant difference in mortality between the various smoking categories. Cigarette smokers showed a higher mortality from lung cancer than pipe smokers and there had been a higher mortality among those who were still smoking in 1951 than among those who had stopped. The lung cancer mortality among doctors who were continuing to smoke 25 or more cigarettes a day at the time of completing the questionnaire was forty times that among non-smokers. The latest results in the American Cancer Society's study had been reported by Dr. Hammond to a meeting of the American Statistical Society in December 1955. This study involved the follow-up of 200,000 men aged 50–69, who had been interviewed by volunteer members of the Society in 1952. The results with regard to lung cancer were closely similar to those of the British study; the mortality had been some ten times higher among cigarette smokers than among non-smokers, higher still among heavy smokers and higher among cigarette smokers than among pipe or cigar smokers.

It was difficult to attribute the results of these two investigations to a tendency for doctors to diagnose lung cancer more readily among heavy cigarette smokers, since the association with smoking was stronger for histologically proven cases than for all cases. Neither could it be due to the effect, postulated by Berkson (1955), of special selection of persons to be included in the study as a result of reticence on the part of heavy smokers to respond to questions about their smoking habits. Such an effect should wear off in the course of a few years, but in the British study the relationship with smoking had remained unaltered over four years, while in the American study it was becoming stronger with the passage of time. It could not be that smoking merely determined the site in which a predetermined cancer developed, since in this case there would need to be a lower mortality from forms of cancer other than lung cancer among heavy smokers—and this was not observed. The simplest explanation of the facts was that cigarette smoking was a major cause of lung cancer. It was impossible to exclude the possibility that the association might be indirect, but in so far as any such mechanism had been suggested which was capable of testing, this had been disproved. For example, the association did not arise because heavy smokers specifically tended to live in big towns where they were exposed to atmospheric pollution. In the British investigation the smoking habits of the doctors were much the same wherever they lived, whereas in the American investigation, which was on a larger scale, it had been possible to show that the relation with smoking held—and was in fact much the same—in all types of residential area. The suggestion that the fundamental factor might be alcohol consumption was disproved by the work of Wynder *et al.* (1956) who showed that there was no significant difference between the amounts of alcohol drunk by patients with and without lung cancer, if the amounts smoked were kept constant.

The conclusion that cigarette smoking was a major cause of lung cancer accorded well with many of the other observed facts about lung cancer. For example, a detailed pathological study of the bronchial mucosa of patients dying of various types of cancer had shown that hyperplasia and metaplasia of the basal cell layer and the presence of carcinoma-in-situ became progressively more common as the amount smoked increased and was commonest of all among patients who had died of lung cancer. The increase in the death-rate in this country had followed the increase in cigarette consumption by about twenty years; it had been more rapid than the increase in cigarette consumption but some of the increase in the death-rate must be attributed to improvements in diagnosis. It remained to be seen whether the lung cancer death-rate would become stable in the future, following the relative stabilization of cigarette consumption over the last decade. The difference in the recorded mortality in different countries correlated well with the annual consumption of cigarettes in those countries twenty years previously; the mortality in Britain was, however, somewhat higher and the mortality in the U.S.A. somewhat lower than would be expected from comparison with other countries. The ratio of the recorded death-rates among men and women accorded with what was known of the past smoking habits of the two sexes.

Dr. Neville Oswald (Physician St. Bartholomew's Hospital and Brompton Hospital): *Medical Effects of Smoking*

Clinical aspects.—Of the dozen or so alkaloids which have been isolated from the tobacco plant, nicotine has established itself as being the most important. The pharmacological properties of nicotine are now well understood, the main effect being upon the sympathetic nerves, which are first stimulated and later, if the dosage be sufficient, paralysed. It is a stimulant to the central nervous system, and in toxic doses may produce convulsions. As with other habit-forming drugs, experimental investigations have been hampered, both in man and animals, by the differences in response to large and small doses in those who have or have not been previously exposed.

The vaso-constrictor effect is seen clinically in peripheral vascular disease and angina pectoris. Whilst no one would claim that either of these diseases was caused by smoking, the symptoms are occasionally intensified by it, and at least a trial period of abstinence should be recommended. Thrombo-angiitis obliterans, if indeed such an entity exists, falls into a rather different category, as it seems to bear a direct relation to smoking, so that smoking should always be forbidden in this disease.

The only parts of the gastro-intestinal tract that are affected by tobacco, so far as is known, are the stomach and duodenum, in which the symptoms of functional dyspepsia and peptic ulceration are thought to be aggravated. This is borne out in clinical practice, and the abandonment of smoking, especially when active ulceration exists, must be regarded as an essential part of proper medical management. It may be as well to remember that, in health, roughly 100 ml. of bronchial secretions are transferred from the trachea to the stomach via the œsophagus in each twenty-four hours and if these, together with saliva, are charged with the products of combustion of tobacco, they are likely to contribute to any effects that blood-borne nicotine may have upon the nerve endings in the gastro-duodenal mucosa. Certainly there seems to be a close association between smoking and minor symptoms of dyspepsia, particularly heartburn.

Amongst other clinical effects of smoking, the transient rise in blood pressure and pulse-rate, extrasystoles and the anti-diuretic effect are not important so far as we know, but smoking in conjunction with malnutrition seems to predispose to amblyopia.

A recital of the possible ill-effects of nicotine may leave the impression that the drug is capable of causing or aggravating a wide variety of diseases. This is offset to a large extent by the pleasant effects, which are related to the central nervous system; were this not so, there would be no problem. Most fresh smokers need to pass through a short period of initiation, which indeed is an accepted part of undergraduate experience. The phases of dizziness, nausea and vomiting are well known, but acute toxic manifestations, such as stupor and convulsions, are very rare. Repeated smoking leads to addiction, in which nicotine is said to soothe the nerves, relieve tension and monotony, and enable a clear brain to be maintained. Certainly, these are the properties which habitual smokers claim to exist.

In recent years, an association between tobacco smoking and bronchial carcinoma has been alleged by medical statisticians. Their case may now be regarded as proved, but clinicians have been slow to act upon this information, principally because of the reluctance of the majority of them to abandon the habit themselves. At first, the evidence was based upon small numbers of deaths from bronchial carcinoma, but reports from various countries during the past year or so confirm the association, which can be no longer disputed. Whether statistical methods will ever be able to determine the extent of the association remains to be seen. Some authors have gone so far as to suggest that heavy smokers have one chance in twenty of dying from bronchial carcinoma, and are twenty times more likely to do so than non-smokers. Perhaps such generalizations should be avoided until more is known of the other variable factors which influence the development of this neoplasm.

By dividing the population into heavy, medium, light and non-smokers, available evidence points to an association between the amount smoked and the chances of developing a bronchial carcinoma. In other words, there is a critical end-point of irritation beyond which epithelial metaplasia takes place. Perhaps future research will be able to determine the extent to which smoking influences this end-point in relation to such other possible predisposing causes as air pollution and a familial tendency to cancer. Clearly, the application of statistical methods can do no more than define the problem, and the real necessity now is for more intensive work upon the isolation of carcinogens from burnt tobacco, such as 3-4 benzpyrine, in the hope that possible noxious substances may be eliminated from tobacco without destroying its pleasant qualities.

The study of smoking in relation to chronic bronchitis is considerably hampered by our lack of a satisfactory definition of chronic bronchitis. The first difficulty is that about one-half of the population have mild respiratory symptoms from time to time which are not sufficiently severe to be labelled bronchitis, but which include the so-called "smoker's cough". Beyond this, with no sharp dividing line, are the true bronchitics who are disabled by one or more of the triad of infection, diminished air-flow, and reduced alveolar surface. In order to determine whether the possible effects of smoking could be expressed in figures, a form was completed upon 5,844 clerical workers in two London offices of the Civil Service. In this way, comparable groups of males and females were obtained having similar age, work, incomes, domestic circumstances and exposures to respiratory infections. The results (Table I) show consistently higher figures both for bronchitis and mild respiratory symptoms in smokers, compared with non-smokers, and are of the order which might be anticipated from clinical impressions. No estimate can be made of the quantitative effect of tobacco upon respiratory symptoms from this series, because some of the figures are insufficiently large for the differences to be statistically significant, but the consistent trends towards a higher prevalence of symptoms among smokers is most unlikely to be fortuitous. Table I also shows the higher prevalence of bronchitis in the older age

TABLE I.—PREVALENCE OF MILD RESPIRATORY SYMPTOMS AND BRONCHITIS IN 5,844 CLERICAL WORKERS (3,602 MALES, 2,242 FEMALES) IN THE CIVIL SERVICE IN LONDON, ACCORDING TO SMOKING HABITS (Oswald and Medvei, 1955)

	Age 15–39		Age 40–65	
	Smokers	Non-smokers	Smokers	Non-smokers
Males:				
No respiratory symptoms..	276 (40·6%)	255 (49·9%)	674 (34·8%)	260 (54·9%)
Mild symptoms	340 (50·0%)	235 (46·0%)	906 (46·8%)	139 (29·3%)
Bronchitis	64 (9·4%)	21 (4·1%)	357 (18·4%)	75 (15·8%)
Total	680	511	1,937	474
Females:				
No respiratory symptoms..	159 (40·6%)	352 (54·1%)	198 (34·3%)	317 (51·0%)
Mild symptoms	193 (49·2%)	258 (39·6%)	271 (46·9%)	229 (36·9%)
Bronchitis	40 (10·2%)	41 (6·3%)	109 (18·8%)	75 (12·1%)
Total	392	651	578	621

group in both sexes. This is hardly surprising, but the close correlation between the prevalence of bronchitis and sex in each group of smokers and non-smokers is remarkable, strongly suggesting that, when age, domestic and working conditions are standardized, the different rates for bronchitis in men and women are related to smoking habits.

The tobacco habits of 1,000 bronchitics have been investigated at the Bronchitis Clinic, Brompton Hospital. All except 106 had smoked at some time, and they were asked their opinions of the effect of smoking upon their bronchitis. The results are set out in Table II.

TABLE II.—TOBACCO HABITS OF 1,000 BRONCHITICS (Oswald *et al.*, 1953)

	Yes	No	Don't know
Does smoking aggravate bronchitis?	479	381	34
Has smoking been abandoned or cut down because of bronchitis?	532	359	3
If "yes", has bronchitis improved?	395	136	1

The majority agreed that their bronchitis was aggravated by smoking and a surprisingly high proportion of them had cut down or abandoned the habit with benefit.

The precise relationship between smoking and bronchitis cannot be defined. The suggestion has been made that tobacco smoke acts as a chemical poison upon the bronchial epithelium; certainly, it promotes the excessive formation of mucus, and it seems to predispose to chronic bronchitis. Its effects are likely to be influenced to some extent by individual differences in response to bronchial irritation. The commonest effect is the expectoration of mucoid sputum, which diminishes rapidly on the cessation of smoking, at least in the early stages; later, the condition may become permanent, causing little disability. At any stage in this process, bronchospasm may supervene, in which case breathlessness becomes apparent, and the sooner smoking is abandoned the better; unfortunately, once clinical bronchospasm has become evident, it is extremely difficult to eradicate unless it does so fairly promptly on the withdrawal of tobacco.

The excessive formation of bronchial mucus from any cause, and one cause is undoubtedly tobacco smoking, inevitably leads to a predisposition towards bronchial infection the so-called "resistance lowering effect" of mucus. To this extent, smoking hastens the onset of true chronic bronchitis, in which clinical evidence of an infective element exists, and this effect may well be enhanced by any poisonous action that tobacco smoke may have upon the bronchial epithelium.

[*March* 8, 1957]

MEETING HELD AT THE WHITTINGTON HOSPITAL, LONDON

Intrahepatic Portal Hypertension Due to Mucoviscidosis.—T. ST.M. NORRIS, M.D., M.R.C.P., D.P.H.

The association between cirrhosis of the liver and fibrocystic disease of the pancreas was first noted by Anderson in 1938, and in 1944 Farber when reviewing the post-mortem findings in 87 cases of the latter condition mentioned that in a small number he had found an unusual type of cirrhosis which appeared to be secondary to intrahepatic biliary obstruction. He held that the sequences leading to these obstructive changes were similar to those seen in the pancreas.

During the last ten years it has been recognized that hepatic cirrhosis may be one of the features of fibrocystic disease of the pancreas and its incidence according to different authorities is shown in Table I.

TABLE I.—INCIDENCE OF HEPATIC FIBROSIS AS A FEATURE OF FIBROCYSTIC DISEASE OF THE PANCREAS

Authority	Year	No. of cases reviewed	No. of cirrhotics	Percentage cirrhotics
Bodian	1952	62	"About a quarter"	25%
Webster and Williams ..	1953	116	5	4·4%
May	1954	"Several Hundred"	1	Less than 1%
Craig *et al.*	1955	160	7	4·37%
Sant' Agnese and Blanc..	1956	116	25	22%

Sant' Agnese and Blanc (1956) state that one-third of the cases of cirrhosis seen in children of the pædiatric age-group is due to fibrocystic disease of the pancreas.

CASE REPORT

A schoolgirl aged 14 was admitted to the Archway Wing of the Whittington Hospital on October 26, 1956, because of hæmatemesis. There was nothing unusual in the family history, the father and mother, who are not cousins, are alive and well, one brother aged 9 is apparently well.

There were no previous illnesses until the age of 4 when the child had whooping cough; since that illness she has suffered from recurrent "colds" and cough. At the age of 11 because of a cough, she was X-rayed and hepatomegaly without splenomegaly was noted, chest X-ray was normal. Her serum albumin was 5·1 g.% and serum globulin 3·5 g.%.

Diagnosis: cirrhosis of the liver.

On admission to the Whittington Hospital she gave a history of hæmatemesis on the previous day with recurrence on two occasions since; there had been no dyspepsia, but diarrhœa with the passage of pale bulky stools had been noted.

On examination she was pale with a hæmoglobin of 48%. The liver edge was palpable two to three fingerbreadths below the costal margin and the spleen, though not felt on admission, was palpable two days later. Naked-eye examination of the stools showed them to be pale and unusually bulky.

She made a satisfactory recovery from the hæmorrhage and the following investigations were carried out.

Chest X-ray.—A small area of diminished translucency is seen in the right infra-clavicular region (Fig. 1); this is probably healed pulmonary tuberculosis. The diaphragm is not flattened and the intercostal spaces not broadened.

Barium swallow.—Filling defects in the lower third of the œsophagus are characteristic of varices (Fig. 2).

Barium meal.—Small duodenal ulcer.

Follow through.—N.A.D.

X-ray lumbar spine and right femur.—Nothing abnormal.

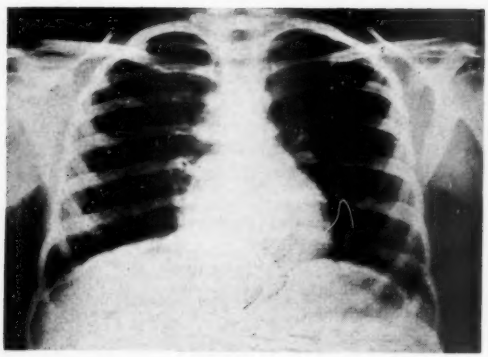

FIG. 1.

A B C

FIG. 2.

Hb 48%. W.B.C. 6,700 (polys. 61%, eosinos. 1%, lymphos. 34%, monos. 4%).

Prothrombin time: 21 seconds. Control 15 seconds. Serum proteins 6·2, albumin 3·8, globulin 2·4 grams.%. Paper electrophoresis of serum proteins: N.A.D. Serum bilirubin 0·1 mg./100 ml. Alkaline phosphatase 21·5 units/100 ml. Thymol turbidity 3 units/100 ml. Bromsulphthalein test normal. Absolute indices on day after admission: Hb 43%. P.C.V. 20%. M.C.V. 91 cμ. M.C.H.C. 32%.

C.S.U.: N.A.D. W.R. and Kahn negative. Serum calcium 10·4 mg.%. Serum inorganic phosphorus 5·6 mg.%.

Duodenal intubation was attempted but was not satisfactorily completed because the patient became distressed. However, it was established that trypsin, bilirubin and bile salts were present in the duodenal juice. Tryptic activity was present in dilutions up to 1 in 50 and in fæcal dilutions up to 1 in 100. (Normal dilutions of 1 in 50 to 1 in 100.) Fat balance showed average daily excretion of 22·7% of intake. Glucose tolerance curve showed an increase of 92 mg.% above resting value 60 minutes after glucose feed. No glycosuria. Urinary calcium: 0·15 gram in a total of 1,450 ml. Folic acid absorption test normal. Sweat test: Sodium 122 (normal 4–52), chlorides 129 (normal 9–40) m.eq./litre.

In January 1957, at laparotomy by Mr. W. W. Davey, no duodenal ulcer was found, but the liver was coarsely nodular and unusually firm. A small portion was taken for section which showed a coarse fibrosis in the portal systems with areas of acute and chronic

FIG. 3.—Very low power showing groups of normal lobules with coarse and irregular portal fibrosis. × 8.

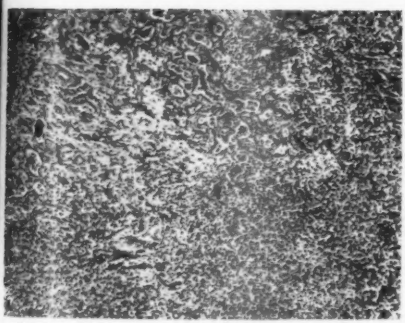

FIG. 4.—Low power showing an area of portal fibrosis with chronic inflammation and a few concretions in bile ducts. × 53.

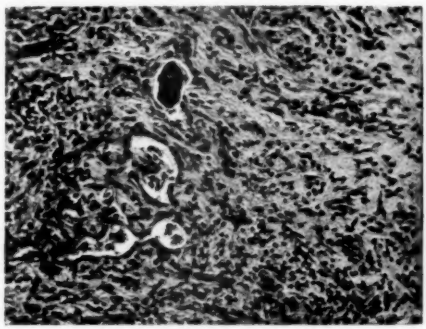

FIG. 5.—High power of Fig. 4 to show concretions. × 133.

inflammatory infiltration and conspicuous proliferation of bile canaliculi containing eosinophilic secretion and some concretions (Figs. 3, 4, 5).

There is no doubt that this girl suffers from an unusual type of hepatic cirrhosis which is associated with steatorrhœa. The diagnosis seems to lie between cirrhosis due to fibrocystic disease of the pancreas or mucoviscidosis and a nutritional cirrhosis secondary to dysfunction of the small intestine and malabsorption.

In favour of the former diagnosis we have: The sweat test. The liver biopsy. The normal folic acid excretion test and absence of evidence of any intestinal abnormality. The evidence in favour of the latter diagnosis is negative only, being:

The tryptic activity in the duodenal aspirate and the absence of radiological evidence of emphysema or bronchiectasis.

We are satisfied that the former is the correct diagnosis.

If we accept this diagnosis we are faced with a problem regarding treatment. Should this girl be submitted to surgery with a view to a shunt operation? or should she be treated conservatively? In considering this problem a summary of Sant' Agnese and Blanc's 5 cases in which the diagnosis was confirmed by liver biopsy may be helpful (Table II).

Case 1 died of pulmonary complications.

Case 4 died after three operations, the first a lieno-renal shunt; this thrombosed and hæmatemesis recurred. A porta-caval shunt was then carried out, but again hæmatemesis

TABLE II.—SUMMARY OF SANT' AGNESE AND BLANC'S 5 CASES

Sex	Age	Duodenal tryptic activity	Sweat Cl.	Sweat Na.	Lung involvement	Gastro-intestinal bleeding	Shunt operation	Present state
M	4	0	78	—	+	+	+	Died 18/12
M	6	0	94	95	+	+	+	Well 2/12
M	6	320 units per ml.	98	120	+	0	0	Alive
F	10	0	72	84	+	+	+	Died 19/12
F	10	131 units per ml.	84	95	+	+	+	Alive 6 years
			CASE UNDER REVIEW FOR COMPARISON					
F	14	1–100 dilution Normal 1–50 to 1–600	129	122	History only	+	0	

recurred. A third operation was attempted, but the girl did not long survive and at post-mortem it was found that the portal vein had thrombosed.

In the case under review it is a difficult decision to make. Firstly there is the slight possibility that the hæmorrhage originated in the duodenal ulcer and not from œsophageal varices. Secondly, this disease involves other important organs such as the lungs and the pancreas besides the liver, and the expectation of life is in any event not beyond the middle twenties.

It therefore seems rather drastic to resort to major surgery at present and my own view is that she should be kept under close observation on conservative treatment.

18.10.56	55	37,200	96	1	—	3	—	No primitive cells seen	1,185,000	14 mm.
13.11.56	73	62,000	90	3	2	5	—	Platelets numerous. One myeloctye noted		
28.12.56	105	71,200	93	1	—	5	1	No primitive cells seen		2 mm.
25.1.57	102	61,800	93	2	—	4	1	No primitive cells seen	786,000	2 mm.

Imferon. Enlargement of the spleen was detected for the first time on 19.10.56. General condition gradually improved and the signs of cardiac failure disappeared during the next two months. Present condition: fully ambulant, colour good, spleen 3 cm. below costal margin.

Investigations.—Table I gives a summary of the blood findings. 23.11.56 and 30.1.57: *Sternal Puncture*—Marked hyperplasia of erythroid, myeloid and megakaryocytic elements (*see* Figs. 1 and 2). Fæcal occult blood reaction negative. Barium enema unsuccessful.

13.2.57: *Blood* (*see* Fig. 3). R.B.C. 6,880,000; Hb 117%; P.C.V. 58%. M.C.V. 85 cμ. M.C.H.C. 29·9%. W.B.C. 65,800 (neutros. 93%, eosinos. 4%, basos. 1%, lymphos. 1%, monos. 1%). *Platelets* 922,000 per c.mm. *Film:* Low-grade increase in polychromasia but no primitive red or white cells seen.

22.1.57: Serum vitamin B_{12} 1,000 μμ/ml.

14.2.57: Leukocyte alkaline phosphatase (*see* Fig. 4)—marked increase.

Comment.—The early hæmatological features suggested the diagnosis of neutrophilic leukæmia, and the findings in the peripheral blood are similar to those described by Tuohy (1920). Subsequently, however, polycythæmia developed and the later blood examinations disclosed a pancytosis. These changing hæmatological features support the unitarian hypothesis of the myeloproliferative syndromes (Dameshek, 1951). The occurrence of neutrophilia in polycythæmia vera is well recognized (Weber, 1933; Rosenthal and Bassen, 1938), but for polycythæmia to present with such a marked neutrophilia without immature white cells in the peripheral blood is most unusual. Estimation of the leukocyte alkaline phosphatase activity by the histo-chemical method of Wiltshaw and Moloney (1955) shows a marked increase with intense staining in the cytoplasm of most leucocytes (*see* Fig. 4); this reaction is found in the leucocyte abnormality of polycythæmia vera and is unlike the results obtained in chronic myeloid leukæmia.

Bilateral Uretero-Sigmoidostomy, Acidosis, Osteomalacia.—ARNOLD BLOOM, M.D., M.R.C.P.

R. R., male, aged 45. September 1953: Total cystectomy and transplantation of ureters into colon performed for carcinoma of bladder (Mr. P. T. Savage). Defaulted on after-care and readmitted in January 1954 with thirst, an "ammonia taste" in the mouth, lassitude, anorexia and vomiting. Blood chemistry revealed acidosis and hypokalæmia (alkali reserve 12·1, serum potassium 3, sodium 126, chlorides 90 mEq./l. blood urea 120 mg./100 ml.). Potassium bicarbonate by mouth led to rapid improvement and correction of biochemistry (alkali reserve 22·2, potassium 6·7, sodium 141, chlorides 101mEq./litre: urea 50 mg./100 ml). He was again admitted in April 1954 with a similar relapse and response to therapy. Thereafter, he took alkalis sporadically but failed to attend out-patients: for the six months prior to his last admission, he developed increasing weakness in the limbs and became almost unable to get out of bed. When seen in November 1956, some three years after cystectomy, he walked slowly and stiffly, with a waddling gait and using two sticks. To get out of a chair, he "climbed up himself", i.e. hands on knees, then up his thighs. There was marked tenderness over the entire thorax, especially over left second rib. Transverse abdominal creases and loss of head to pubic height suggested collapsed vertebræ (crown to pubis 32 in., pubis to feet 34 in., span 71 in.). Muscles were weak and spastic with myotonic irritability and increased reflexes. Plantars flexor.

Investigations.—X-rays: rarefaction of vertebral column with marked wedging of thoracic vertebræ (Fig. 1): fracture of left second rib. Intravenous pyelograph: kidneys failed to visualize.

Bone biopsy (Von Kossa stain of undecalcified cancellous bone): numerous pale osteoid borders on surfaces of dark calcified portions of bone trabeculæ: excessive fragmentation of bone trabeculæ is an artefact: appearances typical of osteomalacia (Fig. 2).

Biochemistry: Calcium 8·2, phosphorus 3·5 mg./100 ml.
Alkali reserve 12·1, chlorides 111, sodium 130, potassium 3·6 mEq./l.
Alk, phosphatase 14·5 KA units. Acid phosphatase 1·5 units.
Protein: albumin 3·2, globulin 2·8 grams%.
Blood urea 60 mg./100 ml.

FIG. 1.—Partial collapse of vertebral bodies.

Treatment and progress.—On the suggestion of Professor C. E. Dent, calciferol alone (15 mg. I.V. followed by 5 mg. I.V. twice weekly) was administered for two weeks, but with no improvement. Calciferol by mouth (3·5 mg. daily) and alkalis (sodium lactate 2 grams and potassium bicarbonate 1 gram t.d.s.; later sodium bicarbonate 3 grams t.d.s.) were then administered. He was given a low salt diet and advised to empty his bowels at frequent intervals. Over the next three months, progress was steady; he became able to walk freely without sticks, and could get up from a chair without use of his hands. No chest tenderness. February 1957: X-ray of chest showed callus formation at site of rib fracture. Bone biopsy: "The osteoid borders have disappeared. One or two localized areas of narrow fibrosis and irregularity of cement lines suggest remodelling following mild trauma."

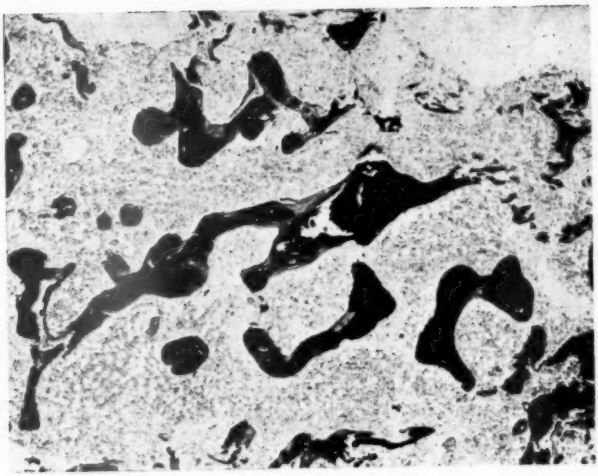

FIG. 2.

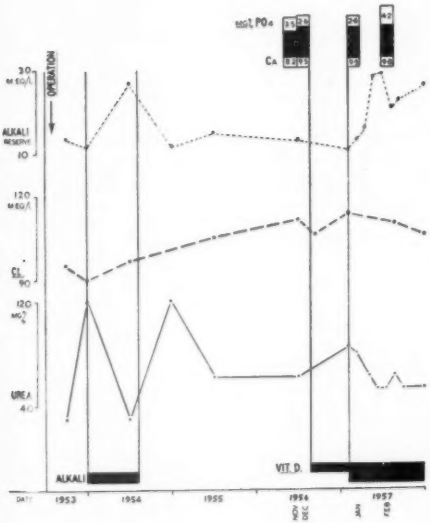

FIG. 3.

FIG. 2.—Bone biopsy showing osteoid borders. ×17.

FIG. 3.—Chart showing effect of alkali on biochemistry.

Calcium 9·8; phosphorus 4·2 mg./100 ml; alkali reserve 22·2, chlorides 107 mEq./l. (Fig. 3.)

Comment.—Two mechanisms may be responsible for the persistent acidosis occurring after uretero-sigmoidostomy. Firstly, there appears to be a selective absorption from the lower bowel of urinary chlorides, perhaps combined with ammonia derived from bacterial breakdown of urea. Secondly, since the kidneys are usually damaged by chronic retrograde infection, the renal acid-base regulating mechanism is disturbed and the acidosis cannot be corrected. Prolonged acidosis in its turn leads to loss of fixed base. In this patient, although initially there was hypokalæmia, in the later stages the most striking feature was resorption of calcium from the bones and consequent osteomalacia. These symptoms can be avoided by daily administration of alkalis, by restriction of salt and by frequent emptying of the lower bowel. However, the likelihood of electrolyte imbalance

is a serious disadvantage of bilateral uretero-colostomy, particularly in this case where the patient was unco-operative.

Mr. E. W. Riches hoped that the occasional occurrence of severe acidosis would not lead to the complete abandonment of the operation of uretero-sigmoidostomy. When the kidneys were not grossly damaged before operation there was no reason to condemn the patient to a permanent urinary fistula, and acidosis could be avoided by giving alkalis, reducing salt intake, and insisting on regular three-hourly evacuation of the rectum. How many would prefer an ileostomy with the need to wear an appliance rather than a controlled rectal bladder? If the kidneys were damaged uretero-ileostomy made it possible to save them from further injury, and had a useful place in the treatment of carcinoma of the bladder.

He had seen one case of osteomalacia following uretero-sigmoidostomy. This patient also had defaulted in taking alkalis, and had eventually gone to another hospital where the condition had not been recognized; orthopædic rather than biochemical methods of treatment had been instituted without success. Under treatment by alkalis he had made a good recovery.

Cervical Pain as a Symptom of Hypotension During Treatment with Ganglio-plegic Drugs.—E. MONTUSCHI, M.D., M.R.C.P.

G. T., male, aged 45.

History.—First seen in 1953 with a spontaneous left pneumothorax which resolved with bed rest. B.P. 180/100.

In 1954 he was admitted for congestive cardiac failure. Auricular fibrillation. B.P. 240/160. Cardiac enlargement. Left ventricular hypertrophy on clinical examination and in ECG. Good renal function.

Treatment started with digitalis and pentolinium; the dose of Ansolysen Retard was gradually increased to 25 mg. in the morning. The congestive failure cleared and he was followed up in out-patients. He then reported that at the height of the effect of the drug, one to one and a half hours after injection, he would experience severe pain in the posterior cervical region on standing and on physical exertion; the pain would subside on lying down. The symptom would disappear in the afternoon, whatever the posture.

Readmitted to hospital in September 1956 when a change was made from pentolinium by injection to Mecamylamine by mouth. On that occasion serial blood pressure readings were taken after an injection of pentolinium.

Since taking Mecamylamine there has been no recurrence of posterior cervical pain.

On examination.—Fundi show hypertensive retinopathy with hæmorrhages. Pulse 80. Auricular fibrillation. Considerable cardiac enlargement with heaving apex beat. Wide splitting of first and second sounds at all areas. The split of the second sound widens on inspiration. No evidence of congestive cardiac failure. ECG tracings show a change from left ventricular hypertrophy pattern to right bundle branch block.

Comment.—This patient was the first of a series of six to draw my attention to a symptom not described before.

The symptom is pain in the nape of the neck which is severe, radiating across the shoulders when a rapid fall in blood pressure caused by ganglio-plegic drugs reaches its lowest point. The pain is aggravated by exertion and immediately corrected by assuming a reclining posture. No ECG changes, suggestive of myocardial ischæmia, have been recorded at the height of the symptom. If patients are unaware of its cause pain may be prolonged and lead to misdiagnosis. One patient had been referred to the physiotherapy department for cervical spondylosis. No explanation is offered as to the mechanism of this symptom.

Idiopathic Hypercatabolic Hypoproteinæmia.—W. R. CATTELL, M.B., M.R.C.P. (for T. St. M. NORRIS, M.D., M.R.C.P., D.C.H.).

Mr. A. W., a librarian's assistant, aged 20, was admitted to the Archway Wing of the Whittington Hospital in March 1956, with a history of ankle swelling for ten days. In addition, he had had malaise and lassitude for some months and a history of mild constipation with abdominal discomfort for many years. His diet was normal in quality and quantity.

There was no history of serious illness in the past. He had had the usual childhood exanthemata without complications. At the age of 17 years he developed mild flexural eczema which has persisted. There was no history of acute allergic disorders.

There was no relevant family history. He is an only child.

On examination he was pale and thin, but appeared normally developed. There was slight œdema of both ankles but no evidence of cardiovascular disease. He also had a dry flexural eczema affecting the elbow and popliteal areas. There was slight abdominal distension but no abnormal masses and no hepatic or splenic enlargement. All other systems were normal.

Estimation of his serum proteins showed a hypoproteinæmia, the total serum protein on admission being 4 grams/100 ml. Subsequent examination showed that the hypoproteinæmia affected albumin and globulin alike and paper electrophoresis showed reduced albumin, much reduced gamma globulin and increased alpha globulin.

Other special investigations were as follows:

Hb 58% (8·5 gram/100 ml.). R.B.C. 4,370,000. P.C.V. 32%, M.C.V. 73 cμ., M.C.H.C. 27%. W.B.C. 6,450 with normal differential count and no eosinophilia. Fæcal trypsin was present in normal quantities; F.T.M. normal; fat balance—average daily excretion of 3·8% of fat intake; fæcal nitrogen excretion 0·5 gram daily while on intake of 70 grams daily. Sigmoidoscopy normal; Ba meal and follow through normal; straight X-ray of abdomen normal; Ba enema showed dilatation of the whole length of the colon and rectum—the appearances being consistent with those found in chronic constipation. Serum bilirubin 0·2 mg./100 ml., alkaline phosphatase 3 units (King Armstrong), thymol turbidity 2 units/100 ml., bromsulphthalein excretion normal; prothrombin time 18 seconds against control of 15 seconds. Liver biopsy (3.5.56) showed slight œdema of otherwise normal liver tissue. Repeated urinalysis showed no proteinuria and no abnormality on microscopic examination of the centrifuged deposit. Blood urea <20 mg./100 ml. Water concentration and dilution test was normal. Examination of the urine by two dimension paper chromatography showed no abnormal amino-aciduria. Serum calcium 8·7, inorganic phosphate 2·7, cholesterol 143 mg./100 ml. Wassermann and Kahn reactions negative. Mantoux positive to 100 T.U. only. X-ray of chest normal.

His mother (his only close living relative) had her plasma proteins estimated and these were normal, as was the electrophoretic pattern.

A diagnosis of idiopathic hypoproteinæmia was made and the patient was given a high protein diet (average daily intake of protein being 100–120 grams). He was also given oral iron and the iron deficiency anæmia rapidly improved, although the Hb has never reached 100%. A mild iron deficiency anæmia persists (Hb 84%, R.B.C. 5,200,000, M.C.V. 78 cμ., and M.C.H.C. 30%). and is associated with weakly positive stool benzidine tests. The exact site of this intestinal bleeding has not been located.

His œdema rapidly disappeared after admission to hospital and has only occasionally been noted since. As can be seen from Table I there has been no significant change in his serum protein levels over twelve months, despite a high protein intake.

TABLE I.—SERUM PROTEINS

	Total serum proteins grams/100 ml.	Albumin grams/100 ml.	Globulin grams/100 ml.	A/G Ratio
Normal	6·3–8·2	3·5–5·7	1·5–3·0	
24.3.56	4			
9.4.56	4·2			
27.4.56	4·3			
11.5.56	4 2	2·8	1·4	2/1
2.7.56	4·2	2·6	1·6	1·6/1
20.8.56	3·9	2·8	1·1	2·5/1
18.12.56	4·2			
2.3.57	4	2·9	1·1	2·8/1

In February 1957 studies were carried out to determine the fate of intravenously injected human serum albumin labelled with radioactive iodine. Figs. 1 and 2 show the fate of intravenously injected labelled serum albumin in a normal young man and in this case. It will be seen that the initial fall off in plasma levels is similar in each case and represents mixing of the labelled albumin with native albumin throughout the body. The subsequent fall in plasma levels can be taken to represent the gradual elimination or breakdown of the injected albumin. If the daily urinary output of radioactive iodine is measured over this period it can be shown that paralleling the fall off in plasma radiaoctivity, there is actual elimination of radioactive iodine in the urine and if the twenty-four-hour urine radioactivity is divided by the total radioactivity in the plasma at the middle of the twenty-four-hour period, one may estimate the proportion of plasma albumin broken down per

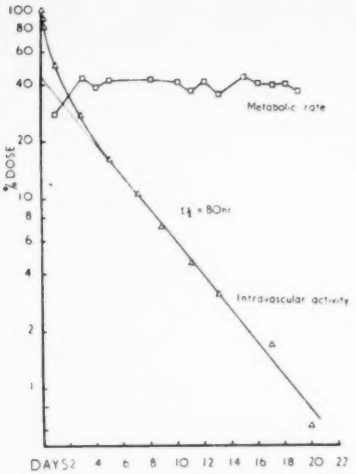

FIG. 1.—Idiopathic hypoproteinæmia.

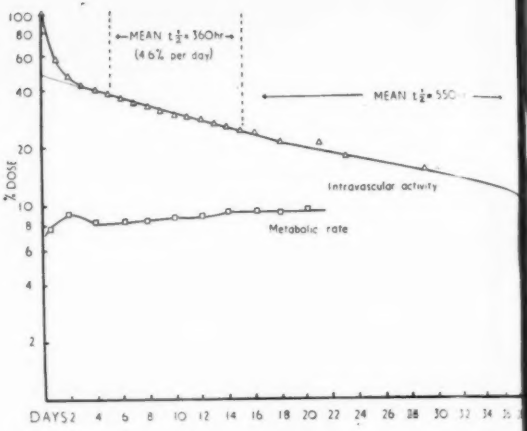

FIG. 2.—I^{131}—Human albumin in normal human.

day. This is represented in the graph as the "metabolic rate"—expressed as a percentage of total plasma albumin.

It can be seen that there is a marked difference in the metabolic rates in the normal and in this case. It would, therefore, seem that in the patient there is an excessively rapid breakdown of plasma albumin (and probably other plasma proteins) within the body. As his plasma protein levels remain relatively constant, we must presume that to meet this excessive breakdown, the rate of synthesis must be increased.

The findings in this study agree with those of Schwartz and Thomsen (1957) using similar methods. Both studies combine to oppose the originally held view that the underlying defect in this condition is one of defective synthesis of plasma proteins. They do not, however, indicate the site of this abnormal breakdown or the primary cause of such a disturbance in plasma protein metabolism. We propose to carry out further studies in this case in an attempt to elucidate these points further.

We would like to acknowledge the assistance and advice given to us by Dr. A. S. McFarlane of the National Institute for Medical Research who supplied the labelled albumin and carried out the subsequent estimations of plasma and urine radioactivity,

[*March* 7, 1957]

Spontaneous Pneumothorax in the Royal Navy

By Surgeon Commander J. M. CLIFF, M.B., B.Chir., M.R.C.P., R.N.

DURING the last thirty years a large number of series of cases of spontaneous pneumothorax have been reported from various parts of the world and the increasing number of such reports indicates that the condition can no longer be regarded as rare although Perry considered it as "comparatively rare" as late as 1939. There is no doubt that this apparent increasing incidence is due to improved diagnosis, both in the use of radiology and awareness of the condition, as in Perry's (1939) 85 cases where only 26 were recorded in the first seven years against 59 in the second period of seven years. Blackford (1939) noted an incidence of one per thousand male students at the University of Virginia while Schneider and Reissman (1945) found that one in five hundred men examined for military service in the United States gave a verified history of spontaneous pneumothorax.

Kjaergaard (1932) had a clear conception of the condition when he included every case "that appears without demonstrable cause in healthy persons in whom tuberculosis cannot be demonstrated, either by examination of the sputum, by auscultation or by X-ray examination, and in whom the lesion is not accompanied by fever or by pleural effusion".

The material for this investigation was drawn from the admissions to the three Home Port Naval Hospitals at Chatham, Haslar and Plymouth during the years 1943 to 1953 inclusive. During the war years the number of admissions was far in excess of normal and while those joining the Service either voluntarily or for National Service were of the age groups normally serving in the Royal Navy they were supplemented by pensioners and retired officers over the age of 40; there is therefore some bias towards the older age groups in 1943–1946 inclusive. During the eleven-year period under review there are records of the admission of 163 patients suffering from or subsequently found to have a spontaneous pneumothorax; only 3 were female.

Hospital admissions give some idea of the incidence of a disease but few statistics have been published for this condition, and the figures for civil and Service hospitals are not strictly comparable on account of the particular age group and predominance of males in the Armed Forces, the greater tendency to admit Service patients to hospital where the problems of accommodation of the sick in Ships and Establishments often do not permit nursing or even observation, and the fact that Servicemen are selected fit men (Tables I and II).

TABLE I.—ADMISSIONS OF CASES OF SPONTANEOUS PNEUMOTHORAX TO ROYAL NAVAL HOSPITALS

Year	Total No. of admissions	No. of cases of spontaneous pneumothorax	Rate per 1,000 admissions
1943	40,748	20	0·49
1944	40,058	14	0·35
1945	41,788	22	0·53
1946	30,824	17	0·55
1947	20,990	16	0·77
1948	18,729	11	0·59
1949	18,791	9	0·48
1950	17,278	10	0·58
1951	19,402	9	0·46
1952	18,968	13	0·68
1953	20,389	22	1·08
	Totals 287,965	163	0·57

TABLE II.—ADMISSION RATES FOR SPONTANEOUS PNEUMOTHORAX

Author	Period	Source	No. of cases	Rate per thousand admissions for all causes
Perry (1939)	1924–1937	London Hospital	85	0·6
Cohen and Kinsman (1946)	1941–1944	U.S. Army Hospitals	41	0·22
Du Bose, Price and Guilfoil (1953)	1946–1952	Veterans Administration Hospital	75	0·02
Jones and Lyons (1954)	1949–1953	U.S. Naval Hospital Philadelphia	70 (60 analysed)	1·0
This series	1943–1953	Royal Naval Hospitals	163	0·57

Age and sex distribution.—The age of patients prone to spontaneous pneumothorax is shown to be low in all reports, and in civil practice many authors have substantiated West's (1884) observation that the young adult male is particularly prone (Table III). No adequate

This series	Royal Navy	18–60	25	—	45 (27%)	90 (55%)	20 (12%)	4 (3%)	4 (3%)	—

theory has been advanced to explain this observation; it has been suggested (Wilson, 937) that there is an innate sex-linked tendency but a more probable reason is that emphysem tous blebs are more likely to develop in the sex which plays all sports and performs fe s of strength in which the intrapleural pressure is built up against a closed glottis (Ornstei and Lercher, 1942).

Physique.—Wilson (1937) noted that all his 11 Yale University students were sing arly tall and lean while Norris (1940) observed that two-thirds of his patients were 10- lb. underweight and Hyde and Hyde (1948) reported that almost all their 63 patients were thin and underweight. Wilson (1937) argued that it is the tall thin young man with low diaphragm and a predominantly diaphragmatic type of breathing who is more like to concentrate tension on the apices of the lungs, but the opposite argument may well be used since the well-built youth is more likely to take part in strenuous exercise and ther fore overdistend the apices of the lungs which are unsupported by the thoracic cage.

It was not possible to assess the physique of the patients in this series accurately from their medical records but there were available the weights of 128 patients and the average weight of the 127 males was 141·2 lb. (Table IV).

TABLE IV.—WEIGHTS OF PATIENTS IN THIS SERIES

Weight (lb.)	110–120	121–130	131–140	141–150	151–160	161–170	171–
Number of cases	11	17	41	25	25	3	5

Family history of spontaneous pneumothorax.—A familial occurrence has occasionally been observed in this condition, Willis (1937) noting it in a brother and sister, Bachmann (1940) in a father and daughter, Brock (1948) reporting 2 patients whose near relatives had had pneumothoraces, and Young (1936) mentioning 2 patients in the same family who developed a pneumothorax while straining at stool; similarly Atwood (1926) observed the condition in a father and son and Rottenberg and Golden (1949) in 2 brothers. It has been suggested that the cause might be hereditary lung cysts in all these familial cases but this condition is rare and Perry (1939) did not feel that there was sufficient evidence for such a diagnosis, pointing out that there was no indication that the condition was transmitted as a Mendelian dominant as in congenital cystic disease of the kidney. There were no familial cases in this series.

Previous history of chest disease.—A previous history of pulmonary disease other than spontaneous pneumothorax was uncommon in this series, 157 (96%) admitting to no such history; of the remaining 6, 3 were asthmatics, 1 had had pleurisy, another pneumonia and the sixth a contralateral pleural effusion.

Emphysema is often considered an unusual causative factor since it is rare in the young (except in asthmatics) and the blebs do not tend to become overdistended with air because they communicate with the surrounding lung tissue, but Perry (1939) found that 20 (91%) of his patients over the age of 40 had clinical, radiological and spirometric evidence of emphysema. In this series the 5 (3·1%) patients with radiological signs of unilateral or generalized emphysema were aged 23, 23, 31, 45 and 55; it was not possible to determine the cause of the unilateral emphysema in the 2 younger patients, 1 not being traced and the other symptom-free nine years later.

The presence of respiratory tract infection at the time of onset of the spontaneous pneumothorax.—Leach (1945) found that 18 (14%) of his patients had an upper respiratory infection and 13 had a cough but in only one did the pneumothorax occur during a bout of coughing. In this series there was a history of such an infection in 18 cases (11%) but the month of admission to hospital does not suggest that this condition is more likely to occur when these infections are most common (Table V).

TABLE V.—MONTH OF ONSET OF PNEUMOTHORAX IN THIS SERIES

Month	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.
Number of cases	14	12	12	12	13	16	17	15	14	13	14	10

(No record in one patient.)

Activity at onset of the spontaneous pneumothorax.—The relation between physical exertion and the onset of a spontaneous pneumothorax is of considerable interest both physiologically and from a medico-legal aspect, the latter problem being well demonstrated by 13 (22·4%) of Ornstein and Lercher's (1942) patients being industrial compensation cases. Kjaergaard (1932) found no history of preceding physical exertion in 78·7% of the episodes in his report, 16% occurring while the patient was in bed; similarly 4 (6·3%) of Hyde and Hyde's (1948) patients were wakened by symptoms of a pneumothorax and Jones and Lyons (1954) found that 11 (13·3%) of their patients were asleep or just rising. In this series the activity of the patient at the time of onset of the pneumothorax was recorded in 100 cases; 36 were at rest or asleep, 48 were carrying out mild exercise and 16 were taking strenuous exercise. There is therefore no close relationship between physical activity and the onset of a pneumothorax but it remains possible that exertion plays an occasional part.

Asymptomatic spontaneous pneumothorax.—The accidental finding of a pneumothorax at routine chest X-ray is not unusual; Kjaergaard (1932) noted 2 such patients, 5 of Wilson's (1937) 11 cases were detected in this way and Schneider and Reissman (1945) found that 5% of their 100 cases were asymptomatic. In this series 5 men were found to have a pneumothorax at their annual mass miniature radiograph but only one was completely symptom-free, the remainder admitting to cough, chest pain or dyspnœa on exertion, on direct questioning.

Lung involved in this attack of spontaneous pneumothorax.—In this series there were 80 right-sided attacks while 82 involved the left side, a ratio of 0·97:1; in 1 patient there

was a bilateral partial pneumothorax. In 1,001 cases from the literature 529 were right-sided, 453 left-sided and 19 bilateral, alternating or unspecified (Table VI) but there is

some evidence that the left side is more often involved when there is a concurrent mediastinal emphysema.

Recurrence of pneumothorax.—Recurrence is frequent at some later date, often in the absence of any evident predisposing cause, and many patients are instructed to lead quiet lives; they are advised not to close the glottis, or to avoid high altitudes or heavy lifting, yet these restrictions seem unnecessary since relapses may well occur while the patient is at rest and much avoidable invalidism may be encouraged. The relapse rate varies from 4·7% observed by Perry (1939) to 29·8% reported by Ornstein and Lercher (1942) with an average of about 20%; the relapse may be in the contralateral lung, as in 20% of Hyde and Hyde's (1948) and 35% of Ornstein and Lercher's (1942) patients. Schneider and Reissman (1945) found that only 10% recurred if two years had elapsed but Rottenberg and Golden (1949) noted the average time between attacks to be nearly two years although 15 (62·5%) of their cases had their relapse within a year (Table VII). 20 (12·3%) patients in this series

This series	116	14	12·12

(NOTE: the figures from the literature are not strictly comparable with those in this investigation since some authors do not state the period of observation which was from one to eleven years in this series.)

gave a verified history of previous pneumothorax, 12 (7·4%) having had single ipsilateral attacks, 4 (2·4%) two or more ipsilateral attacks, 2 (1·2%) one or more contralateral attacks, while the side of the previous attack was unknown in 2.

Degree of collapse of lung.—Estimates of the degree of collapse vary with the observer and radiological technique and therefore both Leach (1945) and Rottenberg and Golden (1949) divided their cases into only two groups, less than or more than 50% collapse; minimal collapse may not be detected unless radiographs are taken in full expiration and the technique is superlative. In this series the pneumothorax was reported as partial in 97 (59·5%) and complete in 65 (39·9%), while in 1 it was bilateral and partial (Table VIII).

Presence of adhesions in the pneumothorax radiographs.—The importance of adhesions which prevent further collapse of lung has been stressed in the American literature on account of the greater incidence of subsequent active pulmonary tuberculosis in these patients but they are a group self-selected for the development of pulmonary tuberculosis, the adhesions often being due to a previous tuberculous pleurisy. None of the 6 (9·8%) patients noted to have adhesions by Kjaergaard (1932) developed pulmonary tuberculosis but this did happen to all 3 (5·2%) of Ornstein and Lercher's (1942) cases; similarly Cohen and Kinsman (1946) had 5 (13%) cases with adhesions, 2 having no lung lesion after expansion, 2 inactive minimal tuberculosis and 1 active disease. In this series adhesions were noted at the time of the pneumothorax in 8 (5%) patients but none of the 4 patients followed up for two to nine years developed active pulmonary tuberculosis.

Presence of a simultaneous pleural effusion.—Small effusions are frequent, rapidly absorbed and of no significance and in his definition of pneumothorax simplex Kjaergaard (1932) allowed a trace of fluid in the costophrenic angle so long as it could not be detected clinically; when fluid rises above the level of the diaphragm a hæmopneumothorax or a tuberculous effusion is almost certainly present. In a collected series of cases from the literature a small effusion was present in 31·5% (Table IX) but it was only present in 17·8% of the cases in

this report; the reason for the disparity of these figures is not clear but it is possible that Service patients are admitted to hospital earlier than in civil life and the chest radiographed before fluid has formed. In one patient in this series the trace of fluid was aspirated and found to be clear, containing 96% lymphocytes.

Presence of fever.—A low-grade fever is often noted in the first week, as in 11% of Hyde and Hyde's (1948) patients, but a temperature repeatedly above 99·6°F. indicates either a tuberculous effusion or a hæmopneumothorax and it is significant that the two of Cohen

and Kinsman's (1946) 39 patients to have fever were both found to have active pulmonary tuberculosis. Temperature charts had been preserved in 66 cases in this series; 14 (21·2%) showed a fever of 99–100°F. for less than a week, while there was no recorded fever in 52 (78·8%).

Laboratory investigations.—Little useful information is obtained from routine investigation of the erythrocyte sedimentation rate (E.S.R.), the white cell count, sputum examination for tubercle bacilli or the tuberculin skin test in spontaneous pneumothorax. Jones and Lyons (1954) found a normal E.S.R. in all 60 cases except one who had pulmonary tuberculosis while Hyde and Hyde (1948) noted that a slightly raised E.S.R. or white cell count was not of diagnostic value. In this series the E.S.R. was normal in 100 (97·1%) of the 103 patients examined and the fact that it was 18, 23 and 25 mm. in one hour in the remaining 3 did not prove useful in the ultimate prognosis, each patient making an uneventful recovery and remaining well for one to ten years; similarly the blood picture was normal in the 49 patients examined and the sputum repeatedly negative for tubercle bacilli in all 67 examined.

A negative tuberculin skin reaction is strong evidence against a tuberculous ætiology for the pneumothorax and there are limited reports in the literature that about half are positive in the absence of active pulmonary tuberculosis (Table X). In this investigation 5 out of 9 patients showed a positive reaction.

Mediastinal emphysema.—Many ingenious theories have been put forward to explain the unmistakable physical sign of a clicking pneumothorax but no experimental evidence was forthcoming until Macklin (1939) showed that over-inflation of the lung of a cat ruptured alveoli causing pulmonary interstitial emphysema, subcutaneous emphysema in the neck and often a concurrent pneumothorax, the air passing to the mediastinum via the vascular sheaths and not by the bronchial sheaths. Scadding and Wood (1939) separated two groups of cases with transitory noises over the præcordium; in the first a chiefly systolic clicking sound always indicated that a left pneumothorax was present while, in the second, churning, crunching or crackling sounds in systole and diastole occurred in mediastinal emphysema, both sorts of sound being found when a pneumothorax was present in association with mediastinal emphysema.

There are a number of case reports in the literature of a left-sided pneumothorax in the presence of mediastinal emphysema (Wolferth and Wood, 1930; McGuire and Bean, 1939; Miller, 1944; Hamman, 1937, 1939) and in the only possible case of a right-sided clicking pneumothorax (Black, 1948) the sound was not observed clinically. In the present series there was radiological evidence of mediastinal emphysema in 2 patients; in both there was a left-sided pneumothorax and an audible and palpable clicking noise was heard over the præcordium.

Air travel.—Air travel may prove dangerous in the removal of patients with a pneumothorax to special treatment centres on account of the expansion of the air in the pleural space when the barometric pressure falls. In this series a large lung cyst ruptured while a man aged 20 was flying as a passenger and he was in immediate respiratory distress while a second patient became increasingly breathless when he was flown to England from the Mediterranean before the lung had completely expanded after a pneumothorax.

Treatment.—Treatment was symptomatic until there was evidence of considerable re-expansion. Air was aspirated from the chest in 16 (9·8%) cases (in 9 for the relief of tension, and in 7 to hasten expansion).

The potential danger of the development of a contralateral pneumothorax and the economic loss from the prolonged sickness under conservative treatment have led to continuous intrapleural suction being advised in order to obtain early expansion of the collapsed lung and Jones and Lyons (1954) employed this method in 15 (25%) of their patients

where the lung had not shown any evidence of expansion after five to seven days on conservative treatment. There is a danger of sepsis with empyema formation, as in one case in this investigation.

Time for expansion of the collapsed lung.—Leach (1945) found that those with less than 50% collapse took about nineteen days to expand while the remainder took about forty-eight days and Cohen and Kinsman (1946) reported an average stay of their Service patients in hospital of forty-one days; in civil practice Schneider and Reissman (1945) observed that their patients were away from work for three to four months and even longer in compensation cases. In this series records are available for 136 patients, the average time for expansion being 39·75 days but there were 8 (4·9%) patients in whom expansion was delayed for 104–171 days. It is in these latter cases that a persistent bronchopleural fistula may be present and Brock (1948) brought to notice the chronic ill-health and marked loss of weight in 46 patients in whom the average duration of the pneumothorax was fifteen months (Table XI).

TABLE XI.—TIME FOR EXPANSION OF LUNG

Time for expansion (days)	Cases No.	Cases %
1–7	5	3·7
8–14	14	10·3
15–21	18	13·2
22–28	20	14·7
29–35	22	16·2
36–42	13	9·5
43–49	9	6·6
50–56	9	6·6
57–63	5	3·7
64–70	5	3·7
71–77	5	3·7
more than 77	11	8·1

Average time for expansion—39·75 days
In 92 cases (68%) lung expanded within six weeks

Death in spontaneous pneumothorax.—Kjaergaard (1932) found references to only 6 deaths in 200 typical cases and in 4 it was due to hæmopneumothorax. Rottenberg and Golden (1949) had two (2·1%) deaths due to tension pneumothorax and several other single cases have been reported. There were no deaths in this series.

Abnormal chest radiograph after expansion.—The final chest radiograph was abnormal in 25 (15·3%) patients; in 13 there were ipsilateral or contralateral calcified lesions, in 6 ipsilateral or contralateral bullæ, in 5 ipsilateral or generalized emphysema and in 1 an apical pleuritis. 5 of these patients had had previous attacks of spontaneous pneumothorax. Cohen and Kinsman (1946) reported similar findings in their Service patients, 17% having minimal inactive lesions.

Final disposal on recovery from the spontaneous pneumothorax.—148 (90·8%) patients returned to full duty while 15 (9·2%) were invalided from the Royal Navy as a direct or indirect result of their spontaneous pneumothorax, the invaliding diagnoses being: inactive pulmonary tuberculosis (4), emphysema (4), recurrent pneumothorax (2), asthma (2), multiple bullæ (1), effort syndrome (1), following pleurodesis (1). In the U.S. Army Air Force Leach (1945) found that 74% returned to duty, 10% were invalided, and the disposal was unknown in the remaining 16% while Cohen and Kinsman (1946) stated that 80% of their men in the U.S. Army were retained and 7% invalided.

THE FOLLOW-UP

119 (73%) of the patients were traced, 3 of whom were dead, leaving 116 (71·2%) for this analysis (Table XII).

TABLE XII.—NO. OF PATIENTS TRACED IN EACH YEAR

Year	1943	1944	1945	1946	1947	1948	1949	1950	1951	1952	1953
No. of cases in original investigation	20	14	22	17	16	11	9	10	9	13	22
No. traced	14	10	14	10	12	8	5	8	7	9	19
Deaths	1	1	—	—	—	—	1	—	—	—	—
No. without recurrence	13	8	13	8	9	7	4	7	6	8	19

Deaths.—One patient died in status asthmaticus at the age of 30, six years after his pneumothorax, and another as the result of a road accident, also six years after his attack;

the third patient died at the age of 59, four years after his pneumothorax and following invaliding on account of emphysema. None of these patients had had a recurrence of his pneumothorax.

Recurrence of pneumothorax.—14 (12·1%) of the patients had had an ipsilateral, contralateral or bilateral recurrence of spontaneous pneumothorax. The relapse rate may therefore be summarized as follows: 20 (12%) of the original 163 patients had had a previous pneumothorax and 14 (12%) of the 116 patients followed up for one to ten years had had a recurrence but this includes only 1 of the original 20 and he was an asthmatic (Table XIII).

TABLE XIII.—PATIENTS WITH RECURRENCE OF PNEUMOTHORAX

Patient	Follow-up in years	Side of relapse	Time interval from first attack	Final chest X-ray after first attack
1	11	Ipsilateral	30 months	Ipsilateral emphysema
2	10	Ipsilateral	3 months	Bilat. calcified lesions
3	10	Ipsilateral	12 months	Normal
		Ipsilateral	30 months	
4	9	Ipsilateral	9 years	Normal
5	8	Contralateral	4½ years	Ipsilateral apical bullæ
6	8	Ipsilateral	2 years	Normal
		Contralateral	6 years	
7	7	Contralateral	25 months	Normal
8	7	Contralateral	7 years	Normal
9	7	Contralateral	7 months	Generalized emphysema
		Ipsilateral	13 months	
		Bilateral	30 months	
10	6	Ipsilateral	3 years	Normal
11	5	Ipsilateral	21 months	Normal
12	4	Contralateral	16 months	Normal
13	3	Contralateral	12 months	Contralateral cysts
14	1	Contralateral	12 months	Generalized emphysema

No recurrence of pneumothorax.—There was no recurrence in 102 (87·9%) of the patients traced (Table XII).

Significance of adhesions in the pneumothorax radiograph.—A follow-up was obtained on 4 of the 8 patients in whom adhesions had previously been observed; 2 had had their pneumothorax in 1945, 1 in 1949 and 1 in 1952 but none had developed pulmonary tuberculosis and only 1 had had a further pneumothorax (contralateral), this patient being known to have generalized emphysema.

Symptoms.—87 (75%) of the patients traced were symptom-free while 29 (25%) attributed their breathlessness on exertion (in 27) or winter bronchitis (in 2) to their spontaneous pneumothorax (Table XIV).

TABLE XIV.—PATIENTS WITH AND WITHOUT SYMPTOMS AT FOLLOW-UP

Year	1943	1944	1945	1946	1947	1948	1949	1950	1951	1952	1953
Number traced	14	10	14	10	12	8	5	8	7	9	19
Symptom-free	11	4	10	7	12	5	4	7	5	7	15
Chest symptoms present	3	6	4	3	—	3	1	1	2	2	4

Chest radiographs.—81 (69·8%) patients had had a normal chest radiograph within the previous two years while 22 (19%) had had no further chest film following recovery from their pneumothorax. 13 (11·2%) patients had abnormal chest X-rays but in 10 (8·6%) the abnormality was known to have been present following expansion of the collapsed lung, leaving 3 (2·6%) who had developed lung lesions during the follow-up period. In one patient a large ipsilateral bulla appeared and lobectomy was performed, another was appealing to the Pneumoconiosis Board for compensation after a chest film had shown some reticulation in both lung fields, while the third had developed open pulmonary tuberculosis. This last patient had had a left spontaneous pneumothorax on three occasions (age 17, 18 and 19), followed by a right-sided attack at the age of 20 with a normal chest film after expansion and he did not develop tuberculosis of the left upper lobe until he was 23 years of age.

Development of pulmonary tuberculosis.—The absence of any relationship between a previous spontaneous pneumothorax and pulmonary tuberculosis is well demonstrated by the long follow-ups in the literature (Table XV) but occasional cases are found where the

TABLE XV.—SERIES IN WHICH PULMONARY TUBERCULOSIS WAS NOT OBSERVED AT FOLLOW-UP

Author	No. followed up	Maximum length of follow-up	Active pulmonary tuberculosis

Niehaus (1947)	21	12 years	Nil
Hyde and Hyde (1948)	18	8 years	Nil
Total	166		

presence of pulmonary tuberculosis has no bearing on the ætiology of the pneumothorax. All the 126 men in the U.S. Army Air Force reported by Leach (1945) had been X-rayed before entry or subsequently, yet one had proven active disease, and in a rather similar series from the U.S. Navy Jones and Lyons (1954) found one case of open disease, while Cohen and Kinsman (1946) reported two cases of open pulmonary tuberculosis and seven others with apparently inactive lesions amongst 39 patients in the U.S. Army.

Once a pneumothorax has fulfilled the definition of Kjaergaard (1932) it may be regarded as a benign condition and there is no greater chance of the development of pulmonary tuberculosis than in the average individual in the community. Perry (1939) could find only 6 (2·4%) patients out of a total of about 250 in the literature who developed pulmonary tuberculosis and there was no such case in his series of 85 patients (Table XVI).

TABLE XVI.—DEVELOPMENT OF PULMONARY TUBERCULOSIS AFTER SPONTANEOUS PNEUMOTHORAX

Author	No. of cases followed up	Maximum period of follow-up	No. developing pulmonary tuberculosis	Lung	Time interval

Totals	391		9		

Summary.—The case records of 163 patients admitted to the Home Port Naval Hospitals with a spontaneous pneumothorax during the period 1943–1953 inclusive have been reviewed. It is essentially a disease of the young adult male of average physique, associated with no marked constitutional upset, involving either lung equally unless mediastinal emphysema is present when the left lung is more often involved, and it usually absorbs within 6 weeks; physical exertion is not an important precipitating factor but there is a considerable risk of recurrence. 116 (71·2%) of the patients were followed-up for one to eleven years; 3 (1·8%) had died without a recurrence of the pneumothorax, 14 (12·1%) had had further attacks and one (0·9%) had developed contralateral active pulmonary tuberculosis three years after his last pneumothorax.

This investigation confirms that the incidence of pulmonary tuberculosis in patients who have had a spontaneous pneumothorax is no greater than in the general population but it remains important to exclude tuberculosis at the time of occurrence of the pneumothorax.

BOOK REVIEWS

Medical Ethics. A Guide to Students and Practitioners. Edited by Maurice Davidson, M.A., D.M., B.Ch.Oxon., F.R.C.P. (Pp. viii + 165; illustrated. 20s.) London: Lloyd-Luke (Medical Books) Ltd. 1957.

This book contains a collection of essays dealing with various aspects of the personal relationships met with in practice. Each of the distinguished authors writes in characteristic style on the subject allotted to him, and thus a pleasing variety is afforded.

The functions of the General Medical Council are well outlined by Mr. W. K. Pyke-Lees, and Dr. Clegg gives some wise advice to those doctors who write for the lay press or take part in broadcast or television programmes. Lord Cohen of Birkenhead deals with the doctor-patient relationship with his accustomed clarity, while Sir Heneage Ogilvie writes in plain language about the way in which a doctor should behave towards his colleagues. There is a short but welcome note on "Medicine and the Church" by the Bishop of Durham. Dr. Neville Stafford contributes a chapter on "The Doctor, the Law and the Police" which is excellent but would be almost more appropriate in a textbook on forensic medicine. Dr. Roques delivers wisely conservative judgments on the questions of contraception, therapeutic abortion, sterilization and artificial insemination. There are two useful chapters on clinical subjects—the Management of the Hopeless Case written by Dr. Lindsey Batten, and the Care of the Dying from the pen of Dr. Clifford Hoyle. The last essay is an excellent account of the Hippocratic Oath by Dr. Douglas Guthrie.

We have left for special mention the other two contributors. Professor McCance writes a much-needed chapter on the practice of experimental medicine in which he carefully lays down the safeguards required by therapeutic experiments on the human being. This is the first time we have seen such an essay on this most important subject and we commend it to all workers on the forefront of medicine. Finally the editor of the volume, Dr. Maurice Davidson, has written not only the introductory chapter but also two short essays on difficult subjects—the doctor's responsibility to his own family, and the problem as to what should be told to gravely ill patients. These are written with true humanism, and though the writer says that "judgment, discretion and initiative are not to be taught by rule of thumb" we believe the first two of these can be cultivated by reading such a book as this.

One impression stands out prominently after reading this book, i.e. the immense influence which is still being exerted by the ethical teaching of Hippocrates on the medical profession of to-day. There is much to be said for Dr. Guthrie's plea that some form of the Hippocratic oath should be put before if not taken by every graduate of medicine.

There is some overlapping and on one question we detected difference of opinion. On the question of euthanasia one contributor states that "the doctor must not be the arbiter of life and death" while another comments surprisingly "the law forbids in theory but ignores in practice, thus tacitly accepting the common-sense view that doctors here, as in other spheres, should be protected from the consequences of steps honestly taken in the interests of patients".

De Motu Cordis. Movement of the Heart and Blood in Animals. An Anatomical Essay by William Harvey. Translated by Kenneth J. Franklin. (Pp. xii + 209; illustrated. 17s. 6d.) Published for the Royal College of Physicians of London. Oxford: Blackwell Scientific Publications. 1957.

This excellent translation of the most important medical work ever written will undoubtedly take its place at once as the standard English text. It is written in lucid English, accurate, and altogether a joy to read. Professor Franklin, who is at the same time a distinguished physiologist and classical scholar, has so closely entered into the thought of Harvey that the translation reads as if the work had been primarily written in English. We can give but a few examples of the felicity of translation.

Harvey's resolution to free himself from the bondage of Galen is vividly portrayed. "However, the die has now been cast, and my hope lies in the love of truth and the clear-sightedness of the trained mind." Again, the picture Harvey draws of the failing heart

is wonderfully reproduced—"And while the heart is slowly dying, one can sometimes see it—so to speak—arouse itself and, in reply to two or three auricular beats, produce a single ventricular one slowly and reluctantly and with an effort".

An example of accuracy. At the end of Chapter 9 Harvey wrote—"Ego in illa disquisitione jam sum". This had been rendered by a previous translator—"I shall now discuss this point", and a critical note had been added that Harvey had forgotten to discuss it. Professor Franklin translates correctly and in modern idiom—"I am now busy with that research".

We should like to continue quoting passages which specially appealed to us but shall not do so, for everyone should read the whole book for himself. For the medical student the reading of Harvey's immortal work should be compulsory, and now that this most readable translation is available there is no excuse if he does not become acquainted with it. The reading of the De Motu Cordis is the beginning of physiological wisdom, and every doctor and man of science will enjoy and profit from this beautifully produced volume.

Battle for the Mind. A Physiology of Conversion and Brain-washing. By William Sargant. (Pp. xxiv + 248; illustrated. 25s.) Melbourne, Toronto and London: William Heinemann & Co. Ltd. 1957.

In this book, Dr. William Sargant reiterates his views about abreaction and its reformulation in terms of the Pavlovian conditioned reflex. He goes much farther and considers what he believes to be the close relationship of political indoctrination, religious conversion, and the work of the Freudian psychoanalyst. By political indoctrination he refers to what has been inelegantly called "brain washing". By religious conversion he refers to the rapid and tumultuous changes of heart which apparently occur in some American revivalist meetings after the audience or part of it has been moved almost to the point of frenzy.

The author is at some pains to make it clear that he is not concerned with the validity of any belief but only with the mechanics of its indoctrination. Nevertheless the treatment of the subject matter lacks delicacy of touch and there are passages which might have been written differently without making the author's task more difficult. We read that the Apostle known to most Christians for his wise and moving first epistle to the Corinthians, was acutely excited, transmarginally inhibited, hallucinated, and showed "other inhibitory hysterical manifestations" just outside Damascus. Is not the clinical record in Acts perhaps a little too old and a little too scanty to permit these deductions to be made? True, as Dr. Sargant reminds us, St. Luke was a doctor—but perhaps as a medical journalist, psychiatry may not have been his best subject. When we are told, too, that Chinese Communists have been helped in their task of political conversion by a study of Catholic Missionary methods, one wonders if the author has not over-reached his authority. Certainly it would be interesting to have the views of a Catholic Missionary who has worked in China.

The book is intended to appeal to a wider audience than a purely medical one and "too technical a style has been avoided". This design places difficulties in the path of any writer and perhaps accounts for some loss of accuracy. Thus, "much of our human life consists . . . in the unconscious following of conditioned reflex patterns originally acquired by hard study". How are conditioned reflex patterns studied? Surely the author means acquired habits which become automatic by repeated use. A grown man shaves himself automatically, and even unconsciously but no one would suggest that shaving is a conditioned reflex. Conditioned reflexes as defined and established by Pavlov play a very small part in integrated human behaviour. On pages 7 and 8 there is, included under the term conditioned reflex, a remarkable mixture of what most people would call reflexes, conditioned reflexes, habits, attitudes and sentiments. Precision in the use of language seems to be wholly abandoned when the author, in speaking of E.C.T., explains that John Wesley too was a great believer in electric treatment and possessed a Leyden jar—though he stopped short of convulsions!

A series of illustrations at the centre of the book begins with a Quaker Meeting, goes on to show some excited Negroes, some even more excited revivalists and ends with Rock and Roll, and Wesley in a death cart. The book itself is well written and agreeably produced. It will certainly arouse discussion but it is to be hoped that psychiatrists generally will not be thought to have a *Weltanschauung* as sterilely mechanistic as this. Experience has shown that such a view is still very prevalent and makes the clinician's task needlessly difficult.

DISCUSSION ON THE RADIATION TREATMENT OF CANCER OF THE ANTRUM AND ETHMOID

Miss Margaret D. Snelling (The Middlesex Hospital, London):

The Treatment of Carcinoma of the Maxillary Antrum and Ethmoid

The method used in the treatment of cases of carcinoma of the maxillary antrum at the Middlesex Hospital was introduced in 1936 and was described by Professor Windeyer in the Skinner lecture of 1943 (Windeyer, 1943, 1944; Windeyer and Wilson, 1955). The whole of the antrum is irradiated with deep X-rays to a dosage of 5,000–5,500 r in five to six weeks. No surgical treatment is given at this stage apart from a biopsy to confirm the diagnosis and, where there is infection, drainage by Caldwell-Luc antrostomy. One month after the completion of the deep X-ray treatment a palatal antrostomy is performed when residual tumour and necrotic debris are removed and a biopsy is taken of any suspicious area. Active growth in the antrum is then treated by an intracavitary radium applicator while any recurrence in the ethmoid region is implanted with radium needles or gold seeds. Since the effect of applicator or implant is necessarily localized to a small volume, this treatment is unsuccessful in cases where there is extensive infiltration and we have in recent years endeavoured to avoid the necessity for this additional irradiation by extending the volume and improving the dosage distribution of the original deep X-ray treatment. As a result of these alterations in our technique the local recurrence rate has diminished considerably.

Table I shows the results obtained in all cases of malignant disease of antrum and/or

TABLE I.—THE RESULTS OF TREATMENT OF CARCINOMA OF MAXILLARY ANTRUM AND ETHMOIDS: 1929–1950

	Total seen	Five-year survival	Full treatment given	Five-year survival
1929–1935	41	3 (7·3%)	33	3 (9·1%)
1936–1940	38	7 (18%)	33	7 (21·2%)
1941–1945	36	8 (22·2%)	27	8 (29·6%)
1946–1950	41	17 (41·5%)	39	17 (43·6%)
Totals				
1929–1950	156	35 (22·4%)	132	35 (26·5%)
1936–1950	115	32 (27·8%)	99	32 (32·3%)

ethmoids seen at the Middlesex Hospital from 1929 to 1950 inclusive. The cases are divided into an early group treated by varied techniques before 1936 and three later groups each of five years, all treated by our present method. The five-year survival rate has improved steadily, rising from 9·1% in *treated* cases before the introduction of the present method to 21·2%, 29·6% and 43·6%. Not all the five-year survivors are free from disease and of the 17 patients in the last group who were alive five years after the first treatment 7 were thought to have disease still present—an apparent cure rate of 25·6%. The result of the more intensive treatment has been, therefore, not only to increase the number of cures but also to increase the average length of life in the failures. An attempt was made to assess the relation between the results of treatment and the histology of the tumour but there were too few cases in each group for any definite conclusions to be drawn except, perhaps, in the case of adenocarcinoma in which the results confirm the impression of apparent cure followed by late recurrence.

Causes of failure.—10 of the 132 cases developed blood-stream metastases and in 11 there was spread to the lymphatic glands. The most important complication by far was the local recurrence which occurred in no less than 35 of the 132 patients—11 times in the antrum and 24 in the orbit or ethmoids.

While recurrence in the antrum is rare with our present technique, recurrence in the orbit and ethmoid remains a very serious problem, which must be overcome if the results are to be further improved. Because of the high incidence of involvement of orbit and ethmoid when the cases are first seen—it was present in 65·8% of the cases treated between 1946 and 1956—these are presumed to be involved in every case, and are therefore included in the first treatment with deep X-rays. The sight of the eye on the side of the growth is thereby endangered but loss of sight is rare except where the orbit is extensively infiltrated or

infected. Every precaution is taken to reduce the irradiation received by the other eye and each case is carefully planned with this object.

Fig. 1 shows a transverse section through the middle of the antrum. Superimposed upon it is the plan and dosage distribution of a four-field deep X-ray treatment. (For this physical chart, as for most of the others, I am indebted to Mr. C. Gregory, now working in the Physics Department at Mount Vernon Hospital.) On the side of the tumour, there are two long fields, 4 or 6 cm. wide, which extend from above the level of the frontal sinus down to below the floor of the antrum; the lateral field is directed medially and forwards and the

anterior field backwards and medially. On the unaffected side, there is an anterior field —usually 4 cm. wide—which extends from the lower margin of the orbit to below the hard palate. This field is directed medially and backwards, the angle depending upon those of the other fields and upon the anatomy of the part.

Since with three fields only the dose is too low posteriorly a lateral field is usually added on the sound side and is directed medially through the back of the normal orbit and antrum to the posterior part of the diseased antrum and orbit. The addition of this field brings the posterior part of the antrum into the high dosage area.

Fig. 2 shows a transverse section through the centre of the orbit. The same four field plan is being used but we are now above the level of the small anterior field on the sound side and the dose received is due to a combination of anterior and lateral fields on the side of the diseased antrum and the lateral field on the sound side. The dosage in most of the orbit and ethmoid region is satisfactory but an inadequate quantity of radiation reaches the anterior ethmoid cells and the antero-medial part of the orbit, which are often infiltrated with growth. A small field, usually 2 cm. wide, is therefore added at the inner canthus on the sound side (Fig. 3) and is so placed and angled as to reduce to the minimum the dose received by the eyeball to be preserved. In this example the medial part of the eyeball receives a maximum dose of 30% of that received by the tumour. The cerebrum also receives little radiation.

Fig. 4 shows a coronal section through the centre of the antrum and anterior part of the eyeball. The antrum, floor of orbit and ethmoids are all seen to be in the high dosage area, while the orbit on the sound side receives relatively little radiation.

I should like to thank Miss Hewland and Mr. Turney of the Art and Photographic Department of The Middlesex Hospital for their help in the preparation of the illustrations in this paper.

Dr. T. W. Backhouse for Professor B. W. Windeyer (The Middlesex Hospital, London):
The Treatment of Carcinoma of the Maxillary Antrum and Ethmoids by Supervoltage Irradiation

I wish to describe the ideas we have had at Mount Vernon Hospital for the treatment of carcinoma of the maxillary antrum and ethmoids by the supervoltage machines installed there.

The 1,000 curie cobalt^{60} Theratron is designed to be fully rotational; that is, in one plane, it will rotate for 360°, or less, around the patient. It is impossible accurately to rotate in the sagittal or coronal planes, and we are limited in this type of case to a plane parallel to Reid's base line. The large size of the cobalt source, compared to the focal spot of X-ray machines results in an unavoidable and considerable penumbra.

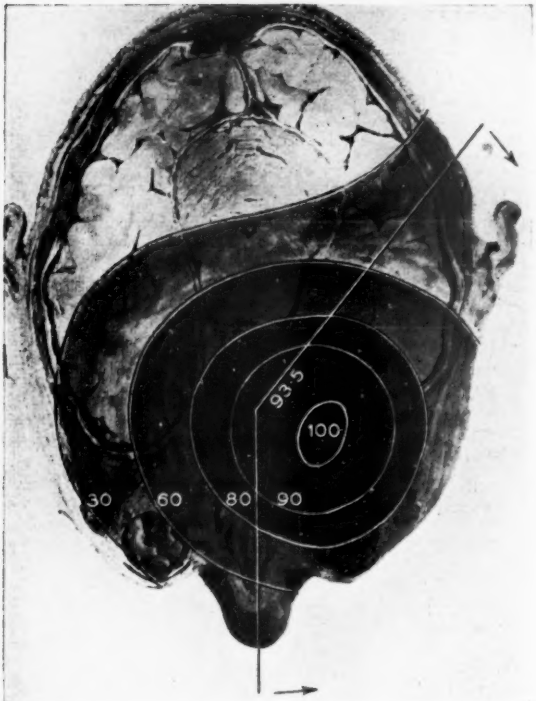

Fig. 1 is a plan of a partial rotation of 140° superimposed on an anatomical specimen to show the distribution of dose. The anterior ethmoidal cells are relatively underdosed and too great a volume of tissue is irradiated. The contralateral eye receives a higher percentage dose, chiefly as transmitted radiation and therefore unavoidable, than we can accept if sight is to be preserved in that eye. Fig. 2 illustrates the coronal distribution.

We have therefore concluded that rotation therapy on the Theratron is unsatisfactory in these cases.

The 4MeV Linear Accelerator has so far been available for fixed field therapy only. It has very sharply defined beams, variable over a wide range of size. Fig. 3 is a typical dosage distribution achieved with two fixed fields, the posterior oblique receiving only half the anterior incident dosage. Fig. 4 confirms that a satisfactory distribution in the anterior and posterior ethmoids and the sphenoidal sinus is not obtained at the expense of the contralateral eye. The mid-line may be transgressed and the eye still spared by using a lead shield 7 cm. thick. A dose rate of 1,200 rads per week to the tumour volume has not led to any serious reaction while the total dose delivered has been of the order of 7,500–8,000 rads.

It is too early to discuss the final results of treatment. Although the Theratron has now been in use for two and a half years, all the cases accepted for treatment were considered untreatable by any other means and yet achieved considerable palliation in the regression of the primary lesion. The Linear Accelerator has only been in use for one year.

I have great pleasure in acknowledging the work of the Physicists at Mount Vernon Hospital, particularly that of Mr. C. Gregory, the help of the Medical Artists at the Middlesex Hospital, and the co-operation of the Photographic Departments of Mount Vernon and the Middlesex Hospitals.

Dr. V. M. Dalley (Royal Marsden Hospital, London):

Cancer of the Antrum and Ethmoid—Classification and Treatment

The following classification of cancer of the antrum, based on the anatomy of the maxilla, has been developed at the Royal Marsden Hospital:

(1) Zygomatic; (2) Palatine; (3) Frontal; (4) Alveolar.

(1) 16 patients belonged to the zygomatic group and the main feature was pain. Orbital invasion occurred early and trismus was frequently present. Nodes occurred in 4 cases out of 16.

(2) 17 patients belonged to the palatine group where disease has usually spread to the nose and often through the palate into the mouth. The external swelling was in the region of the naso-labial fold. Nodes were never present initially and developed in only one case.

(3) Tumours occurring in the region of the frontal process showed considerable pathological variety. Eye signs and symptoms predominated and epiphora was often present. Nodes were present in 6 cases and widespread metastases in 5 cases.

(4) The alveolar group was the largest, comprising 55 cases. Disease had spread to the mouth either as ulceration of the upper alveolus or as a mass palpable in the upper sulcus. 7 of the squamous group had nodes initially and 7 developed later.

11 of the 130 cases were unclassified either owing to the advanced nature of the disease or to the patient being seen only post-operatively.

At the Royal Marsden Hospital, treatment has always been a combination of radiotherapy and surgery. Preliminary radiotherapy in the form of external radiation is preferred for three reasons:

(1) An extensive tumour is more easily treated by radiotherapy than by surgery.

(2) An impaired blood supply is commonly thought to diminish the radiosensibility of neoplastic tissue.

(3) Subsequent surgery may be more safely restricted, particularly in relation to the orbit, as a result of treatment.

The two exceptions to this policy are (*a*) the very early case where the disease can obviously be completely removed by surgery, and (*b*) the zygomatic group of cases where the presence of cancer and sepsis in the dense bone of the zygomatic arch reduces tumour sensitivity and increases the risk of radionecrosis.

Preliminary drainage operations are not considered necessary. The treated area includes the maxilla, ethmoid, nasal fossa and orbit on the diseased side. 220 kV X-rays are usually used with 3 fields so arranged as to spare the whole of the orbit on the normal side. The usual dosage is 4,500–5,000 r in five to six weeks. Direct corneal shielding is used on the diseased side. Bilateral cataracts occurred in 6 patients and unilateral cataract in 10. 3 of these mature radiation cataracts have been removed and good central vision resulted. 9 exenterations and 8 enucleations of the eye have been performed for disease and 2 eyes have been enucleated by the plastic surgeons but not one eye has been removed for radiation damage. Of those patients who had ocular surgery for disease, only one survives.

Our usual custom if nodes are present initially is to treat with radiotherapy, frequently using teleradium, at the same time as the primary is treated. 3 block dissections were performed in this group and all 3 patients survived five years. Cases treated with radiotherapy alone were usually too advanced for surgery to be performed. The early cases, and recently those with involvement of the zygomatic arch, were treated by surgery with subsequent radiotherapy. Intracavitary radium is not used as the primary method of treatment since by this method one cannot achieve adequate irradiation of ethmoidal or orbital extensions. Its use is restricted to: (i) local recurrence, and (ii) as a post-operative measure when residual disease is present after previous external radiation and has not been entirely removed.

Material and Results.—These are summarized in Tables I and II.

Dr. Robert Gibb (Christie Hospital and Holt Radium Institute, Manchester): *The Treatment of Carcinoma of the Maxillary Antrum and Ethmoid by Radium*

In carcinoma of the maxillary antrum and ethmoid, the problem of treatment of the primary divides itself into three groups: (1) where the antrum alone is involved, (2) where the tumour is limited to the ethmoid, and (3) where both sinuses and the nasal cavity are involved.

The tumours in all these sites taken together, registered at the Christie Hospital from 1940–1950 inclusive, are first reviewed in a general way and thereafter the value of local radium as a treatment method, separately for the early and the late cases, is considered in more detail.

The material available for study is shown in Table I. Tumours of the antrum are certainly the predominating problem and it is perhaps surprising that in only 17 cases were antrum and ethmoid both considered to be involved.

TABLE I.—TUMOURS OF MAXILLARY ANTRUM AND ETHMOID 1940–1950 (inclusive)

The pathological distribution in each of the three groups was similar and they are therefore shown together in Table II. The major group consists of carcinoma and the reticulo-endothelial group will not be further considered here. The "other" group consists of mixed salivary tumours, melanomata and myelomata.

The sex and age distribution shown on Table III, agrees closely with that quoted in Windeyer's (1943) series, with nearly one-third of the patients under 55 years of age.

The staging of these tumours is not very satisfactory, but we have accepted as early for antrum those cases where the estimated tumour volume was not greater than a sphere of 4 cm. in diameter, and where there were no metastases when the patient was first seen. The late group consists of those with a primary tumour of diameter greater than 4 cm., or with metastases already present.

The results of all methods of treatment in the treated cases are shown in Table IV. This shows a reasonable survival rate in the early group, but in the late cases the results are unsatisfactory.

	285	21

The early cases are now considered in more detail. The first, and main, group consists of those early cases with disease confined to the antrum, and treated by means of a radium tube within the tumour mass. The background to this method of treatment is of some importance. Before 1937 a preliminary lateral rhinostomy was done, with removal of the main mass of the tumour, and a radium source enclosed in a sphere of sorbo rubber was introduced into the resulting cavity. Unfortunately the operative mortality from this combined procedure was high—12 patients out of 48 so treated died post-operatively of hæmorrhage and sepsis. The method was clearly too severe for older patients, and those whose general condition was poor. It was therefore decided to use the tumour itself as the radium holder.

The method is well known (Paterson, 1948; Tod, 1948); briefly, the intention is to insert a radium tube as accurately as possible into the centre of the tumour, and to keep it there long enough to deliver the desired dose to the selected volume.

Since the object is to raise this volume to a radiotherapeutic tumour lethal dose, a high central dose must result, and since the bone is involved in the malignant process, sequestration of involved bone is to be expected. If drainage from the antrum is satisfactory following treatment, the reaction is not unduly severe and debris escapes via the hole through which the radium tube was inserted. Occasionally drainage becomes inadequate due to closure of the sinus by healing, or to its blockage by debris, and sepsis within the antrum may lead to severe local pain with later, if the condition is not relieved, a general toxæmia. The re-establishment of drainage, and the clearing out of sequestra, becomes essential in such cases, and is best achieved by removal of half of the palate, although in some cases sequestrectomy through the sinus is sufficient.

The actual radium used is a 25 mg. tube, 2 cm. long, and 0·3 cm. in diameter. It is contained in thin rubber tubing, one end of which is left long. The usual route of insertion is via the canine fossa, but occasionally, where palate or cheek is involved, it may be more satisfactory to go straight through the involved area. The tube is retained in position by stay sutures through the cheek, tied to the long end of the rubber tubing which protrudes into the mouth. The final position of the tube is shown in Fig. 1. The dosage varies, but in

FIG. 1.—Typical position of antrum tube—lateral view.

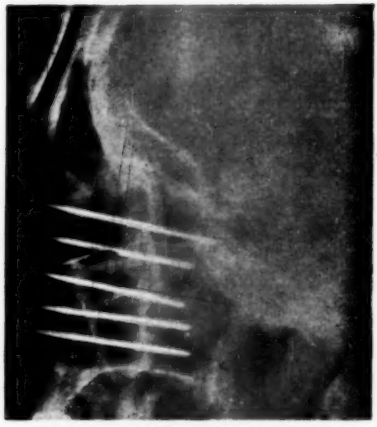

FIG. 2.—Ethmoid implant—lateral view.

general 8,000 r at the surface of a sphere 2 cm. from the radium source, was delivered. Where the tumour was more extensive, this dose was given at 2·25 cm. or at 2·5 cm. from the tube; in some advanced cases additional radon seeds were implanted in the palate, or a plane of radium was inserted in the cheek, to increase the dose in those areas.

The results of this method of treatment in the early antrum cases are shown in Table V.

TABLE V.—TUMOURS OF MAXILLARY ANTRUM—EARLY
Treated—Radium Tube
Five-year Crude Survival Rate

	No. treated	% survival
All cases	60	45%
Histologically proved carcinoma	53	45%

The next group to be considered is ethmoid carcinoma treated by a radium needle implant to the ethmoid area. In principle this has similarities to the antrum tube approach in that the dose is taken 1 cm. from the plane of the needles—and not at 0·5 cm. as in the ordinary single plane implant. This again means a high central dose, with a minimum dose, in seven days, of 6,000 r–8,000 r, at the sides of a slab of tissue and bone 2 cm. in width. The needles are inserted horizontally through bone and tumour, and vertically above each other, in the mid-plane of the growth. 3 mg. needles of 6 cm. total length, 4·5 cm. active length, are used. With the patient supine, a track for the upper needle is made first. Using a twist drill, or some other similar device, of the same diameter as the needle, a hole is made through the skin and nasal bone, 0·75 cm. from the mid-line, at the level of the resting pupils. A dummy needle is then pushed backwards through the ethmoid cells for a distance of 6 cm. in a plane parallel to the sagittal plane of the body, the end of the needle being aimed at a point about two fingerbreadths above the external auditory meatus. The dummy is removed, and the top needle inserted through the channel made for it. The remainder of the implant is then completed, with the needles rather closely together in order to achieve a dose rate of the order of 1,000 r per day at 1 cm. from the plane (Fig. 2).

The results in the ethmoid cases so treated are shown in Table VI. Unfortunately only a fraction of the cases treated in this way were registered as early.

TABLE VI.—TUMOURS LIMITED TO THE ETHMOID
Treated—Ethmoid Implant
Five-year Crude Survival

	No. treated	% survival
Early	5	40%

The next group to be discussed consists of those patients treated by antrum tube combined with ethmoid implant, where both areas were considered to be involved. It has been necessary here to take the early and late cases so treated together, as most were designated late on the principle that when more than one site is involved the condition should be so staged, and even so the numbers are small. In general 8,000 r at 2 cm. from the tube, and 6,000 r at 1 cm. from the implant, were delivered in about seven days (Fig. 3). The results are shown in Table VII.

FIG. 3.—Combined antrum tube and ethmoid implant—lateral view.

TABLE VII—TUMOURS OF ANTRUM/ETHMOID
1940–1950
Treated Antrum Tube and Ethmoid Implant
Five-year Crude Survival

No. treated	% survival
8	50%

In these early groups there were 3 deaths within one month of treatment and the main complication was the expected sequestration of involved bone. In only 16% of the patients, however, was hemi-palatectomy or sequestrectomy necessary. The use of local radium, producing as it does a 5-year survival rate in the three groups of about 40%, appears to be a satisfactory treatment method in reasonable cases.

In the late cases, forming as they do more than half the patients referred, the situation is far less hopeful, and little difference is made to the results either by the site, the pathology, or the type of treatment. The detailed figures are shown in Table VIII. It is of interest that

TABLE VIII.—TUMOURS OF ANTRUM AND ETHMOID
1940–1950
Late Cases Only
Five-year Crude Survival Rate

	No.	% survival
Total Maxillary Antrum	144	8

Antrum (Histologically proved carcinoma)	91	8
Total Ethmoid	24	8
Ethmoid (Histologically proved carcinoma)	16	6
Total Antrum/Ethmoid	12	36

the five-year survival of all cases having block dissection of the neck for secondary nodes was also 7%. Apart from the antrum/ethmoid group, in which the staging may well be fallacious, as mentioned previously, and which includes some cases treated by tube and implant, advanced cancer in these sites is in the category of lung and œsophagus, so far as curability is concerned. Where the lesion is greater than 4 cm. in diameter, antral tube is certainly no better than any other method of treatment, and the only likelihood of improving the salvage is by producing a better X-ray technique. We have found conventional beam directed X-ray therapy to be unsatisfactory, and in view of this a number of patients with advanced lesions, considered to be beyond the scope of local radium, have been treated, since 1951, by a wedge field technique, using 250 kV radiation. This consisted of an anterior pair of wedge fields backed up by a single non-wedge field from behind. The tumour dose was 4,500 r or 5,000 r in three weeks, and 8 out of 17 patients treated are well at two years after treatment. This is certainly promising and worth persevering with, but it is too early to say how the ultimate result will compare with previous methods. It is certainly unlikely to be worse.

On the strength of this initial success, a series of advanced cases is now being treated by an anterior pair of wedge fields on the 4 MeV Linear Accelerator. This lends itself admirably to the use of wedges, as the dose distribution diagram suggests (Fig. 4), and although I would not substitute it at the moment for the radium approach in the early case, it may well improve considerably the results in the more advanced case, and in time, enter into competition with radium as a treatment method for the early.

Mr. C. P. Wilson (The Middlesex Hospital, London):

There is a natural tendency to emphasize the results of treatment and this emphasis is directed primarily towards the percentage of five-year cures or survivals; although the previous speakers have shown steadily improving results we must beware of adopting an attitude of complacency.

A 60% failure rate does not sound as good as a 40% cure rate and yet the incentive to progress must be in the investigation of failures rather than in the analysis of successes. The main factors emerging from an analysis of the failures suggest that direction of spread

and localization of growths are considered in too narrow terms. In a few cases it is possible to talk of growth localized to the alveolar region, or the palate or antero-lateral wall, but in the majority one should think of the antra and ethmoids as one entity and not as two separate regions. [Mr. Wilson then showed two slides to emphasize this point.]

Fig. 1 showing the extent of spread of growths when cases first presented for treatment is a

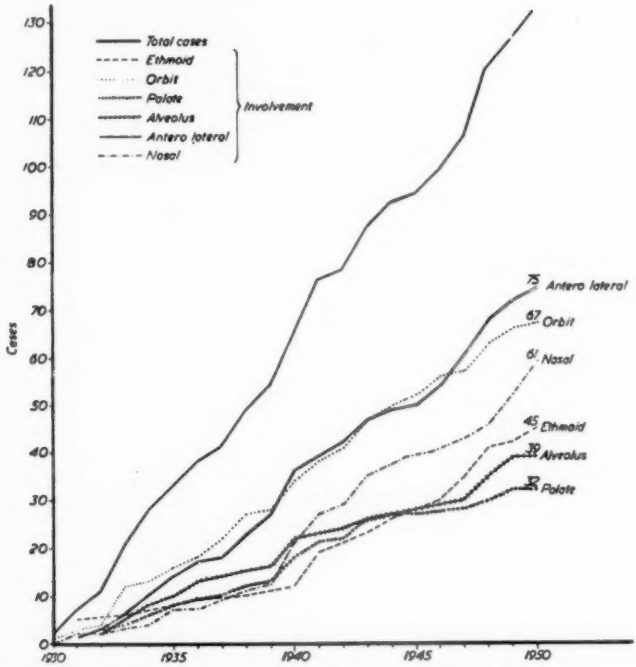

FIG. 1.—Malignant disease of antrum and ethmoid. Extent of disease before treatment.

composite graph. The top line represents the total number of cases seen. The other lines represent the cases in which antero-lateral wall, orbit, nasal wall, ethmoid, alveolus and palate respectively were clinically involved in the spread of the tumour. They add up to very nearly three times the total number of cases. In other words, on first examination, spread had been on the average in three directions outside the antral cavity and antral walls. This extensive spread has made it evident, as stressed by Miss Snelling, that the conception of the volume of tissue to be covered in the original planning has in the past been far too conservative and must be revised very drastically if the whole of the tissue likely to be involved in the disease is to be included in the area of primary effective radiation.

A margin of cover of some 50% more than would appear to be necessary as the result of clinical investigation should be considered and from what has been said it would appear that my radiological colleagues are fully aware of this and in agreement with it.

From the surgical aspect I have in general performed an intra-oral palatal antrostomy with exenteration of the whole ethmoidal region back to the sphenoidal sinus except in cases which were limited to the alveolar regions or the antero-lateral wall or palate. Occasionally this was modified by using a type of Moure's incision if the floor of orbit was obviously involved and sometimes I have gone on to interference with the orbit.

I have rarely practised exenteration of the orbit except in cases of recurrent tumours where it should obviously have been done at the original operation but in which I have not had the courage to advise it because the sight in the eye involved was not impaired.

If it is felt that the radiological cover should be more extensive and complete than that hitherto given then the subsequent surgical exposure must follow suit as far as practicable.

Instead of intra-oral palatal antrostomy being the routine operation the surgeon should consider whether it is not really an operation to be used only in those cases limited to alveolus or antero-lateral wall or palate.

In many other cases where the antro-ethmoidal angle is involved the cheek must be turned aside and the whole of the inner wall and floor of the orbit removed. In those cases where there is at any stage clinical evidence of involvement of the orbital tissues, as shown by proptosis or other form of ocular displacement, exenteration of the orbit must be accepted as the logical form of surgical help, although I doubt if one could, in practice, justify destruction of an eye with normal vision.

If, as I believe is now the case, a logical and determined effort is made to irradiate effectively the whole of the affected area then the subsequent surgical intervention must be sufficient to expose that area as far as is technically possible.

Renal Arteriography in Hypertension

By C. J. HODSON, M.R.C.P., F.F.R., D.M.R.E.

Deputy Director Radiological Department, University College Hospital, London

SOME five years ago when we started investigating the potentialities of radiology in the study of renal changes associated with hypertension our preliminary survey suggested various lines of investigation. One of these was the demonstration by means of arteriography of arterial changes in such kidneys and to this end it was necessary to establish (*a*) what such arterial changes might be, and (*b*) how far they might be defined by means of renal arteriography *in vivo*. This contribution is a brief outline of some of the positive results which have derived from this study.

To define the arterial changes we carried out an extensive investigation of the arterial trees of normal and abnormal kidneys of all kinds using the injection of post-mortem and excised specimens with radio-opaque material and subsequent radiographic examination as our method. At the same time we evolved a radiographic technique to define as far as possible the renal arterial and capillary circulation *in vivo*, carrying out aortography by means of catheterization of a femoral artery, and exposing X-ray films at the rate of one a second, with the radiographic factors adjusted so as to give maximum detail of the renal arterial tree.

Generalized renal arterial changes associated with hypertension.—Injection of a number of specimens showed that the changes which occur in hypertension are largely those due to degeneration of the walls of the arterial tree. They consist of (1) tortuosity of the finer branches of the arterial tree, (2) diminution in the number of interlobular vessels and arterioles, (3) diminution in the distance between the zone of the arcuate vessels and the surface of the kidney, i.e. a narrowing of the true renal cortex.

In the normal arterial tree tortuosity of the vessels is conspicuous by its absence. When early degenerative changes are present the first sign is tortuosity of the branches at the level of the arcuate vessels with a diminution in the number of twigs. In the more advanced cases these changes are accentuated, there being tortuosity of the interlobar vessels and sometimes of the main branches of the renal arteries with again further diminution in the number of peripheral twigs and a decrease in the thickness of the renal cortex.

Comparing these findings with the results obtained by renal aortography, tortuosity affecting the main branches, the interlobar branches and, in a good film, the arcuate vessels might be defined. As well, the thickness of the renal cortex can be shown during the capillary or "cortical blush" phase, but the diminution in the number of interlobular vessels is beyond the power of definition *in vivo* at the moment. In any case it appears that renal arteriography as a means of defining the generalized vascular changes occurring in arteriosclerosis is not likely to be of any great practical value although it certainly may give some evidence in doubtful cases. Renal biopsy appears likely to be an easier and more accurate means of determining these changes during life.

Localized changes.—In those cases of hypertension where the disease is not diffuse but is localized to a part of the kidneys or to part of one kidney the underlying pathological condition is usually localized chronic pyelonephritis, or, in a small minority of cases, a lesion of the main renal artery. Other rare conditions may be unilateral hydronephrosis or some form of obstruction to the urinary tract. I intend to deal only with the first two groups of cases.

Localized pyelonephritis.—The structural change in the kidney which can be assessable radiographically is a coarse localized scarring, either atrophy or fibrosis or both, of a relatively

large segment of the kidney substance. This is almost always associated with expansion of the adjacent calyx and is thus represented on the film by a marked localized diminution in thickness of the renal substance with a localized depression of the outline and with "clubbing" of the calyx. This lesion is readily recognizable in an intravenous pyelogram providing the exposure factors are adjusted to demonstrate the renal outlines.

In an early case in which this defect was present (Fig. 1) it was considered likely that these

A B

FIG. 1.—Localized chronic pyelonephritis. Injected specimen. A shows the marked narrowing of renal substance. B, the contracted tissue round the upper calyx appears to be supplied by a very small separate polar branch of the renal artery suggesting that its cause might originally have been a vascular lesion.

FIG. 2.—Localized chronic pyelonephritis. "Cortical blush" phase of aortography showing irregularity of outline of lower pole with areas showing cortical blush interspaced with contracted "ischæmic" areas.

contracted areas might be associated with a demonstrable abnormality of a branch of the renal artery. Further cases have not directly supported this idea, or, if such an arterial change has been present, it has been overlaid in the radiographic picture by neighbouring vessels. Arteriography can help in the demonstration of this condition during the "cortical blush" phase of the arteriographic cycle when the scarred region stands out sharply against the normal renal cortex which is rendered more opaque by the contrast medium (Fig. 2). The use of renal arteriography to this end is of very limited value, as experience has shown that these lesions can be diagnosed very readily by intravenous pyelography. Aortography should certainly not be regarded as a routine procedure in this group. 3 cases illustrating the value of arteriography in localized pyelonephritis were demonstrated by slides. In each case aortography added very little to the assessment of the case by means of excretion pyelography. In each case there was a smaller renal artery on the affected side and the areas of scarring were shown to alternate with areas of good cortical vascularization. These results were shown to compare faithfully with the injected kidney after surgical removal (Fig. 3A, B, C, D).

Lesions of the main renal artery.—It is in the small but important group of cases where hypertension develops following a lesion of the main renal artery that arteriography comes into its own. The lesion may be thrombosis or embolism, intimal thickening or atheromatous degeneration, aneurysm or pressure from extrinsic causes. It recalls the experimental pioneer work of Goldblatt (1937) in which a temporary rise in blood pressure in experimental animals was obtained by narrowing one, and a permanent rise by narrowing

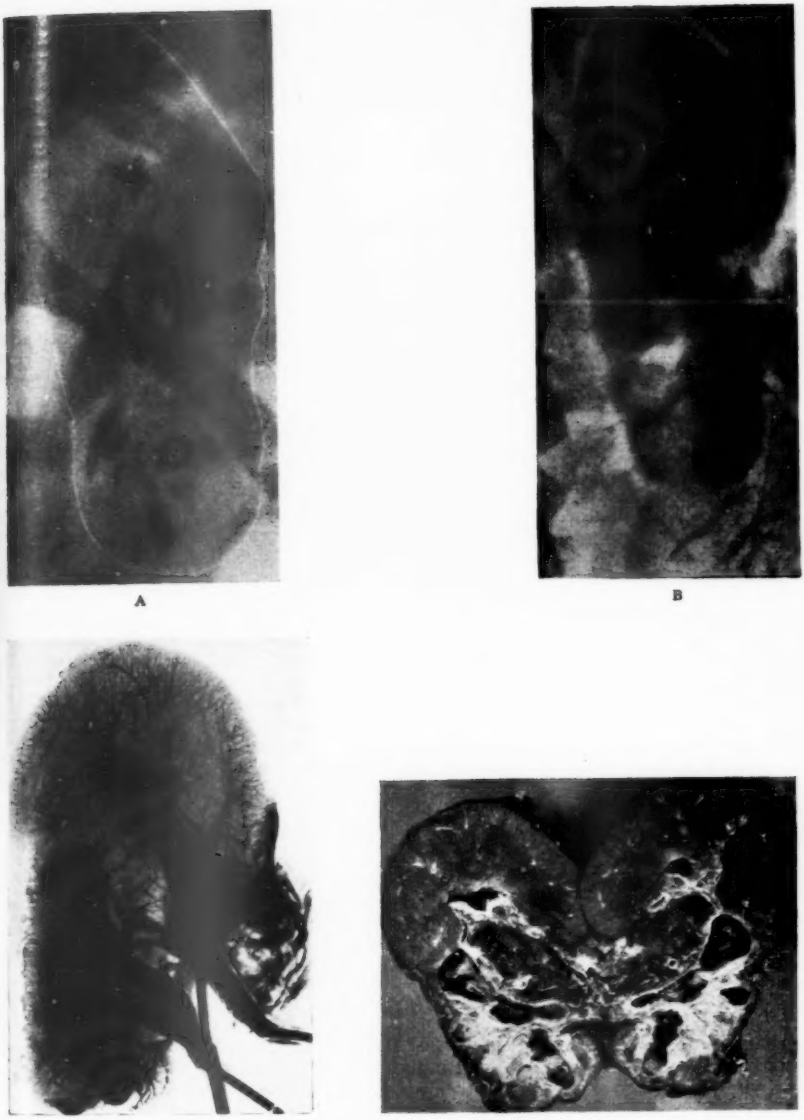

FIG. 3.—Localized chronic pyelonephritis: A, Excretory pyelogram. B, Aortogram—cortical blush phase. C, Injected surgical specimen. D, Surgical specimen; showing value of pyelogram in diagnosis.

both renal arteries. Examples of this group of cases have been described in increasing numbers in recent years, particularly in American literature, and in which nephrectomy (Thompson and Smithwick, 1952), thrombectomy (Freeman *et al.* 1954), or by-passing of the lesion by means of arterial grafts (Poutasse *et al.*, 1956) has resulted in relief of hypertension.

The changes in the affected kidney vary from a slight diminution in size, Howard *et al.* (1954), with almost normal histology, to the classical changes of complete or partial

infarction. Radiographically the main finding is a decrease in size of the kidney as a whole, or, in the case of partial infarction, of a portion of the kidney which corresponds to the size of the vessel affected. On intravenous pyelography there may be no appreciable change or a complete absence of excretion on this side.

Arteriography is probably the most efficient way of investigating this type of lesion. Not only is it the only means of defining its site and extent but it forms the basis of surgical treatment. Asymmetry of the electrolytic contents of urinary specimens by ureteric catheterization gives some indication of a damaged kidney, the main findings being a diminished flow of urine and a lower sodium concentration on the affected side, but I understand these results are not always reliable. It seems likely that renal asymmetry, as shown radiographically, will turn out to be a valuable primary sign in this condition. In our series of cases 2 may fall into this group. One was a man of 36 years with a blood pressure of 180/130 who had been diagnosed elsewhere as a case of right-sided hydronephrosis due to aberrant renal arteries. Of these one had been tied with the result that the lower pole of his kidney had atrophied. The remainder of this kidney looked almost normal at pyelography. On aortography a moderate short-length stenosis of his right renal artery near its origin was shown, and it was thought that this might be producing an ischæmic effect. Hypertension had been present for at least three years and nephrectomy was thought advisable. In fact there was no change in the blood pressure level after operation.

The second was a man of 28 years, with a short history of headaches, a blood pressure of 230/145 and grade II retinal changes. His right kidney was slightly smaller than the left, with a normal calycine pattern on pyelography. An ischæmic kidney was considered. Aortography showed a marked short-length stenosis of his right renal artery just distal to a small branch artery to the upper pole of the kidney. Beyond the stenosis was a marked dilatation. It was considered, however, that ureteric catheter specimens did not support a diagnosis of ischæmic kidney, and so far surgical treatment has not been attempted. In some of these cases the clinical story points to the nature and side of the lesion and the aortogram may then be a conclusive accessory to diagnosis. In others there may be no helpful clinical sign beyond a recent onset of hypertension in a patient, either young or old, in whom there is no family history. If in such a case the difference between the long axes of the two kidneys measured on an X-ray film is over 1·5 cm., and particularly if such asymmetry is supported by demonstrable generalized narrowing of the renal substance on the smaller side, then this is a strong indication of unilateral disease, and if supported by asymmetry on analysis of ureteric specimen, is a reasonable indication for aortography. These statements are based on an analysis of over seven hundred pyelograms in which one of the most striking findings is the symmetry displayed by normal kidneys and in which asymmetry with a normal pelvicalycine pattern on both sides has been associated in a dramatic way with hypertension. The inference that such asymmetry may result from a lesion to the main renal artery is supported by both experimental and published work and by our own experience.

Dangers of aortography in hypertension.—It is too early to be definite as to the dangers of aortography in hypertension. There are the complications inherent in all arterial injections whether by needle or catheter, and presumably when the puncture site is not under one's direct control there is an increased risk of hæmorrhage. Apart from this, there is, as yet, no direct evidence that hypertension carries an increased risk to aortography. In a series of 36 cases only one serious complication occurred in a hypertensive woman of 67 years in whom there was a non-functioning kidney on one side and only the one renal artery had been demonstrated on aortography. Following this examination there was a partial suppression of urine for several days during which the blood urea rose to 348 mg.%. After three weeks she was recovering rapidly with treatment and in six weeks her blood urea was normal again. Details of this case will be published after a follow-up.

Summary

(1) Renal arteriography is likely to be of little value in the general assessment of details of the renal arterial tree in cases of diffuse arteriosclerosis.

(2) The "cortical blush" phase of the arteriogram is of limited value in assessing narrowing and irregularity of the renal cortex in localized chronic pyelonephritis.

(3) In the small group of cases in which lesions of the aorta or main renal arteries are causing hypertension the accurate assessment of the lesion by means of contrast medium offers a major diagnostic weapon.

(4) There may be positive evidence of such a change in an intravenous pyelogram.

(5) Apart from a possible increased tendency to hæmorrhage in cases where the pressure

site is not under one's control aortography in cases of hypertension does not appear, as yet, to carry an added risk.

Renal Phlebography

By R. E. STEINER, Ch.M., F.F.R.

Director Radiological Department, Hammersmith Hospital, London

RENAL vein thrombosis with or without obstruction of the inferior vena cava, has frequently been reported since its original description by Rayer (1840–41). In the past the condition has been recognized only at necropsy, but with renal phlebography it is now possible to confirm the clinical diagnosis radiologically. Four main clinical types of renal vein obstruction can be recognized:

(i) Thrombosis of the inferior vena cava with secondary involvement of the renal veins.

(ii) Obstruction of the inferior vena cava due to invasion by malignant neoplasm, or to external pressure with renal vein obstruction.

(iii) Primary thrombosis of the renal veins.

(iv) Renal vein thrombosis secondary to primary renal disease.

Thrombosis of the inferior vena cava is usually due to spread of thrombus from the lower limb or pelvic veins.

Primary thrombosis of the renal vein is exceedingly rare except in infancy when the renal blood flow may be reduced due to salt-loss, vomiting, or severe diarrhœa. In a review of 228 cases of renal vein thrombosis by Abeshouse (1945) 40% of the patients were under 2 months old.

Renal vein thrombosis secondary to primary renal disease, such as glomerulo- or pyelonephritis (Schröder, 1926) or renal amyloidosis (Vilk, 1940) can occur as a complication of the renal disorder where the blood flow has been reduced.

The indications for renal phlebography have been defined by Harrison *et al.* (1956), as follows:

In patients with proteinuria with or without œdema in association with the following abnormalities:

(i) Abdominal wall veins with upward blood flow; (ii) unexplained œdema of the lower trunk associated with proteinuria of less severity than occurs in the nephrotic syndrome; (iii) unexplained pulmonary infarction; (iv) malignant disease; (v) single kidney.

THE RADIOLOGICAL INVESTIGATION

There are two main methods of approach: either by injection of contrast medium from below through the saphenous vein using 30 ml. of 70% diodone, or by retrograde injection through a cardiac catheter direct into the renal vein using 15 ml. of 50% diodone.

In the case of caval thrombosis injection from below is unsatisfactory, as it will only demonstrate a blocked vena cava and the collateral circulation; in those patients, retrograde injection through a cardiac catheter which has been threaded under fluoroscopic control through an antecubital vein into the superior vena cava, inferior vena cava, and renal vein, is the method of choice. During the injection a Valsalva manœuvre is carried out to augment retrograde filling of the branches of the vena cava and of the renal veins.

The problem of the clinical aspects of renal vein thrombosis and their radiological investigation, together with a large number of illustrations, has already been published elsewhere (Harrison *et al.*, 1956; and Steiner, 1957).

Aorto-arteriography in Obliterative Vascular Disease of the Lower Limbs

By T. PHILP, M.B., Ch.B., F.F.R., D.M.R.D.

Radiodiagnostic Department, Royal Infirmary, Edinburgh

AORTO-ARTERIOGRAPHY implies simultaneous examination of the abdominal aorta and the arteries of the lower limbs, and is a procedure which has enjoyed increasing popularity in recent years in the investigation of peripheral vascular disorders. At first the examination tended to be confined to the aorta, its pelvic branches and to one lower limb, but the importance of simultaneous examination of both legs has become increasingly recognized.

The technique of injection commonly employed is as described by dos Santos *et al.* (1929), using a percutaneous translumbar approach. Only one film of the abdominal aorta and its pelvic branches is necessary, but serial films of both lower limbs are taken. A manually-operated cassette tunnel may be used to obtain the latter films, and with one injection it is usually possible to examine all the main arteries below the level of puncture (L.V. 2–3).

The majority of the cases examined can be placed into two categories, those with degenerative disease, that is to say atheroma or atherosclerosis; and those with thrombo-angiitis obliterans, usually comprising a younger age group.

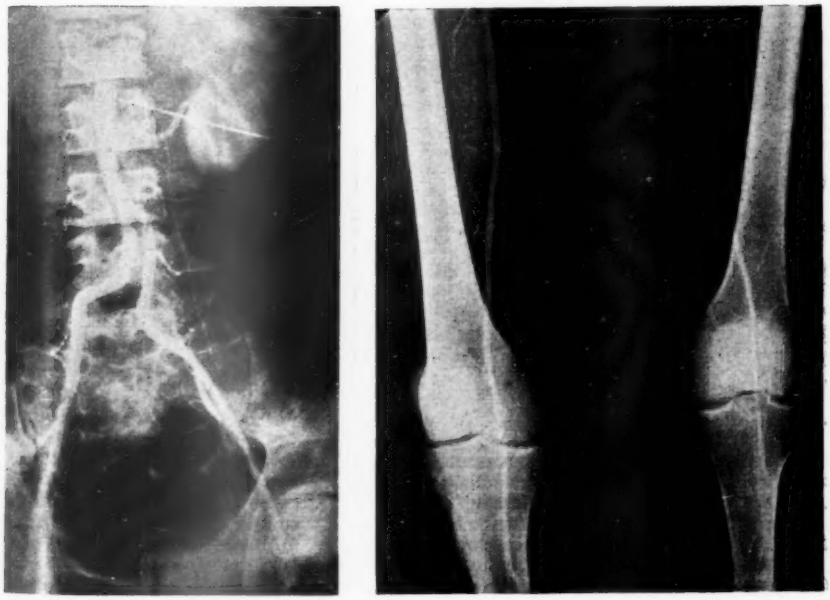
The symptomatology and the effect on the tissues is similar in both these conditions, and they present as intermittent claudication, coldness and numbness of the extremities with diminished or absent pulses, trophic changes and gangrene.

FIG. 1.—Bilateral femoral thrombosis. Symptoms referred to left leg only.

Normal vessels are distinguished by their smooth walls, straight or gently curved course and regular calibre up to the origin of a main branch or until the vessel itself divides. There is an absence of the small tortuous vessels which constitute the collateral circulation. Variations of the normal are not infrequently encountered, e.g. aberrant renal arteries, ectopic kidney, high division of the aorta, short common iliac arteries, &c.

Vessels which are affected by atherosclerosis show tortuosity, diminution of calibre, irregularity of lumen consisting of alternating areas of narrowing, dilatation, and a characteristic ragged outline. The vessel walls may show calcification both on plain radiographs and when filled with contrast medium.

Thrombo-angiitis obliterans affects predominantly the distal arteries, but proximal



vessels do not escape. In the earlier stages of the disease the vessels retain their smooth walls and there is no tortuosity. It is not uncommon to find both normal and abnormal vessels in the same area, the latter showing only a diminution in calibre with a gradual transition from the normal to the abnormal segment. In the late stages of the disease, areas of dilatation may occur, the vessel walls may become irregular and differentiation from atherosclerosis is often impossible. Mural calcification, absent in the early stages, may also appear later.

Thrombosis of insidious onset is commonly found affecting the peripheral vessels in both atheroma and Buerger's disease, and in the case of the former it may extend to involve the aorta.

By clinical examination it is usually possible to detect the presence of the block, but it is not always easy to define its exact site or its full extent, particularly in the case of high blocks involving the aorta and iliac arteries. Moreover, short blocks are occasionally missed and multiple blocks may be present where only one is suspected.

Though symptoms may be referred to one side only, it is unusual for only one limb to be affected and simultaneous examination of both legs may reveal advanced disease, perhaps even with thrombosis on the contralateral side. Fig. 1 shows bilateral femoral thrombosis though in this case symptoms were referred to the left leg only. Such knowledge gained is of considerable value in planning treatment, and the necessity for subsequent arteriography may be avoided.

Other conditions causing arterial occlusion are comparatively rare and include embolism and tumour involvement of the arterial wall. In Fig. 2A the smooth filling defect in the

A B

FIG. 2.—A, Filling defect in lower abdominal aorta due to tumour involvement. B, Tumour cell embolism causing block at origin of left posterior tibial artery.

left wall of the lower abdominal aorta proved to be due to neoplastic involvement and a block at the origin of the left posterior tibial artery was due to a tumour cell embolus (Fig. 2B).

Numerous complications have been attributed to aortography, due either to the contrast medium or to the technique of injection. The dangers of the former, particularly in high concentrations, are more apparent when injection is made at or above the level of the renal arteries, that is to say, higher than is usual in the investigation of peripheral vascular disorders. Of the others the commonest is extravasation and hæmatoma formation.

Extravasation may occur during the course of injection and be detected on the radiograph but leakage may occur only after removal of the needle. Many such cases have been seen at subsequent sympathectomy.

Recently, Gaylis and Laws (1956) have stressed the danger of dissection following intramural injection and suggest that this complication is more common than has been suspected. Occasionally a small amount of contrast may be injected into the wall of the aorta and remain localized to the level of the puncture.

Direct injection into one renal artery rarely occurs but occasionally the majority of the contrast may enter the renal arteries if the puncture is at the same level. Similarly an excessive amount of contrast may be directed into an aberrant vessel or into a lumbar artery. Fig. 3 shows an excessive amount of contrast in the right testicular artery due to the point of the needle lying adjacent to the origin of this vessel.

FIG. 3.—Excessive contrast in right testicular artery.

FIG. 4.—Small air emboli in branches of the left profunda femoris artery.

Reviewing complications following aortography, McAfee and Willson (1956) state that although it is possible to introduce air directly into the aorta by the injection, no actual cases are known. Any air remaining in connexions between the aortic needle and the syringe or injection apparatus is liable to produce such emboli which will show as small filling defects with convex upper and lower margins (Fig. 4).

Recent reports suggest that the early claims for radical surgery may have to be modified (Szilagyi *et al.*, 1956), and operative procedures may, in future, be limited to the larger vessels, particularly the iliac arteries and the aorta itself. The most important prognostic factors remain the severity and the extent of the obliterative disease, and it appears evident that the radiological investigation will still have an important part to play in diagnosis, and in the planning of subsequent treatment.

I should like to acknowledge my appreciation of the co-operation of my surgical colleagues in this work and for access to clinical records.

Section of Anæsthetics

President—KATHARINE G. LLOYD-WILLIAMS, C.B.E., M.D., F.F.A.R.C.S.

[*January* 4, 1957]

DISCUSSION ON ANÆSTHESIA FOR OBSTETRICS: AN EVALUATION OF GENERAL AND REGIONAL METHODS [*Abridged*]

Dr. O. P. Dinnick: *Some Aspects of General Anæsthesia*

Speed of induction, certainty of effect and the ability to relax the uterus when necessary, are among the reasons why general anæsthesia is indicated for many major obstetrical procedures; in addition it is more suited to the temperament of many patients and obstetricians than are regional analgesic methods. These are powerful arguments, but general anæsthesia for obstetrics cannot be advocated without considering its most serious complication—the risk of maternal death from inhalation of vomitus.

Hingson in America and Parker in this country have both drawn attention to this very real hazard; their figures are in surprising agreement, with an estimate that there is one death from this cause in approximately 34,000–39,000 deliveries. Parker has noted the difficulty of converting these figures into terms of deaths relative to the number of anæsthetics, as distinct from the number of deliveries, but some attempt must be made to do this.

From the Ministry of Health Report for 1954 giving the results of their Hospital Anæsthetic enquiry, it may be calculated that the number of obstetric operations in the Health Service hospitals under general anæsthesia is approximately 67,600 per annum or 15·6% of the 432,000 hospital deliveries. A further 19,000 operations (4·4% of deliveries) are performed using regional analgesic methods. This figure of 15·6% is an overall figure, but it does not seem to be an unreasonable estimate. The anæsthetic rate is obviously much higher in certain special obstetric units, for example, at the Middlesex until recently it was 60%. (These figures bear no relationship to those for the provision of general analgesia earlier in labour.) If we assume, and we must remember that this is not proven, that all of Parker's estimated 20 fatalities per year from inhalation of vomit occur in these 67,600 hospital anæsthetics, then there is one death in 3,380 obstetric general anæsthetics. On the other hand, this figure of 1 in 3,380 renders less valid the assumption that all these cases occur in hospital; for Parker's figure of no deaths in 3,048 domiciliary forceps cases, on which he partially bases his conclusion, is thus not statistically significant.

This estimate of 1 death in 3,380 anæsthetics, though indeed serious, nevertheless compares favourably with the overall anæsthetic mortality in most series reported from general surgical services (e.g. Beecher and Todd, 1954). Moreover it is not difficult to find higher (Greenhill, 1947) death-rates—including death from inhalation of vomit—where spinal analgesia has been employed (Hingson and Hellman, 1956). However, little purpose is served by arguing on the basis of these figures because it is generally accepted that the skill of the anæsthetist is of greater importance than the method he employs.

The figure of 20 deaths per annum must remain but an estimate until the Ministry of Health announces the full results of its confidential inquiry into obstetric deaths. Meanwhile it must be considered in relation to the recently published figures in the Registrar-General's 1953 Statistical Review which do not entirely support the quoted statement (*Brit. med. J.*, 1956) that anæsthesia is the commonest cause of death in operative obstetrics, at any rate in this country, where there are 150 deaths listed as "complications of delivery". It must never be forgotten that many of the mothers at risk have been admitted to hospital for delivery because of some anticipated obstetric abnormality, which might if untreated lead to an equally fatal result. Even if the 20 deaths due to inhaled vomitus are concealed in the figures of 33 for antepartum hæmorrhage, and 24 for postpartum hæmorrhage, plus 27 for retained placenta and 24 for prolonged labour among other causes, they will still not amount to the most common cause of death.

In trying to view this hazard in its proper perspective, I do not minimize its gravity, nor seek to deny that it should be largely preventable.

The risk of aspiration of vomit, though increased in obstetric cases (La Salvia and Steffen, 1956) is not peculiar to this specialty; it looms large in all emergency and pædiatric surgery, and indeed is an ever-present hazard in every anæsthetic, and is the largest single cause of anæsthetic deaths in this country (Edwards *et al.*, 1956). In cold surgical cases every effort is made to ensure that the patient's stomach is empty before operation. Nevertheless, vomiting sometimes occurs, often from simple disregard of instructions, and not infrequently from delayed gastric emptying due to apprehension. Ruthless logic suggests that a large-bore stomach tube should be passed before every anæsthetic, not just in cases where vomiting is anticipated; but even this precaution is not necessarily effective in the presence of an undiagnosed œsophageal pouch, or in some cases of hiatus hernia. Moreover, it is an

unacceptable, time-consuming, and often unenforceable precaution, as is the alternative suggestion of passing a cuffed endotracheal tube under local analgesia. Another suggested solution is the induction of vomiting by apomorphine pre-operatively (Holmes, 1956). Apart from the humanitarian objections to this, there is some doubt as to its effectiveness. For example, Hersheshon and Brubaker (1947) administered apomorphine 1/50 grain two-hourly, as a sedative in labour, and stressed that not all their patients vomited. Moreover, apomorphine has been known to produce circulatory collapse as in a case recently described by Parr (1956) and this author, while underlining its potential dangers, also mentions that it is not successful in inducing vomiting after every administration. We must, therefore, reject all these approaches for routine use, and though a considerable proportion of women vomit during labour, and thereby reduce the risk to themselves, *we can never assume that such an episode—no matter how induced—guarantees an empty stomach.*

Hiatus hernia is being increasingly recognized and is not uncommon in pregnancy; for example, 9% in a series examined by Mixson and Woloshin (1956). Regurgitation of acid stomach contents is a common accompaniment of this abnormality, and has been suggested as an explanation for some cases of heartburn of pregnancy. Indeed a hiatus hernia was found in 27% of women with this symptom in their series, and the incidence was considerably greater—70%—in a small series of cases examined at the Middlesex Hospital (Whiteside, 1956).

It may well be that this mechanism accounts for some of the unexpected regurgitations which are encountered; indeed, regurgitation and aspiration has been known to occur in normal sleep with this condition (Hadley, 1956). Antacid tablets give symptomatic relief of heartburn, and it seems possible that their administration in labour, at least to mothers with a dyspeptic history, would provide an effective prophylaxis for the serious consequences of aspirating acid described by Mendelson (1946).

It has also been suggested by Coleman and Day (1956) that all obstetric cases, because of their well-known tendency to vomit, should be considered and anæsthetized in the same fashion as a case of intestinal obstruction. Such a conclusion seems too sweeping, is not practical, and overlooks the distinction between regurgitation and vomiting; moreover, they experienced trouble in two cases out of a hundred.

One of the perhaps unexpected findings in the Association of Anæsthetists report (Edwards *et al.*, 1956) was that fluid vomitus was a much more serious hazard than the solid undigested meal; the inhaled material being fluid in at least 92 cases out of the 110 reported fatalities. This finding is perhaps less surprising in the light of O'Mullane's elucidation of the mechanism of regurgitation; and of the extreme rapidity of its occurrence. This is certainly in line with clinical experience, for I cannot recall a regurgitation of solids, out of many sordid episodes—save perhaps in cases with an obstruction, or a pouch of the gullet. Vomiting on the other hand is a co-ordinated reflex act, which gives warning of its imminence.

In parenthesis, one might draw attention to an implication of O'Mullane's (1954) work which has perhaps not been sufficiently considered—namely, the importance of ensuring that the œsophagus as well as the stomach is empty in cases of intestinal obstruction. I have been experimenting with a double-bore ballooned tube to meet this need, but as yet my results are inconclusive.

It would seem therefore that the cases most at risk are not those who have just eaten a good meal, but on the contrary, it is the 3–5% of prolonged labours who are the more likely to produce the copious fluid vomit. The evidence of Parker's (1954, 1956) cases supports this contention, and indeed this is the common experience with these mothers. It is now generally agreed that "keeping up the mother's strength" in labour is a policy to be applied with the strictest caution by the oral route. Any meal should be of a bland low-residue type, and above all, strong hypertonic glucose drinks should be avoided. Again I suggest that cautious medication with antacids is worthy of extended trial.

Though seldom necessary, there should be no hesitation in resorting to intravenous feeding should serious dehydration or acidosis appear in the course of a long labour.

Continuous extradural block has been advocated in these protracted confinements, not only for analgesia and any operative procedure, but also as a treatment for the uterine dysfunction (Johnson, 1954; Johnson and Clayton, 1955; Youngman and Lloyd, 1956; Ball and Chambers, 1956), and this approach seems worthy of further trial.

Nevertheless, there will still be a considerable number of women who will need a general anæsthetic after a prolonged labour. Here the need for obstetric intervention can sometimes be foreseen, and therefore carried out as a planned procedure, and in this small group of cases it does indeed seem reasonable that they should be treated in the same fashion as is an intestinal obstruction. This implies, of course, that there should be available all the ancillary equipment of modern anæsthesia, including a sucker and some form of tilting table for the skilled anæsthetist who wishes to use them. Morton and Wylie (1951) have discussed in great detail the problems associated with this type of anæsthetic, and the technique they recommend for the experienced anæsthetist, of induction and intubation of the patient in the anti-Trendelenburg position is much to be recommended. One of the

hazards of this procedure, namely the risk of inducing circulatory collapse, is less likely to be present in obstetric cases, as the majority of mothers are not dehydrated to a serious extent.

There are two main methods of inducing anæsthesia in this position, either using thiopentone and a relaxant, or by inhalation with cyclopropane followed by a relaxant if necessary. My experience with cases of intestinal obstruction leads me to prefer the inhalation method with cyclopropane (Bourne, 1956) and there seems little doubt of its superiority in obstetric cases; moreover, as I hope to show, there are other arguments against the use of thiopentone. In cases of this kind, the use of thiopentone or large doses of relaxants is particularly to be condemned with the patient horizontal and supine, for no matter how slick the anæsthetist, the regurgitation is often too quick for him.

These major techniques with cuffed tubes cannot, and indeed need not, be applied to every obstetric case, because so frequently anæsthesia is required at extremely short notice, and even when a skilled anæsthetist is available, he may yet not have time for the essential preliminaries to this more complicated technique. Moreover, it is not possible for anatomical reasons to guarantee a rapid intubation in every case, and failure in these circumstances may indeed be serious. If endotracheal intubation is not planned, then anæsthesia must be induced by inhalation methods which have the tremendous advantage that, should any vomiting occur, it is a co-ordinated process of which some seconds' warning is given, and, most important, the protective laryngeal reflexes are still active; but this warning may easily be overlooked, and the protective reflexes stifled, if the facepiece is firmly strapped on with a harness. The anæsthetist must always be alert and prepared to treat this complication effectively should it arise, by gravity, suction, and, if necessary, a relaxant and intubation. Intensive postural drainage of the lungs—perhaps with ether-induced coughing—as soon as possible, is an essential part of this treatment, and one which empties those depths of the lungs beyond the reach of bronchoscopes and suckers. This is surely not too much to ask, for, as has been stated, it is a situation which may be met at any time in any anæsthesia, *and it is submitted that an episode of this kind should never have a fatal outcome in a fit patient.* For example, Davis and Gready (1946) described 45 cases of inhalation of vomit in labour (out of 50,000 cases), of which only 2 died, and then the fatalities were due, they state, to mismanagement.

There is an important implication in the treatment of an episode of this nature during labour, namely that it must take precedence over the obstetric manœuvre. This is not only in the mother's interest, for the temptation to hurry and complete the delivery immediately must be resisted as the child would then probably be born severely hypoxic. It is usually better to wait until the mother's airway is restored, and ample oxygen administered which will reach the child through the umbilical cord, enabling a pink baby to be unhurriedly extracted.

The posture of the patient.—No one would deny that obstetric, and indeed all patients should be in the lateral position during emergence from anæsthesia—be it noted that in at least 30% of the series reported by Hingson, the vomiting took place after the birth of the child. Induction in this position has also much to recommend it and, in domiciliary work, where facilities and manpower are limited, the case for anæsthesia and delivery on the side seems overwhelming. In hospital, where there is, or should be, adequate assistance, a tilting table and a skilled anæsthetist, the situation is not comparable, and under these circumstances the obstetrician's request for the lithotomy position can usually be met.

In view of the traditional advocacy—not mainly by the anæsthetists—of the lateral position, we must ask our obstetric colleagues for a clear enunciation of the relative merits of these two positions for delivery.

It has been argued that it is unduly hazardous to use the lithotomy position when the patient is not intubated, as the associated greatly increased abdominal pressure predisposes to regurgitation, but this reasoning overlooks O'Mullane's observation that the raised abdominal pressure *per se* does not render the cardia incompetent in the absence of obstruction to inspiration. Experience suggests that this practice is less dangerous than would at first appear, and even Parker feels that the case against the lithotomy position in hospital is unproven. There is of course no problem—after induction—if the patient is intubated, but such intubation may not always be possible. We must also weigh the merits of a rapid, adaptable and light anæsthesia, against the slower tempo, deeper and possibly more traumatic anæsthesia with the intubated patient. I would remind those who are in favour of routine intubation, that this policy has yet to be proved over a large series of cases. Hingson and Hellman (1956) intubated but 2 patients in 15,000 deliveries and I, also, usually prefer not to intubate, and rely on the ability to recognize the warning of impending vomiting given with inhalational anæsthesia, and treat that condition promptly, should it occur.

Results.—In justification of this policy, which may appear reactionary, I can only say that this has been the practice at the Middlesex Hospital, where we have had no death from inhalation of vomit in the Maternity department for at least twenty-five years. This period has been chosen partly in an attempt to collect enough cases, partly because it is within memory, and

partly because it covers the period when an anæsthetic machine came into general use in the enlarged department.

I have re-examined the notes and post-mortem records of the earlier deaths, and have excluded the possibility that inhalation of vomit was a contributory cause of a death.

Unfortunately the records are not absolutely complete, so I can only estimate the total number of general anæsthetics at about 9,000. It may be that this is insufficiently precise, but there is no doubt about the post-war records of 5,600 consecutive general anæsthetics without a death, from any cause. However, these figures are easily bettered by Lock and Greiss (1955), who reported 18,868 consecutive obstetric anæsthetics without a death. These workers do not give their morbidity figures; in our 9,734 post-war deliveries we must admit to at least three major aspiration pneumonias, a rate comparable to that of 1 in 2,560 deliveries quoted by Hingson and Hellman.

Thiopentone

Opinion is also divided about the use of thiopentone, which can be considered from three aspects: namely, the effect on the fœtus, the facilitation of the induction of the anæsthesia, and the risk of vomiting. With regard to the effect on the fœtus, the drug is undoubtedly transmitted through the placenta, but differing views have been expressed on how quickly equilibrium is reached. Hellman *et al.* (1944) showed that there was an appreciable concentration of the drug in the fœtal blood after five minutes, but that the maximum concentration was not found until twelve minutes after it was administered to the mother. More recently, McKechnie and Converse (1955) have shown that a considerable amount of the drug may be detected after only 45 seconds, and that equilibrium with the maternal blood levels may be reached in as soon as 3 minutes. Crawford (1956) in this country has again shown that the placenta is no barrier, and claims to have shown that the fœtal blood level falls at the same rate as that in the maternal blood. He therefore suggests, contrary to the recommendations of Hellman and many others, that the longer the interval allowed between the administration of thiopentone and delivery, the lower the fœtal blood level will then have fallen, with therefore less likelihood of respiratory depression. There is much force in this argument; nevertheless, some infants in his series, as in those of McKechnie and Converse, had disproportionately high thiopentone levels many minutes after its administration, and one can only speculate on some possible reasons for this. There may be a variation in the volume of amniotic fluid, placental size or choriodecidual blood pooling; moreover, any estimation of serum thiopentone levels should take into consideration the pH of the blood and the ratio of thiopentone in the free or protein-bound condition (Dundee, 1956). These many possibilities, together with the very variable occurrence of fœtal respiratory depression, all emphasize our lack of precise knowledge in this field. There is also a possibility that the fall in blood pressure after the administration of thiopentone may alter transplacental dynamics, and thus embarrass fœtal oxygenation by the same mechanism as with an inadvertent high regional block.

Two factors, however, are clear; thiopentone is transmitted to the fœtus, and this drug is a powerful respiratory depressant. It seems reasonable, therefore, to limit its use. I am aware that many people have used this drug with satisfactory results, and I have, in the past, used it myself—sometimes as the sole anæsthetic—for Cæsarean sections and forceps deliveries, and while it was usual for the babies to cry lustily on delivery, they tended, not infrequently, to relapse into a stuporous condition shortly after delivery, and to give rise to some anxiety for a few hours. I now restrict its use to a minimal dosage of 100 to 200 mg. for very apprehensive mothers, and then only when there is no suggestion of fœtal distress.

It has also been suggested that thiopentone renders induction smoother, and therefore safer for the mother and fœtus. This may be true in some cases, but it seems to me to overlook the fact that most mothers, either from the exertions of labour, or in "cold" cases from the absence of depressive premedicant drugs, usually have a very active respiratory exchange, which renders an inhalational induction easy and rapid. In any case, most mothers are trained to accept, and indeed look forward to, an inhalation at some stage of their labour, and it is not common to find "the horror of the mask" which is often met with in other fields. Indeed, the ability surreptitiously to convert analgesia to anæsthesia is one of the great advantages of inhalational methods.

The more persuasive argument for the use of thiopentone comes from the obstetricians, especially for an assisted breech delivery in combination with some form of local infiltration when undoubtedly a rapid induction with no struggling is of the greatest importance. It is probable that the risk to the fœtus in these circumstances is relatively unimportant as the cord is probably already compressed, but the hazard to the mother of regurgitation and vomiting is then not inconsiderable. I am aware that one of the most skilled and enthusiastic reporters of breech deliveries (Cox, 1950), with an excellent fœtal salvage rate, advocates thiopentone anæsthesia for the after-coming head, but I believe with Law and Ransom (1954), that inhalational anæsthesia can provide equally satisfactory operating conditions with greater safety for the mother.

Conclusions

It is considered that for many major obstetric manœuvres, general anæsthesia by inhalation remains the method of choice. The available drugs must therefore be briefly reviewed. Cyclopropane has many advantages when a rapid induction is of paramount importance, but its use should be confined to this period, for, in my experience, prolonged cyclopropane anæsthesia is more likely to lead to fœtal depression, as would indeed be expected, as this drug is a powerful respiratory depressant. There was some experimental evidence in favour of this conclusion as long ago as 1939, when Smith found that the concentration of this drug in the fœtal blood was as high as in the mother's, whereas in similar circumstances the nitrous oxide concentration was only half the mother's; and Taylor *et al.* (1951) showed that the delay in reaching full oxygen saturation in the fœtus after delivery was greatest after cyclopropane anæsthesia.

Nitrous oxide then, with oxygen, remains, as in many other fields, the mainstay of obstetric anæsthesia, and where relaxation of the uterus is required, ether, which is least depressing to respiration, seems to possess the fewest disadvantages. In practice, any other vapour which happens to be available on the machine—even CO_2—may be used if necessary to speed the induction, although trilene is best avoided where the mother has already received a lot of pethidine. Vinyl ether has much to recommend it, but has the disadvantage of producing considerable salivation. The newer ethers are as yet unproven, are less predictable, and may cause a fall in B.P. As always, the details of administration depend on the ability of the anæsthetist and his familiarity with the method, remembering that one of his aims is to ensure adequate oxygenation of the fœtus before delivery, and this is most easily done with open circuit anæsthesia.

It certainly does seem reasonable to reduce the numbers of mothers at risk by using the simpler regional methods, and that is indeed our policy now. About 22% of our deliveries including the Cæsarean sections and most of the difficult forceps are done under general anæsthesia, though very few of these are intubated; and a further 35% comprising some outlet forceps, and all the repairs, receive local infiltration, often with inhalational analgesia as well. Pudendal block occupies a middle position, according to the progress of the labour, and the skill and enthusiasm of the obstetrician. But there are other arguments for using local methods, besides that of avoiding the risk of inhaling vomitus.

Pudendal blocks and local infiltration are most valuable techniques for the potential general practitioner, or domiciliary obstetricians, and for those going overseas, and are therefore well suited for use in teaching institutions. The administrative simplification and reduction of demand on a busy anæsthetic service is not to be scorned, and this makes it easier to supply a senior anæsthetist for those general anæsthetic cases where his skill is so needed. This reduction in demand may be considerable, as, for example, at the Middlesex, where 50% of recorded "normal deliveries" have either an episiotomy or small tear to be repaired. Finally, it must not be overlooked that this desirable increased use of local methods is not unconnected with the introduction of that excellent drug lignocaine, and perhaps also hyaluronidase, which render these procedures so very much more effective.

I have not been primarily concerned with domiciliary obstetrics, but in fact many of these recommended methods are equally applicable there; local infiltration, and pudendal block are certainly so, and inhalation N_2O–O_2, ether and cyclopropane in the lateral position with little difficulty. Most of the long labours should be, and usually are, in hospital.

Crawford has made the excellent point that obstetric anæsthesia would be simplified, and the standard raised for the less practised anæsthetist, if the routine anæsthetic for these cases approximated to those given for surgical operations; I agree, but instead of advocating the use of thiopentone in obstetrics, I prefer to use this argument in support of the continued teaching of inhalational methods.

I hope I have succeeded in showing that this "old-fashioned" N_2O–O_2 ether sequence is not used in obstetrics because of habit or tradition. On the contrary it is specifically indicated for its flexibility, its relative innocence to the fœtus, its ability to relax the uterus when required (intravenous ergometrine now renders this a safe procedure), and above all, because with it there is warning of impending vomiting, which, should it occur, does so when the protective reflexes are present.

It may be argued that it is a difficult technique, it is no more so than many others, and is, after all, the fundamental technique of our craft, but this argument turns on the old truth, that no method is better than the person who uses it. No one would deny that for the obstetric case in hospital that person should be a skilled senior anæsthetist; he must always be available.

Mr. J. S. Tomkinson: *Requirements of the Obstetrician*

I have thought it best to approach the evaluation of general and regional methods of obstetric anæsthesia, from the point of view of the obstetrician, by stating the requirements of an ideal obstetric anæsthetic and then by mentioning the probable anæsthetic of choice for various obstetric procedures.

The first and most important requirement is absolute safety for mother and child.—To achieve this one must consider firstly the dangers of a full stomach to the mother and the steps which may be taken to minimize these and secondly the hazards of hypoxia to the child.

The mother should be instructed regarding diet following the onset of labour. Heavy meals must be avoided. An emetic dose of apomorphine may be considered as a means of emptying the stomach. A tilting bed at the instantaneous control of the anæsthetist has also proved its value.

Concerning the safety of the baby, important work has been published which demonstrates clearly that the risks of hypoxia to the baby are increased markedly after the 40th week of pregnancy (Walker and Turnbull, 1953, *Lancet*, ii, 312). The oxygen supply to the baby may become inadequate for many reasons including damage to the umbilical cord, placental insufficiency, prolonged uterine contraction or defects on the part of the mother in providing an adequate level of oxygen. Any additional hazard causing further anoxia, such as readily occurs during the induction of general anæsthesia, may tip the balance against the baby's survival. When the oxygen saturation in the umbilical vein falls below 30% there will be evidence of fœtal distress including passing of meconium and irregularity or slowing of the fœtal heart.

Walker suggests that the anæsthetic for the delivery of the anoxic fœtus should be spinal, local or caudal, since during the induction period of most general anæsthetics there is a time when the maternal oxygen uptake may be impaired. Similarly it has been pointed out, by many authorities, that regional methods are safer for delivery in many instances where the fœtus *in utero* is at risk, as in maternal diabetes, pre-eclamptic states and fœtal immaturity.

So far we have only mentioned as our requirements the safety of the mother and baby. Often speed of induction may be demanded by the obstetrician and there can be little doubt that here general methods have the advantage.

The length of time for which pain relief is required is an important consideration. No general method of anæsthesia could provide such a long period of pain relief, with equal safety to the mother and baby, as continuous epidural techniques. They are, however, time-consuming, take great skill in administration and are not invariably successful.

The position of the patient for delivery. I am convinced that the lithotomy position is the best to satisfy the demands of the obstetrician for ease of access to the patient, accurate anatomical diagnosis of the position of the baby relative to the maternal pelvis and for maintenance of asepsis. Furthermore, the fœtal heart is easily checked and the patient is in the correct position for the management of the third stage of labour and for the suturing of an episiotomy.

The advantages of *pudendal nerve block* are numerous and it is now widely used by obstetricians. It is almost completely safe for the mother and completely safe for the baby. It has few complications for the mother and none for the baby. It is easy to learn and one can quickly become efficient at the technique. The equipment is easily carried and can be used in hospital or home. The obstetrician is independent of the skilled anæsthetist. The mother is awake and able to co-operate.

In conclusion, the wishes of the patient must be taken into account. I do not consider it advisable to adopt any one method as being satisfactory in all cases but I certainly think that any anæsthetist who is proposing to co-operate in obstetrics should be able to combat the risks inherent in inhalation anæsthesia in pregnancy and labour and should be skilled in the use of regional methods.

Dr. G. C. Steel: I shall attempt to evaluate the known dangers and virtues of regional anæsthesia against the known requirements of the mother, the child and the obstetrician.

I agree with Dr. Dinnick concerning the hazards of spinal anæsthesia: the immediate dangers to the mother and, through her, to the child, of sudden collapse, hypotension and respiratory embarrassment are very real: but they largely arise from abuse of the method and from simple ignorance of the effects of giving a spinal to the full-term woman: an ignorance which happily is disappearing. Headache is on the debit side of the balance sheet, and Rosenbaum *et al.* (1952) give an incidence of 0·7% for the occurrence of chronic adhesive arachnoiditis in patients who had previously had "saddle block anæsthesia". Spinal anæsthesia, however, scores very heavily on the grounds of efficiency: it does its job in that it cuts the afferent stimuli: it gives the surgeon good relaxation: it largely avoids the dangers of vomiting: blood loss is minimal; and, if proper precautions are taken, it has no adverse effect on the child. It is reasonably easy to perform and can be done quickly; it is swift in action; and the likelihood of laryngeal spasm is small. I deprecate the wholesale use of spinal anæsthesia to secure "painless childbirth" in all cases, but where one is presented with an obstetric emergency it may well appear to be the method of choice. In this and many other instances the anæsthetist is wholly justified in employing spinal anæsthesia. The tragedies of continuous caudal analgesia arose from it being used as a routine: and again, as in the case of spinal anæsthesia, from total ignorance of the effect of a sympathetic block. "Total ignorance" is a far greater danger than "total spinal".

The disadvantages and the dangers are also familiar: injury of a blood vessel and possible injection into it; puncture of the dura; hypotension; over-rapid absorption and the possibility of too rapid rise of the drug; together with prolongation of labour, a high forceps rate, and failure of rotation of the occipito-posterior case. It can be technically difficult, and may be more so than is lumbar extradural block. Finally I am always rather unhappy about its proximity to the anus, especially in the case of an indwelling needle.

In its favour its efficiency is very much greater than is generally thought, that is if it is a true caudal. Probably the great majority of so-called "Failed Caudals" were never caudal blocks at all, but had the solution deposited outside the sacrum. Again, caudal block will get to the sacral roots with rather more certainty than if the lumbar epidural route is used. It possesses the other advantages over inhalational anæsthesia that are inherent in regional blocking, and it is outside the theca.

Its therapeutic uses and their particular application to uterine inertia and cervical dystocia have already been described (Galley, 1950; Arthur and Johnson, 1952; Johnson, 1954; Ball and Chambers, 1956; Youngman and Lloyd, 1956). As an alternative approach, the use of the lumbar extradural block for inertia is perfectly feasible and probably preferable to the caudal route. The salient features are: firstly, the extraordinary efficiency of the method: when a woman is having the heightened pain of the ineffective contractions of uterine inertia, it is wholly gratifying to see the change in her facial expression as the block begins to work. She frequently falls asleep; and this is not a stuporous slumber, but one that comes from complete freedom of pain. The next point is its precision: it seems to me to be so much more rational than the random depression of the function of the sensorium. It is the single bullet hitting the target as opposed to the indiscriminate peppering of the barn door with shot. I am a strong convert to the passage of a catheter with a Tuohy needle in the upper lumbar region, an operation which is simple and perfectly painless. While the continuous method is certainly preferable, a single injection of a mixture of Xylocaine 1½% and Nupercaine 1/600 can well give complete relief from pain for up to three hours, by which time the cervix may be dilated, and, if not, the injection can be repeated. Such a block does not usually control the pain of the pressure of the head down on the perineum, but that is a small problem as compared with that of the pain of inertia. The point on which I should like guidance from the obstetrical side is whether or no the blocking of the sacral plexus from the beginning is essential to the success of the method.

Contrary to general opinion, the acquisition of the technique of extradural block demands but a reasonable amount of patience and of application: in return one

acquires something which is of the utmost value in obstetrical anæsthesia. To locate the space I prefer the Dogliotti method. In a small proportion of cases there is said to be an absence of the negative pressure which obviously vitiates the efficacy of the Odoms indicator and of other similar methods. This does not matter so much in the alternative method because, as the needle comes up to the ligamentum flavum, the feeling of resistance increases sharply. As it does so, a correspondingly increased pressure should be exerted by the right thumb pressing on the plunger: this can be quite considerable. When the needle then enters the extradural space, even if there is no actual negative pressure present, the relative difference of resistance is immediately and unmistakably perceptible. Saline is preferable to distilled water for use in the syringe as, when using the latter, the patient may complain of pain at the moment of entering the extradural space. This has also been noted by Lund *et al.* (1956). The sight of fluid dripping back does not necessarily mean that the dura has been punctured: indeed in the very rare case, the injected fluid can spurt out. The injection of the anæsthetic solution must be done really slowly so as to form a local pool, rather than strip its way upwards. Bromage (1954) recommends that for Cæsarean section the pressor drug should be given before the blood pressure falls: with this I agree, but I have noticed that the fall is much smaller when the woman is in labour rather than when an elective section is being done.

The use of epidural block for Cæsarean section was described by Dawkins (1947). It is the method of choice both for mother and child in the "problem Cæsarean", complicated by factors such as cardiac disease, full stomach, prematurity, postmaturity and the like. In the last year at Queen Charlotte's Hospital I have used this method in 10 out of 23 of my cases (44%) and my total personal series for Cæsareans is just over 50 cases, which compares with 100 (Wendl, 1956) and 125 (Ansbro *et al.*, 1952). Gordon *et al.* (1955) have also described a series done with continuous epidurals, and have expressed a preference for Cyclaine to Xylocaine. They quote a failure rate of 5%. I would rate the efficiency of this method as very high. It has the obvious advantages of regional as opposed to general anæsthesia. When it does fail to give perfect freedom from pain I have found that this does not occur during the incision of the skin or of the peritoneum, but at the stretching of the fibres of the lower uterine segment or during the extraction of the head. On one occasion I found that, whereas the patient did not even feel this, she complained of definite pain when the ergometrine was given and the uterus contracted down very markedly. It is perfectly permissible to give the patient a light gas and oxygen at such a time. Sleep only is needed: full oxygenation can be maintained: and the danger of spasm is minimal. The outstandingly good condition of the mother following operation is a most constant feature.

For the baby I consider this the method of choice, especially when there are complicating factors. This is in agreement with the findings of Stewart (1954) and those of Lund (1955), who, in the case of the full-term fœtus, could find no statistical difference in the variations of the infant mortality when done under spinal, balanced or epidural anæsthesia. He found, however, a statistically significant difference in these rates following Cæsarean section when the fœtus was premature, the mortality rate being lower in conduction anæsthesia than in general anæsthesia. The baby delivered under an extradural block cries immediately and continues to cry. The latter point is of particular interest, for, though many methods are praised on the grounds that the baby cries within a short time, a more certain picture would be given if we excluded from those figures those babies who cried at the moment of delivery or on the clamping of the cord, but who thereafter slumped into a relatively stuporous state persisting for several minutes.

My experience of using lumbar extradural block for forceps is very small and confined to difficult cases where I have found it extremely valuable, although one cannot invariably be sure of the solution tracking down to the sacral roots to give perfect cover. Even if the cover is incomplete, nevertheless it does some four-fifths of the task, especially if intra-uterine manipulations are necessary: and again it minimizes danger by cutting the afferents. In this respect Comerford (1956) recommends that puncture should be done between L.3 and 4, or L.4 and 5, with the patient in the left lateral position and with 20 degrees of reverse Trendelenburg tilt; this, he found, gives perfect analgesia from S.5 to D.8 or 10, using 25 c.c. of 1·5% Xylocaine with adrenaline. He further recommends that this method should be used for all forceps deliveries.

There are some real and many imagined disadvantages of extradural nerve block. Firstly it is said to be time-consuming; this drawback is rapidly overcome by familiarity or by the anæsthetist starting his work fifteen minutes in advance. Secondly, Dr. Dinnick has mentioned the failure rate of extradural block. The success rate of any method is in direct proportion to the experience and the enthusiasm of the operator. Mastroianni *et al.* (1955), who passed one catheter into the lumbar extradural space to control the pain of the first stage and another through the sacral hiatus to stop that arising from pressure on the perineum, quote the failure rate of the former as 4% and of the latter as 25%. Foldes *et al.* (1956) state that in 422 cases of extradural blocks 22 instances occurred in which there was

partial failure—a rate of 5·2%. Initially one's failure rate may be 50%; thereafter it drops steadily, and, provided that one keeps in practice, the partial failure rate goes below 5% and the total failure rate between 1% and 2%. Thirdly, hypotension. The danger of a fall in blood pressure lies in the failure of the operator to remember that it is liable to occur. The pressor drug should be drawn up in the syringe before the block is done. I have never had any trouble in restoring it in Cæsarean sections, though my Registrar at the Royal Free Hospital states that on one occasion she found it difficult to restore it before the baby was born (Goetzee, 1956). No ill consequences resulted. Lastly, total spinal analgesia is quoted as a possible danger. I consider this is very unlikely, and in some of those cases which have been so described, respiratory paralysis may have been due to over-rapid injection of a large amount into the extradural space, with the result of its stripping its way up to the upper dorsal and cervical regions.

The danger to the child through the action of the uterus contracting violently under spinal anæsthesia has been mentioned by Macintosh (1949) and by Ward *et al.* (1952). Ruppert (1955–6), however, states that hyperactive disturbances of motility of the uterus which might endanger the child do not result from epidural analgesia. This difference may be of some significance, in view of the more selective action of drugs placed outside the theca instead of inside it.

I have read of one case of mild meningitis following extradural injection, but I have never known myself of any nerve damage following extradural block in obstetrics and gynæcology. As well as anæmia, hypotension and diseases of the central nervous system, I would hold as one of the contra-indications of the use of epidural any marked degree of stretching or distortion of the spine due to the use of the bridge, since I have personal experience of one case of root injury associated with a high extradural block and prolonged use of the bridge.

Too much significance should not be attached to associated disasters. In December 1956 I considered doing a continuous epidural on a case, but decided not to. Eventually the case was delivered with forceps under general anæsthesia. Ten days later she developed incontinence of urine. No fistula was found, and the incontinence, which still persists, is thought to be of neurological origin. The moral is obvious.

It is my practice to teach the Resident Anæsthetists at Queen Charlotte's Hospital and at Chelsea Hospital by doing a large amount of gynæcological operations under extradural nerve block. In the last year at Chelsea 59% of my anæsthetics for hysterectomies have been done with extradural block. Again I would recommend this practice, because, for lower abdominal surgery, I consider it to be the method of choice, particularly in the outstanding protection that it confers on the patient, together with good relaxation and minimal bleeding. I have said briefly that there are difficulties in applying extradural block to every case of forceps. The practice of the residents at Queen Charlotte's Hospital appears to follow along the same lines as those mentioned by Dr. Dinnick. In the last year out of 323 forceps deliveries 282 were done under inhalation alone and 33 were done with an inhalation plus the use of a relaxant. Other methods total 8.

In my opinion, it is essential that every anæsthetist should be able to undertake regional analgesia with that certainty of success which comes from learning the technique and keeping himself in practice. Whilst its outstanding value is high in the field of obstetrical anæsthesia, it cannot be regarded as being solely concerned with this and it is essential that it should form a routine part of postgraduate teaching. Similarly, of mankind, John Donne said "No man is an island intire of it selfe. Every man is a parte of the continent, a peece of the maine".

Dr. J. M. Holmes: *The Prevention of Inhaled Vomit during Obstetric Anæsthesia*

During labour the stomach continues to secrete a gastric juice of high acid content and in normal labour of even relatively short duration the motility of the stomach is very considerably reduced. This gastric atonia permits the accumulation of large quantities of partially digested food which may be vomited and aspirated into the respiratory passages during general anæsthesia.

Apomorphine hydrochloride has been given intravenously as a pre-anæsthetic emetic to 118 women in labour. The patient is asked to remove her dentures and then 1/40 grain of apomorphine hydrochloride is injected intravenously over 30 seconds from a dry sterile syringe. The needle is left in the vein and the onset of vomiting awaited. On rare occasions it may be necessary to give a further 1/80 grain. After a short period of preliminary nausea the patient vomits profusely within 45 to 90 seconds of beginning the injection and this persists for a further 30 to 60 seconds. The feeling of nausea rapidly disappears as soon as the stomach is completely empty and always within three minutes of beginning to vomit. Atropine sulphate, 1/50 grain is given slowly by intravenous injection through the same needle as soon as vomiting begins and this will rapidly antagonize the slight vagal effects of apomorphine and is also an essential premedication prior to general anæsthesia. The patient is instructed to clear her nasal passages of mucus and, after waiting a few minutes for the atropine to take full effect, general anæsthesia is induced.

During the actual vomiting there is a slight increase in sweating and lacrimation and the pulse-rate rises by 10 to 20 beats per minute. The blood pressure remains unchanged. Occasionally the patient has complained of slight vertigo, which has not persisted for more than a few minutes. There is a marked intestinal hurry and barium meal has reached the cæcum within 5 minutes of taking it by mouth and within 3 minutes of the apomorphine injection. The stomach is therefore emptied not only via the œsophagus but also via the pylorus.

Many patients vomit during the course of their labour and obstetricians have come to accept this as physiologically normal. The apomorphine vomiting which is described does not disturb the patient to any greater extent.

The technique has been used on 118 occasions. 10 patients did not vomit but since they did not vomit during or after the anæsthetic it was assumed that the stomach was already empty. It is believed that the routine adoption of this method would effectively remove the dangers of vomiting and inhalation of gastric contents during obstetric anæsthesia.

Dr. C. J. Massey Dawkins:

If the Tables of Anæsthetic Mortality issued by the Registrar-General are consulted, it will be found that over the last five years, taking the anæsthetics in common use for labour, there were 16 deaths from chloroform, 83 from cyclopropane, 56 from trilene, 106 from nitrous oxide—and none at all from vinyl ether. This is a very remarkable fact and it is unfortunate that the great safety of vinyl ether is not properly appreciated.

It may be argued that vinyl ether is not often administered, but on consulting the explosion survey carried out by the Ministry of Health in the hospitals of England in 1954, it will be found that it was given at least 10,000 times. And as this survey did not cover dental clinics and general practitioner operations where vinyl ether is given much more often than in hospital, the real incidence of use must be at least 20,000 per annum if not much more. An anæsthetic which has been given 20,000 times a year for five years without a fatality is indeed a safe one, and it should be regarded as the anæsthetic of choice in maternity work where it is necessary to anæsthetize the mother.

I would agree with Dr. Steel that epidural block is the ideal method of providing pain-free labour without harm to mother or child and that it should be much more widely used than it is. With regard to pudendal block, American anæsthetists do not claim a success rate of more than 91% and those English anæsthetists with whom I have discussed the method do not claim more than 80% success but I would agree that the method is a very safe one.

Dr. H. R. Youngman:

We teach the junior staff of our obstetric as well as anæsthetic departments to use caudal and pudendal blocks. We invariably add adrenaline to the anæsthetic solution. This does not seem to be universal practice but we regard it as an important safety precaution. Severe toxic reactions have been reported from both kinds of block when it was not used. At Dr. J. A. Lee's suggestion I have recently used amethocaine for epidural analgesia in long obstetric cases; in some each dose has lasted four hours, as compared with two for lignocaine. I find methoxamine an improvement on the other pressor drugs. Its effect is indistinguishable from that of Methedrine except that it does not increase the heart-rate. This suggests that it acts in a more efficient way, and the absence of palpitation is an advantage for the conscious patient.

[*March* 20, 1957]

DISCUSSION ON MAMMARY TUMOURS

Mr. E. Cotchin (Department of Pathology, Royal Veterinary College, London):

Spontaneous Mammary Neoplasms of the Domestic Animals

Neoplasms of the mammary gland are common in the bitch, and form a significant proportion of the less commonly observed tumours of cats, but are of no practical importance in the mare, cow, sow or ewe. There are, in fact, few reports of mammary tumours in the larger domestic animals, and quite large numbers of tumours have been examined by various workers from these species without finding any examples of mammary tumours. Thus Head (1957) informs me that in a series of 116 tumours from horses, 292 from cattle, 106 from sheep and 4 from pigs, no epithelial mammary tumours were found, and only one mesodermal tumour—a mast-cell tumour—in an adult Ayrshire cow, with similar lesions in the supra-mammary, iliac and left prescapular lymph nodes, and the uterine and abdominal walls.

In the *mare*, although few cases of mammary tumour have been reported in recent years, an older report referred to by Feldman (1932) stated that 45 out of the 184 carcinomas found in 39,800 horses slaughtered in Paris abattoirs were in the mamma, and Surmont (1926) apparently had no difficulty in obtaining specimens from the abattoir.

In the *sheep*, Monlux *et al.* (1956), in a series of 66 tumours, found 4 adenocarcinomas which had widespread and peritoneal metastases: although the site of origin was not identifiable, owing to the conditions of slaughter, it was thought that they originated in the urogenital tract or the mammary gland.

In the *sow*, Feldman (1932) found a tumour in the mammary gland, with the histology of a primary adenocarcinoma.

Turning to the *cow*, it has been a matter for comment for a very long time that the cow's udder is hardly ever reported to be affected with cancer, and quite large series of tumours from cattle have been collected which included no such cancer. Thus there was none in the series of 908 bovine tumours examined by Monlux *et al.* (1956) in America and of 1,943 tumours examined by Chandrasekharan Nair and Sastry (1953–54) in India.

This rarity of cancer in the cow's udder is not merely a question of age. Swett *et al.* (1940) made an extensive study of the udders of 313 cows, of which 98 were over 8 years of age, without finding any tumours.

Reports of carcinomas of the cow's udder have been made by Boucek (1906)—only a histopathological description is given; Murray (1908)—the authority of this diagnosis is unchallengeable; Cleland (1908)—this case, from Australia, was considered acceptable by M'Fadyean; Kenny (1942)—the histopathological description of this case is convincing: there was an adenocarcinoma in the left part of the udder, with metastases in the supra-mammary nodes, lungs, bronchial and mediastinal nodes, and liver, and on the peritoneal surface of the diaphragm; Elder *et al.* (1954)—the tumour, in a 3-year-old Aberdeen Angus heifer, is not a typical adenocarcinoma; Poynton (1954–55)—an intraduct carcinoma of the udder is listed as one of the tumours examined in South Australia (it is understood that this case may be reported in detail later).

In these four larger farm animals, then, there is no significant incidence of neoplasms of the mammary gland. In the dog and cat, the situation is quite otherwise. In a series of 3,444 tumours from dogs examined at the Royal Veterinary College since 1940, 840 were from the female genital system, and 694 (20%) of these were from the mammary gland, while of 464 tumours in cats, 44 (just under 10%) were from the mammary gland.

In the *dog*, mammary neoplasms are practically confined to females. They do occasionally occur in male dogs, and it appears, for example (Hoskins *et al.*, 1953, p. 155), that dogs with Sertoli cell tumours of the testis (which have feminizing effects) may sometimes develop mammary tumours, and the writer has recently seen an example of a benign mixed mammary tumour in a dog with an interstitial cell tumour of the testis. In a recent series, the writer has examined mammary tumours from 424 dogs; all but 2 of the animals were entire females—the other 2 were bitches which had been castrated, but not until late in life: one of them, with a benign tumour, two years previously at 8 years of age.

The ages of the affected bitches in this series averaged 9 years, and 77% of them were from 7 to 12 years of age. Only 10% of the dogs were under 7 years of age. This age

distribution is a little later than that for neoplasms in general in the dog, but it is clear that many of the mammary tumours have an onset at a much younger age, and some had been present for several months, or even for a few years, before removal.

While a large number of the affected bitches were spaniels, there is no clear indication of any special breed incidence.

In the bitch, there are generally either four or five glands in each mammary chain, the presence of the third, or abdominal, pair being inconstant. As in previous surveys, the posterior mammary glands were found to bear the most tumours. Of the 160 tumours in this series for which the site of origin was recorded, nearly 7 out of 10 affected one or other of the two posterior pairs of glands, and the third pair was least often affected. This may merely reflect the fact that the posterior glands are the largest.

Clinically, the benign tumours were largely recognized by the owners as forming unsightly "lumps" in the affected gland. Ulceration was not a sure sign of malignancy, nor on the other hand was a well-defined lesion invariably a benign one. Despite the statement in a well-known textbook (Lacroix and Hoskins, 1952, p. 504) that most mammary tumours in the dog are malignant, in our series proof of malignancy, that is the presence of metastases, was found only for 41 of the 424 dogs (just under 10%), although 187 of the tumours were histologically classifiable as malignant.

The current assessment of the lymph drainage of the mammary glands of the bitch is illustrated by Stalker and Schlotthauer (1936), and by Baum (1918). This earlier worker found that lymph vessels passed from the three caudal glands (of the five on one side) to the superficial inguinal lymph node, and from the three cranial glands (of five) to the axillary node. Baum found also (in this respect differing from Stalker and Schlotthauer) that these three cranial glands also drained through the abdominal and thoracic walls to the sternal node. Both reports indicate that there is no direct lymphatic connexion between the mammary glands of the two sides.

In our series, leaving aside 3 cases of sarcoma in, but not of, mammary glands, metastases from 38 tumours were distributed as follows: In under half the cases (17/38), the regional node in the strict sense was involved, and in a quarter (10/38) some other nodes were involved (in one case, for example, the superficial inguinal node was the only site of metastasis from a lesion in the anterior gland, and in another, the axillary node from a lesion in the posterior gland). In 2 out of every 3 cases (25/38), the lungs were affected, and in 1 out of 3 (13/38) there were metastases in more distant areas. Thus, from this series, the prognosis would seem to be poor as regards the operative treatment of malignant tumours once they have metastasized. This should not, however, deter the surgeon, for the histologically malignant tumours outnumbered the clinically malignant (metastasizing) tumours by 4 to 1, indicating that at least some operations may be successful.

From the pathological aspect, there are two striking features of mammary tumours in bitches: one, the common occurrence of mixed tumours containing mucoid, chondroid or bony tissue, and the other, the wide variety of malignant types that occur, including a high proportion of sarcomas and also of what may be mixed malignant tumours (Table I).

TABLE I.—CLASSIFICATION OF 436 MAMMARY TUMOURS FROM 424 BITCHES

Benign tumours	249	Malignant tumours	187
Simple tumours	19	Carcinoma	87 (21 with metastases)
Adenoma	8	Sarcoma	73 (13 „ „)
Fibroma	2	Complex malignant	27 (7 „ „)
Lipoma	9		
Mixed ("complex") tumours	230		

Our experience thus differs from that of Stalker and Schlotthauer (1936), who state that sarcoma of the mammary gland is rather rare.

There is some evidence to suggest that in the process of development of the benign mixed tumours the following stages occur: Firstly, there is a disproportionate proliferation of "interposed" cells, that is, of cells lying between the luminal epithelium of ducts or acini and the surrounding collagenous connective tissue. These "interposed" cells become embedded in mucoid matrix, which they may form, and which may be transformed into chondroid material. Cartilage also appears to form by metaplasia of intralobular connective tissue, and bone, and maybe bone-marrow, is formed either by endochondral ossification of the cartilage (which may have a twofold origin) or by intra-membranous ossification in the intralobular connective tissue.

Although the identification of these "interposed" cells is not always possible, there is sometimes an indication that they are actually myo-epithelial cells, as is shown by their position and their morphology, by their staining reactions, e.g. with Masson's erythron-saffron, and by their positive alkaline phosphatase activity.

Many of the malignant tumours of the bitch mammary gland have the structure of sarcomas—some are osteosarcomas, or chondrosarcomas (23/73 sarcomas), and others are mucoid spindle cell sarcomas (40/73). It seems that these sarcomas are the malignant counterpart of the various types (mucoid, chondroid or bony) of benign mixed tumours. In fact, the origin of some of these sarcomas from "interposed" cells can be seen in sections, and the possible myo-epithelial nature of the sarcoma cells is supported by the occasional demonstration of alkaline phosphatase activity. An interesting and baffling problem of interpretation is provided by malignant tumours which appear to be carcinosarcomas.

It would be premature to conclude that all these diverse types of mammary tumour are basically of one kind, but they are perhaps more closely related than appears at first sight.

In the *cat*, mammary neoplasms show many points of contrast with those of the bitch (Cotchin, 1957). They are chiefly malignant histologically (38 out of 44 tumours) and to a lesser extent clinically (11 of 38 showed metastases); they occur at a relatively somewhat later age (12 years, average); they are chiefly seen in the anterior mammary glands, and are mainly adenocarcinomas. Mixed mammary tumours must be uncommon in cats (although myo-epithelial cells are present in the glands).

Discussion

There arise two very interesting problems in regard to these mammary tumours.

(1) What is the explanation of the remarkable difference between the incidence of mammary neoplasms in the bitch and in the cow? At least three of the four factors (or groups of factors) concerned in the pathogenesis of mammary cancer in mice (Mühlbock, 1956) must be significant in this respect. Nothing is known of the mammary tumour agent in our domestic species, but, as regards genetic constitution, and hormonal and environmental factors, there are, of course, obvious differences in the number, structure, functional activity, and secretion product, between the mammary glands of the different species which must involve the possibility of differences in response of the glands to oncogenic stimuli.

A useful analogy may be drawn between the species differences of incidence of neoplasia, and of infectious diseases. The species differences in incidence of the latter are attributable to differences in the host response on the one hand, and in exposure to the organism concerned on the other.

We might thus expect to find species differences of response and exposure to apply just as well to the relationship of mammary gland to oncogenic stimuli, of which hormonal stimuli will be the most important.

Response.—It is known that the different species vary in their experimental response to the same kind of hormonal stimulus. Folley (1956), for example, shows how animals may be divided into three groups, according to the effect of œstrogen in evoking growth of ducts and alveoli.

Growth Effect of Œstrogen in Physiological Doses

Duct	Alveolus	Animal
+	+	Cow
+	0	Cat
0	0	Bitch

Although reports of the effect of œstrogens in the dog show varying results—*see* Houssay (1935); Trentin *et al.* (1952)—it seems reasonable to conclude that the response to oncogenic activities of hormones would also vary from species to species.

Exposure.—The different species vary in such factors as the occurrence of spontaneous ovulation and the development of pseudo-pregnancy, and their mammary glands are probably exposed normally to varying hormonal stimuli.

Spontaneous ovulation	Pseudo-pregnancy	Animal
+	0	Cow
+	+	Bitch
0	+ (after induced ovulation)	Cat

We might therefore postulate that the cow's udder does not develop neoplasms because it is either not responsive to certain oncogenic stimuli (perhaps a resistance bred in incidentally as a result of breeding for high milk yield?), or is not exposed to them (perhaps this is related to the most obvious function of the cow's udder, for it has been shown that in mice with the mammary tumour agent, lactation—the animals being allowed to suckle their young instead of having them removed at birth—retarded mammary cancer).

On the other hand, the bitch might normally be subjected to effective oncogenic stimuli. Trentin *et al.* (1952) have shown, using ovariectomized dogs, that while œstrogen alone does

not cause mammary development, œstrogens and progesterone may cause development comparable with that seen in pregnancy and that progesterone alone has a similar, but lesser and more variable, effect. In the bitch (Hoskins *et al.*, 1953, p. 280), it is generally considered that mammary neoplasms are more often seen in bitches that have not bred, or have bred only infrequently a long time previously, and have shown abnormalities of the sexual cycle. One important factor has been thought to be the occurrence of lactation after pseudo-pregnancy. Sheppard (1955) suggests that there is an increase of these "false" lactations, and it may be that they are a reflection of the way in which a normal house pet is kept. There is the possibility that the normal pseudo-pregnant stimulation of the bitch's mammary gland, not followed by normal lactation and involution, is a sufficient tumour-producing agent, and that pseudo-pregnancy itself might be looked upon as an abnormal physiological condition.

(2) In the bitch, what is the significance of the common occurrence of mucoid, chondroid and bony tissue in mixed tumours?

Some of the bone, at any rate, seems to form because of the presence of cartilage, and in turn some of the cartilage seems to form because of the presence of mucoid tissue, so that at least part of the problem turns on the significance of the mucoid change, and of the proliferation of "interposed" cells to which it is so often related.

A pertinent observation may be that of Elliott and Turner (1950), who state that it appears probable that a mucolytic enzyme or collagenase is elaborated by the cells of the growing mammary gland of the rat, and who relate this to the invasion of connective tissue by the growing glandular buds. Conversely, McFarlane and others (Turner, 1952) describe the process of involution in the cow's udder as one in which the connective tissue in the interacinar position increases. It would seem that these changes in the connective tissue (and in particular of the "basement membrane") must be related in some very intimate way to the growth and involution changes of the glandular epithelium and myo-epithelium, and it may be that the myo-epithelium plays a particularly important role, as suggested by its position. In the mixed mammary tumour, we may be seeing on a neoplastically magnified scale a distortion of normal growth and involutionary relationships between lumenal epithelium, myo-epithelium and connective tissue. Clearly we need to know more about these relationships, and their possible hormonal control.

Professor Geoffrey Hadfield:

The Hormonal Status of the Breast Cancer Patient

The proliferation of normal mammary epithelium is totally dependent on an adequate supply, in optimal proportions, of ovarian œstrogen and progesterone together with a pituitary mammotrophic hormone. Total hypophysectomy inevitably leads to rapid atrophy of the mammary glands as well as the gonads and adrenal cortex but the atrophic mammæ grow vigorously if supplied with pituitary prolactin, progesterone and biologically active œstrogen. There is now ample evidence that about 50% of human breast cancers are also hormone-dependent, and that progressive cellular proliferation in these hormone-

dependent growths is conditioned by an adequate supply of the same hormones which are requisite for normal mammogenesis.

Lyons, Li and their associates (1955) have reported that, in hypophysectomized and gonadectomized virgin female and immature male rats, the atrophic mammæ which result from these operations show a vigorous growth response if the animal is given pituitary prolactin together with ovarian œstrone and progesterone, but that none of these hormones alone or in pairs can induce this growth response, and any combination of ovarian and pituitary hormones which did not contain prolactin was incapable of doing so. It is probable therefore that the proliferation of the cells of hormone-dependent human breast cancers depends not only on ovarian hormones but also on a pituitary mammotrophic factor which may be prolactin.

A complete endocrinological investigation of human breast cancer patients on a research basis is therefore likely to supply fundamental information regarding hormone dependence of this variety of cancer and may help in rationalizing treatment of this disease by endocrine ablation. Such investigations should include an estimation of urinary œstrogen and pregnanediol, together with a cytological study of the vaginal smear to estimate the degree of cornification of the vaginal mucosa.

In the laboratories of the Imperial Cancer Research Fund, urinary œstrogens are estimated in three fractions—œstrone, œstradiol-17β and œstriol—by the method introduced by Brown (1955) of the Medical Research Council's Endocrine Research Unit in the University of Edinburgh.

Pituitary function and particularly prolactin production is difficult to estimate. Pituitary gonadotrophin can be assayed by a standard method and should form an integral part of a full estimation of the hormonal status of the breast cancer patient. We have shown that pituitary prolactin is excreted in the urine of pre-menopausal women during the second or luteal phase of menstruation, and that if œstrone, progesterone and human female urine are administered to hypophysectomized weanling male mice their atrophic mammary glands show a vigorous growth response which is probably due to urinary prolactin of human origin in combination with the two ovarian hormones. Current research work on this problem may therefore help to divide breast cancer patients into two groups—those who are excreting prolactin in measurable quantities, and those who are not. It will then remain to correlate this classification with the effects on the breast tumour and its metastases of the operation of hypophysectomy. By these means it is hoped to devise a test to determine the selection of those patients who are likely to respond to hypophysectomy.

Mr. W. P. Greening:

Adrenalectomy for Cancer of the Breast

Since cancer of the breast is by far the leading cause of death among women in the mid-period of life, the palliative treatment of advanced recurrent and metastatic disease is a major problem in clinical management.

The treatment of metastatic cancer by the administration of hormones or ablative surgery depends on the fact that certain breast tumours are apparently hormone-dependent.

Adrenalectomy for patients with widely disseminated cancer was first carried out by Huggins in 1948 and is now an accepted surgical treatment for certain cases of malignant disease (Huggins, 1952). Apart from an increasing knowledge due to experience of the clinical aspect of the problem, there have been few advances either on the pathological or biochemical side.

From an historical point of view, Loeb in 1919 published a paper on the origin of breast tumours in mice. He had found that castration between three to six months almost entirely prevented cancer of the breast, whereas in mice castrated at seven to ten months, no immunity was obtained.

Woolley *et al.* (1939) ovariectomized 83 mice at birth, nevertheless 26% developed mammary tumours at an average age of 522 days. A careful check was made at post-mortem for any residual ovarian tissue, but none was found. At six months the uterus was atrophic, but later it became enlarged and hypertrophied, there was also in the breasts extensive duct development with the presence of end buds. It was noted that the adrenals in all cases were enlarged and had yellow nodules in them. The hypertrophy was in the cortex and it was these lesions which were secreting steroids in sufficient quantities to cause activity in the uterus and breasts and to induce tumours in the mammary glands.

Œstrogen-induced tumours in the mammary gland have been described by Cramer and Horning, and Burns and Horning have shown that they may also occur in the uterus and kidney.

The supply of œstrogen must be continuous, and it is interesting that the œstrogen-induced tumours may be limited to one organ only, and even to certain species of animal. Ovariectomy does not eliminate the excretion of œstrogen in the urine and, in time, a considerable rise in its production can be detected. This raised excretion is accompanied by hypertrophy of the cortex of the adrenal glands and they must therefore be regarded as a source of production of œstrogenic hormones.

Beatson is generally accepted as the first to suggest the possibility of hormone responsiveness in tumours in man. He was interested in lactation and noted that the cellular proliferation and desquamation were associated with a cessation of ovarian activity. He, therefore, carried out ovariectomy in cases of breast cancer, but reinforced his operation by giving thyroid. In the mistaken belief that he was advising this treatment for early breast cancer, his work was the object of much criticism.

In 1942, Adair and Farrow reported a remarkable remission in cancer of the male breast following orchidectomy, and this work was confirmed by Treves (1949), who also collected 116 female patients who had prophylactic castration and compared them with 2,893 non-castrated cases. In the non-castrated the five-year survival was 54·4%. In the castrated the five-year survival was 63%.

In an attempt to "neutralize" œstrogen, testosterone was first used by Loeser in 1938, and the remarkable remissions produced by this hormone are well known. Galton (1950) found, in a series of 70 cases, that over 40% were improved. Surprisingly, synthetic œstrogen used by Haddow and his co-workers in 1944 also produced a remarkable remission, for periods of anything from one to nine months. Although this would appear difficult to explain, it is possible that the results achieved are due to inhibition of the adrenocorticotrophic hormones of the hypophysis. The isolation and production of cortisone enabled Huggins, for the first time, to remove the œstrogen-producing adrenals and ovaries and at the same time to maintain the patient in completely normal health. The complete elimination of œstrogen production, however, only caused a remission in 40% of adrenalectomized and ovariectomized patients and this remission, although often apparently complete, was not maintained on an average for more than two years, but occasionally for as long a period as five years. It is assumed, therefore, that one of three things must be happening to cause a further growth of the disease. (1) There is still œstrogen production from ectopic ovarian or adrenal tissue. (2) A hypophyseal mammotrophic hormone may reactivate the cells; or (3) the tumour may no longer be hormone-dependent. The complete removal of the hypophysis eliminating, therefore, mammotrophic hormone production and steroid hormones from the adrenals and ovaries, should, on this reasoning, produce a much higher percentage of remissions, with a corresponding increase in their duration. Surprisingly, the figures are only 10% better.

The reasons, therefore, for removing the adrenal glands and ovaries in mammary cancer are:

(1) Ovariectomy may cause remissions of breast cancer in the human and will delay its onset in animals.

(2) The adrenals can also produce sufficient quantities of steroids to maintain a hormone-dependent neoplasm.

(3) Increased œstrogen excretion in ovariectomized animals is associated with adrenocortical hyperplasia and the production of mammary tumours.

Because there has been no specific test for hormone responsiveness and therefore no reliable method of predicting results, there has been a tendency to reserve the operation for *all* cases where no other treatment is possible. There are a few indications which help, but the success or failure of the operation is so unpredictable that one has hesitated to advise against adrenalectomy in case the last chance of remission is denied the patient. The condition, while it must not be hopelessly advanced, should not be able to be kept under control by simpler methods. Localized bony deposits and isolated pleural effusions are best treated by some form of radiotherapy, and here it is important to remember the variable course of the disease. Metastatic breast cancer may remain static or fail to progress for a considerable time and adrenalectomy should be reserved for those cases that are definitely progressing.

We find that the majority of remissions occur between the ages of 45 and 50. High values of œstrogen excretion in the urine at all times, and particularly after ovariectomy or the menopause, indicate significant adrenocortical activity and therefore the possibility that adrenalectomy will cause a remission.

The histology of the tumour is of little help in most cases. It varies in different parts of the primary and the metastatic deposits and quite commonly one tumour may show different structural variants.

Two methods have been described by Emerson and Jessiman (1956) by which hormone dependency may be evaluated; the sex-hormone stimulation test, in which results are assessed by observation of the increase in urinary calcium excretion and subjective symptoms after the administration of stilbœstrol; and (2) the cortisone inhibition test, in which the result is

judged by the decrease in urinary calcium excretion and improvement in subjective symptoms.

The effects of adrenalectomy are seen as either subjective or objective improvement. Subjective improvement is often dramatic and occurs in at least 60% of cases. It consists of relief of pain from bony deposits, improved appetite, gain in weight and an increased feeling of well-being. This subjective remission is of little importance unless accompanied by objective changes. It is due to the administration of cortisone which not only relieves pain and causes euphoria, but also, in those cases with hypercalcæmia, immediately lowers the calcium excretion in the urine. The symptoms of hypercalcæmia are vomiting, thirst, drowsiness and pain.

Laboratory findings show that by and large there has been little alteration from normal. Apart from those patients with bone metastases, we find no change either before or after operation in the blood calcium or phosphates values. When metastases in bone are present, the blood calcium and the urine excretion values are raised in about one-quarter of the cases.

In a high proportion, nearly half, the serum alkaline phosphatase is elevated. This indicates osteoblastic activity or liver disease. In women with osteolytic secondaries, therefore, elevation of the serum alkaline phosphatase after therapy indicates increased osteoblastic activity and therefore healing of metastases.

Ketosteroid estimations diminish markedly in all patients after adrenalectomy. There is no significant increase in their value before operation.

Œstrogen excretion is temporarily abolished by adrenalectomy and ovariectomy and reference has already been made to the variable levels in breast cancer cases.

Gonadotrophin assays are being carried out but it is too early to say whether we are going to find any significant changes.

From the numerous reports of the effect of bilateral adrenalectomy for advanced cancer of the breast, there appears to be a definite dissociation between subjective and objective improvement. Relief of pain and increased feeling of well-being occur in approximately 60% of the patients. Objective remissions occur in only 30%. The average duration of objective remissions, in which there has been complete, or almost complete, disappearance of metastases, is approximately two years. In all cases when the disease recurs, there is a preponderance of new lesions rather than reactivation of previously healed ones. Both androgens and œstrogens have been used at this stage but have failed to alter the course of the disease apart from accelerating it.

If the recurrences are chiefly skeletal and osteolytic, increased cortisone may help to control the symptoms. It is too early yet to draw any definite conclusions as to the effect of hypophysectomy in adrenalectomized patients, but it would appear that a further remission may be obtained, and this has certainly been our experience in a limited number of cases. In patients who have been adrenalectomized and have thereby obtained objective remission with apparent complete regression of the disease, hypophysectomy is successful in only 40%—a figure similar to that obtained by adrenalectomy in completely unselected cases.

Dr. I. Lewin:

Xanthine Oxidase Activity in Normal and Abnormal Growth

A. Levels of Xanthine Oxidase Activity during Normal Growth

Xanthine oxidase activity was measured in mammæ in a total of 115 C+ mice during the virgin state, pregnancy, lactation and involution. Since this organ undergoes profound changes in size, structure and function during the reproductive cycle, it was necessary to search for an expression of enzyme activity which would permit biological interpretation. Of the many indices, such as wet weight of tissue, defatted dry weight, total nitrogen, DNA and cell count, it would seem that the expression of enzyme activity as a function of the variable cellularity would best reflect the changes in a growing tissue. Also, in order to unify the presentation of the data, the observed absolute values are expressed as a percentage of the baseline value, that is, the average value obtained in breasts from up to 50 virgin mice.

I. *Changes in weight.*—In each case, the five pairs of breast pads were stripped off the underside of the skin and weighed. The tissue was then minced with fine scissors and an aliquot was removed for the determination of water, fat and defatted dry weight compositions.

FIG. 2.—Cell number, DNAP, and DNAP per nucleus in mammæ of C+ mice during the reproductive cycle.

FIG. 3.—Changes of weight and composition of mammæ from C+ mice during the reproductive cycle.

Another sample was taken from a pyrophosphate homogenate for total nitrogen. The results are shown in Fig. 1.

From an average value of about 400 mg. of total mammary tissue in a virgin mouse, the mammæ increase in weight to about 1,800 mg. around the middle of the lactation phase. During the first 16 days of pregnancy the increase in weight seems slower than during the last 3 days of pregnancy. It has not been estimated how much of the further weight increase beyond the moment of parturition is due to milk retained in the ducts and alveoli of the mammæ although the litter is allowed to nurse until the sacrifice of the mouse. According to Folley and Greenbaum (1947), the milk content may be between 40 and 50% of the weight of the mammæ in rats. A decrease in breast weight occurs towards the later part of lactation and is accelerated after weaning.

The wet weight can be thought of as being the sum of the amount of water, fat and defatted dry matter. In the latter the proteins constitute the major proportion. During the virgin state the mammæ are composed of 65·7% fat, 26·5% water and 7·7% defatted dry matter. At the height of development during lactation these values become 12·8% fat, 68·7% water and 18·2% defatted dry matter. After weaning there is prompt return towards the baseline. The amount of total nitrogen per mg. of fresh tissue also increases during pregnancy and continues to do so after parturition, which may be a reflection of milk production and retention. In regard to water, fat and nitrogen content one can distinguish a slow phase of change (up to about the 16th day of pregnancy) and an accelerated phase during the last 3 days of pregnancy.

II. *Changes in cellularity.*—The change in weight of the total mass of mammary tissue is seen to be the resultant of changes in fat, water and protein content. A better measure of the change in tissue mass is an estimate of cell numbers. However, the expression of cell number per unit of weight would also be inadequate since it would be affected by the fluctuations in fat and water content as well as by the amount of milk retained in the mammæ during the later part of pregnancy and lactation. To obviate these fortuitous variations in cell concentration, the total number of nuclei were calculated for all breast pads in a mouse. The nuclei in a sample from a sucrose-$CaCl_2$ homogenate were counted in a hæmacytometer and the number of nuclei per mg. of wet tissue were multiplied by the total weight of the mammæ in a mouse.

In the majority of samples, the sucrose-$CaCl_2$ homogenate was also used for DNA determinations. The homogenate was centrifuged at 20,000 × *g* for 30 minutes at 0° C. the solidified fat layer was skimmed off, the sediment was resuspended and an aliquot was treated with 10% TCA in the cold for one hour. The precipitate was washed with 5% TCA and then heated with two portions of 5% TCA at 90° C. for fifteen minutes each. The two extractions were pooled and boiled for fifteen minutes after mixing with the diphenylamine reagent. The colour was read at 600 mμ in a SP 500 Unicam Spectrophotometer and compared with a DNA standard.

Fig. 2 shows the great increase in total cell numbers from about 30×10^6 in a virgin breast to a maximum of 450×10^6 at around the 4th to 6th day of lactation. The increase in cells is greater (about fifteen-fold) than the increase in weight (about four-fold). This simply reflects the fact that almost all of the rather large adipose cells are replaced by smaller ductile and acinar cells of the mammary gland proper. A decrease in total cell number starts already around the 6th day of lactation. It is suggested that the reason for this early decline is the involution of some of the breast pads, usually the 1st and 2nd thoracic mammæ, which are not used by the litter.

The amount of DNAP (desoxyribose nucleic acid phosphorus) in the total breast parallels the changes in cell number, so that the amount of DNAP per nucleus remains fairly constant during pregnancy and lactation. The average value in this series of forty determinations on mammary tissue is $1{\cdot}196 \times 10^{-12}$ gram of DNAP per nucleus. For mouse liver Laird (1954) and Tsuboi *et al.* (1954) have reported values of $1{\cdot}23 \times 10^{-12}$ and $1{\cdot}36 \times 10^{-12}$ grams of DNAP per nucleus, respectively. These observations would indicate that the determination of the number of nuclei in a homogenate is a valid measure of cellularity.

The series here reported supports the observations that the mammæ continue to grow throughout pregnancy and part of lactation. Greenbaum (personal communication) in studying mammæ of rats has found that on the last day of pregnancy the DNA per gram of wet tissue has increased ten-fold and on the 3rd day of lactation sixteen-fold when compared to the virgin breast which means that the amount of DNA approximately doubles during the first few days of lactation. Histological evidence that the growth of the mammæ continues into lactation has been supplied by Cole (1933) who reported that mitosis of breast cells can be observed until the 7th day of lactation, although in diminishing numbers. However, Turner has stated that in mice the hyperplasia of the mammary gland parenchyma is complete by the 12th day of pregnancy (Turner and Gomez, 1933) and that in rats the amount of DNA content in the inguinal breast pads has reached a maximum at about the

Changes of weight and composition of mammæ from C+ mice during the reproductive cycle.

FIG. 2.—Cell number, DNAP, and DNAP per nucleus in mammæ of C+ mice during the reproductive cycle.

10th day of pregnancy after which it remains level until the time of weaning (Kirkham and Turner, 1953). No explanation can be offered for these differences, except that they may be due to differences in strain and species.

III. *Changes in xanthine oxidase activity of mammary tissue.*—The xanthine oxidase activity of the homogenate was determined by measuring the rate of uric acid formation. The rate per mg. of wet tissue was related to nuclear count. defatted dry matter and total nitrogen per mg. of wet tissue; thus eliminating the variations introduced by the changes in water and fat content of the mammæ during pregnancy, lactation and involution.

Fig. 3 shows the results. From an average baseline level in the virgin breast of $4{\cdot}2 \times 10^{-5}$

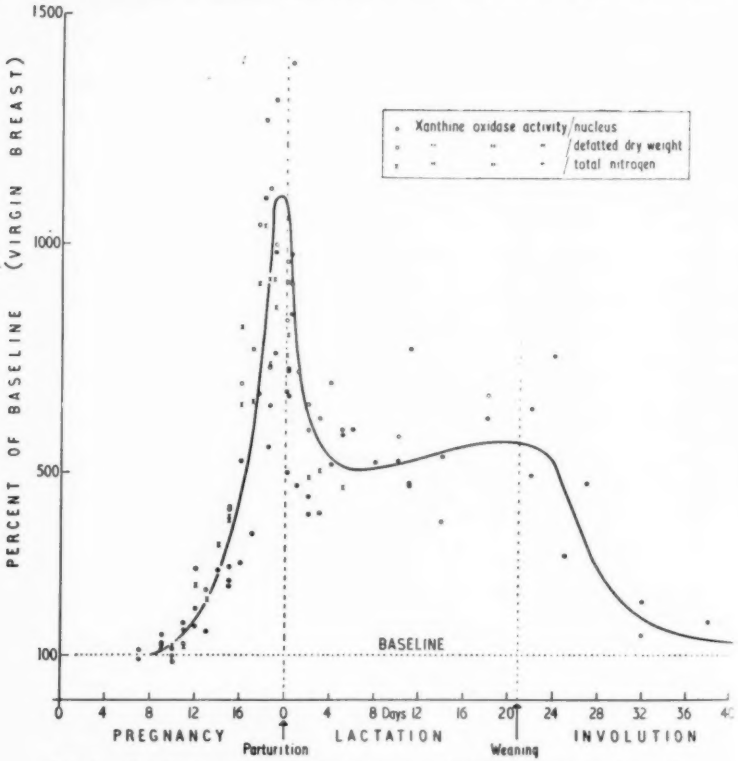

FIG. 3.—Xanthine oxidase activity in mammæ during the reproductive cycle.

micromoles of xanthine oxidized per minute per 10^5 nuclei the xanthine oxidase activity rises from about the 10th day of pregnancy onwards to a maximum value of $46{\cdot}2 \times 10^{-5}$ at a time shortly before parturition; this activity drops precipitously to about half this value for the duration of lactation. A decrease in xanthine oxidase activity becomes noticeable a few days after weaning, but does not seem to reach the baseline level even 17 days after weaning. All three indices (enzyme activity per cell per defatted dry matter or per total nitrogen) yield practically the same curves and indicate the overall net increase in this enzyme.

The peak in enzyme activity just before parturition is surprising and needs further comment.

IV. *Xanthine oxidase activity in milk.*—One of the earliest and richest sources of this enzyme is cow's milk. It was therefore essential in this investigation to evaluate the effect of mouse milk on the determination of xanthine oxidase in mammæ of mice during late pregnancy and lactation. It was noted that in some mice the mammæ were completely filled with milk, appearing engorged and white, whilst in other animals of the same dam in pregnancy or lactation the mammæ were entirely pink and presumably containing no so much milk. However, there was no consistent or significant difference in the xanthine oxidase activity either per unit of weight or per cell between the homogenates from presumably "milk-rich" and "milk-poor" mammæ. In order to follow up this observation a mouse

the 8th day of lactation was separated from its litter for twelve hours and then the breast pads of the left side were freed of milk as much as possible by "milking" and compared with the milk-engorged breast pads of the right side. The results (Table I) show that there is no

TABLE I.—COMPARISON OF XANTHINE OXIDASE ACTIVITY IN MAMMÆ CONTAINING DIFFERENT AMOUNTS OF MILK

Tissue	Appearance	Weight (mg.)	Amount of milk removed (ml.)	Nuclei/mg. of wet tissue ($\times 10^3$)	Micromoles ($\times 10^{-5}$) of xanthine oxidized/minute per mg. wet weight	Micromoles ($\times 10^{-5}$) of xanthine oxidized/minute per 10^5 nuclei
Breast pads of the right side (control)	White; engorged with milk	1,210	0·0	151	32·3	21·4
Breast pads of the left side ("milked")	Entirely pink	800	0·341	184	39·2	21·3

difference in xanthine oxidase activity per nucleus while the activity per mg. of wet tissue is slightly higher in the homogenate of the "milked" mammæ. Had the milk contributed to the xanthine oxidase activity one would have expected the homogenate of the right breast pads (control) to have a greater activity per nucleus and to have the same activity per mg. when compared to the left mammæ.

At this point it should be pointed out that the tissue homogenate is centrifuged at 20,000 × *g* for 30 minutes at 0° C. and the clear supernatant is incubated for one hour in a 37° C. incubator prior to the assay. The effect of these preparatory steps on milk xanthine oxidase was tested on 3 milk samples obtained from mice during lactation. "Milking" was accomplished as follows: the mouse was separated from its litter for twelve hours in order to allow the milk to accumulate, the hair was clipped around the nipples, under ether anæsthesia 1 ml. of Pitocin containing one international oxytocic unit was injected intraperitoneally and the tips of the nipples were cut off three minutes later. After starting the flow of milk by suction with a water pump, the milk flowed freely and could be collected by means of a pipette. Up to 1·5 ml. of milk could be obtained in this way. In each case, high speed centrifugation reduced the activity of the milk by 75–100% of the original value, while incubation hardly altered the enzyme activity (Table II). This is in contrast to the

TABLE II.—EFFECT OF INCUBATION AND CENTRIFUGATION UPON THE XANTHINE OXIDASE ACTIVITY OF BREAST TISSUE AND MOUSE MILK

Material	Centrifugation	Micromoles ($\times 10^{-5}$) of xanthine oxidized/min./mg. wet weight: No incubation	Incubation
Mammary tissue	600 × *g*; 10 min.	21·3	49·8
	20,000 × *g*; 30 min.	—	47·7
Milk	None	17·5	18·6
	20,000 × *g*; 30 min.	—	0·0

tissue homogenate where enzyme activity is increased by incubation but not materially altered by centrifugation.

This difference in response to the centrifugation neatly eliminated the so-called "milk error" usually present when experimenting with mammary tissue during lactation. However, since it could still be possible that the milk in the presence of tissue acts differently from milk alone, the experiment listed in Table III was performed. Breast tissue and mouse milk were

TABLE III.—XANTHINE OXIDASE ACTIVITY IN MIXTURES OF MAMMARY TISSUE AND MOUSE MILK AFTER CENTRIFUGATION AND INCUBATION

Preparation No.	Mammary tissue (g.)	Mouse Milk (g.)	Tissue concentration (%)	Micromoles ($\times 10^{-5}$) of xanthine oxidized/min./mg. wet weight	Enzyme activity as percentage of Preparation No. 1
1	0·3781	0·0	100·0	47·7	100·0
2	0·1441	0·0658	68·8	34·2	71·8
3	0·1009	0·1044	53·5	24·6	51·5
4	0·0550	0·1494	26·9	9·1	19·1
5	0·0	0·3712	0·0	0·0	0·0

mixed in varying ratios and a 1+9 homogenate prepared in pyrophosphate buffer (0·1 M, pH 8). The assays were performed in the usual manner after high-speed centrifugation and incubation of the material. In comparing the last column with the tissue concentrations it is evident that the entire xanthine oxidase activity in the tissue-milk mixture is accountable for in terms of the tissue enzyme alone.

The fact that the xanthine oxidase activity of mouse milk is sedimentable corroborates the finding of Morton (1954) that in cow's milk this enzyme is attached to lipoprotein particles which can be sedimented by centrifugation at 14,000 × *g*. Our own experiments have shown that in homogenates of mouse breast and liver and of rat liver almost all of the xanthine oxidase is recoverable from the supernatant fraction after high speed centrifugation (20,000 × *g*) and that no activity can be found in the particulate matter. Meikleham *et al.* (1951), Villela *et al.* (1955) and Morell (1955) have already reported that the xanthine oxidase from rat liver and the xanthine dehydrogenase from chicken liver are in the supernatant fraction after high speed centrifugation. It would be of interest to establish the point during milk formation and secretion at which the soluble tissue enzyme becomes a sedimentable component of milk.

Although it could be shown that the milk xanthine oxidase does not affect the determination of this enzyme in mammæ during lactation, the situation might be different in regard to the milk accumulating in the breasts prior to lactation. In order to test this possibility a mouse was "milked" at the beginning of parturition. This first milk, or colostrum, however, was similar to the milk obtained at the height of lactation: centrifugation caused a virtual disappearance of the xanthine oxidase activity of the colostrum. One possible explanation, therefore, for the peak in xanthine oxidase activity preceding parturition is that it represents an accumulation of intracellular enzyme proper ready to be incorporated into milk enzyme. The disappearance of this peak during lactation would thus reflect the high rate of milk production and secretion.

V. *Xanthine oxidase activity in liver.*—Pregnancy and lactation are associated with profound hormonal and metabolic changes. It was therefore of interest to compare the liver with the mammary tissue in regard to xanthine oxidase since this enzyme in the rat liver is very sensitive to fluctuations in protein metabolism (Westerfeld and Richert, 1950). The average level of xanthine oxidase activity per nucleus did not vary significantly throughout the reproductive cycle and when compared to the livers from virgin mice. It was seen that, while the enzyme activity per cell is about 60% greater in the liver than in the breast during the virgin state, the enzyme activity becomes three to five times greater in the breast than in the liver during late pregnancy and lactation. There is a small but statistically significant increase in the total number of liver cells during pregnancy, lactation and the observed period after weaning.

B. Levels of Xanthine Oxidase Activity during Abnormal Growth

The increase in the number of mammary cells leading to a functioning gland is associated with an increase in xanthine oxidase activity per cell. Two questions arise from this observation: (1) What are the levels of xanthine oxidase activity in tumours as compared to the tissue of origin? (2) What happens to the enzyme during the growth of the tumour?

The data reported in the following section have been obtained in an attempt to answer these questions.

I. *Xanthine oxidase activity in spontaneous breast tumour.*—The design of this experiment entailed a comparison of xanthine oxidase activity in mammary tumour and in mammary tissue from cancer-susceptible and cancer-resistant mice of the same strain. Inbred mice of the C— strain constituted the cancer-resistant group. These mice do not possess the milk agent (Bittner factor) and develop mammary tumours only rarely even after many pregnancies. Cancer-susceptibility was imparted to the C— strain by foster-nursing on C_3H mice, thus incorporating the milk agent. Mice of this highly-inbred sub-line, here called C+, rarely develop mammary tumour if they remain virgins, but will have a 100% tumour incidence at an average age of 7 months if force-bred. The material for the tumour series was obtained from these C+ mice.

The results are summarized in Fig. 4. The differences in the average levels of enzyme activity per cell are highly significant, $P = < 0{\cdot}001$ when comparing groups A and C to B. Relative to the enzyme activity of breasts from C— mice, the activity in breasts from C+ mice is 57·7% and in tumours 24·9%. It should be stressed that the breasts in group B derive from animals that had no tumour and would as a rule not develop such. The difference in xanthine oxidase activity in the mammæ of C— and C+ mice can therefore be related to the absence or presence of the milk agent in the cytoplasm and not to the genetic constitution or the actual presence of a tumour. The enzyme activity in the normal parts of the breasts from mated C+ mice with tumours is similar to that in breasts of C+ virgin mice.

In contrast to the enzyme in the breast, the xanthine oxidase activity in livers of C— and C+ mice does not differ materially. This is in line with the observation that the liver contains relatively small amounts of milk agent. However, Figge and Strong (1941) found a marked difference in xanthine oxidase activity of livers from mice with a high and mice with a low incidence of breast tumour, the C_3H and JK strains respectively. But the desi of

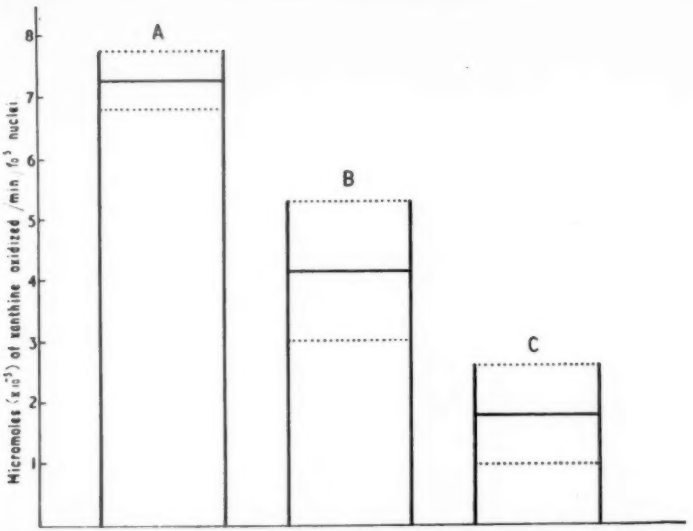

FIG. 4.—Xanthine oxidase activity during carcinogenesis in mouse breast. A, Virgin breast from low tumour strain (C−) without milk factor; 25 animals. B, Virgin breast from high tumour strain (C+) with milk factor; 50 animals free of tumours. C, Spontaneous mammary tumour from mated (C+) mice; 24 animals. (Dotted line indicates ± S.D.)

their experiment makes it difficult to decide whether the difference in enzyme activity reflects a difference in cancer-susceptibility or in genetic constitution.

The tumours used ranged from 0·3 grams to 7·0 grams and could be divided into solid, firm grey and soft, hæmorrhagic purplish tumours. Histologically, they were all adenocarcinomas but showed varying degrees of dedifferentiation. For purposes of the assay necrotic material was avoided. There was no significant difference in the enzyme activity of the different kinds of tumours. Each average mammary cancer cell possesses one-fourth the xanthine oxidase activity contained in the average normal mammary cell and one-half the activity present in a precancerous breast cell (a cell infected with the milk agent).

Since there is no statistically significant difference in the cellularity of breasts from virgin mice of the C+ and C− strain, it is concluded that the xanthine oxidase activity is lowered in the precancerous state, whether expressed as enzyme concentration (activity per mg.) or as content (activity per cell).

II. *Xanthine oxidase activity in liver tumours.*—These experiments were performed in collaboration with Dr. E. Reid and the methods of producing liver tumours in rats by means of azo-dye are described by him (Reid and O'Neal, 1957). The data are presented in Fig. 5. Since nuclear counts were not performed in this series the enzyme activity is expressed per mg. of wet tissue. Because of the small number of observations a statistical analysis of the difference of the means was not performed, but the graph reveals no overlap of the individual values comprising each group.

There is good agreement between the observations here reported and those previously published involving different techniques of assay, different strains and different tissues. Westerfeld *et al.* (1950) have studied the xanthine oxidase activity in rat livers during carcinogenesis by measuring the consumption of oxygen and have reported a 50% decrease in enzyme activity per dry weight in tumour-free livers from rats receiving *p*-dimethylaminoazo-benzene for four weeks. Greenstein (1947) reported on the xanthine dehydrogenase activity, measured by reduction of methylene blue, in transplanted mouse and rat hepatomas as compared to the respective tissues of origin: of six different hepatomas, five had an enzyme activity per mg. nitrogen of $\frac{1}{2}$ to $\frac{1}{4}$ the level in normal liver.

Deficiency states in tissues from tumour-susceptible animals, in precancerous tissues or in fully developed tumours have been demonstrated repeatedly. Bittner found that the esterase level is lower in livers from cancer-susceptible than in livers from cancer-resistant mice. Weiler (1956) was able to show by an ingenious histo-serological technique the loss of a liver-specific antigen during azo-dye carcinogenesis. However, β-glucuronidase has a higher

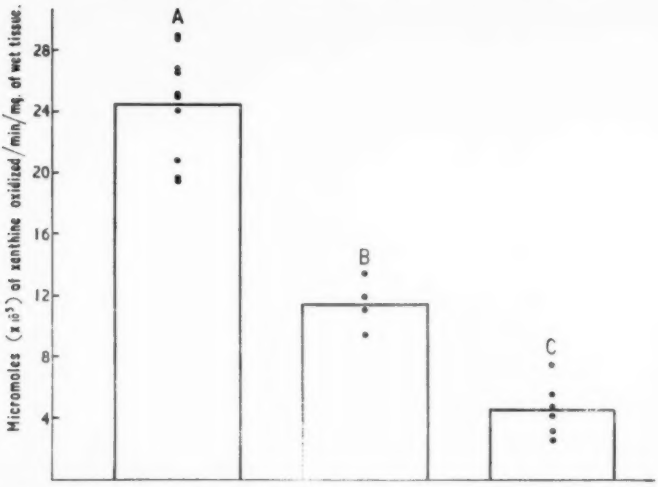

FIG. 5.—Xanthine oxidase activity during carcinogenesis in rat liver. A, Normal liver from rats on normal diet. B, Tumour-free liver from rats fed azo-dye for a short period. C, Liver tumour in rats fed azo-dye. (Dots indicate individual values.)

level in tumour than in the mother tissue; but here too the precancerous tissue has an intermediate level of enzyme activity. It would seem that changes during carcinogenesis are in the direction that leads to the ultimate state existing in the tumour.

III. *Growth and xanthine oxidase.*—The data of the enzyme activity in breast pads from pregnant mice and in spontaneous mammary tumours was expressed as a function of growth, that is, enzyme activity per cell was plotted against the fresh weight of the total tumour or total breast pads. While growth of the mammæ leading to the formation of a normally functioning tissue is associated with an ever-increasing level of enzyme activity per cell, no such gain in enzyme activity is present in the cells of growing mammary tumours.

Growth in the case of the tumour means no more than cell multiplication resulting in an increased tissue mass, whereas in the mammæ there is also a change in function besides the increase in cellularity. Since growth can proceed without an increase in xanthine oxidase activity per cell, as in the mammary tumour, or even in the virtual absence of this enzyme, as in embryonic tissue, the increase of this enzyme per cell in the mammæ is best related to their gain in specialized function preparatory to the secretion of a product so rich in this enzyme. Hence, if one assumes, as one should, I believe, that the cell of origin is the same for the lactating mammæ and the mammary cancer, the failure of the tumour to increase its level of enzyme activity is just another expression of the loss of specialized function of this dedifferentiated tissue.

Section of Orthopædics

President—E. STANLEY EVANS, C.B.E., F.R.C.S.

[*March* 23, 1957]

MEETING AT KING'S COLLEGE HOSPITAL, LONDON

117 CASES were shown demonstrating the following conditions:

High femoral osteotomy; Double hip operations; Median and ulnar palsy; Diffuse hæmangioma of leg; Unusual rheumatoid arthritis; Dysfunction of the first metatarso-phalangeal joint; Acute osteomyelitis; Lesions of the feet in diabetes; Idiopathic pes cavus; Leg lengthening; Congenital phocomelia; Late results of slipped upper femoral epiphysis; Fractures of the tibia; Monostotic fibrous dysplasia; Caffey's disease; Knock-knee following osteomyelitis of lower end of femur; Congenital bowing of leg; Arthroplasty of elbow; Pseudarthrosis of elbow; Acroparæsthesia treated by means of a splint; Talipes equino-cavus—metatarsal osteotomy; "Genuine" congenital dislocation of the hip.

The use and abuse of the "Resettlement Case Conference" was discussed on four particularly difficult medico-social problems with Dr. F. S. Cooksey.

After Demonstrations of pathological specimens (Professor H. A. Magnus) and Occupational Therapy appliances for disabled persons, the following papers were read:

Conservative Treatment of Carpal Tunnel Syndrome.—Dr. R. HIERONS.

Tendon Lesions in the Rheumatoid Hand.—Dr. D. A. BREWERTON.

Presentation of Group of Fractures of the Tibia.—Mr. R. H. FREEMAN.

Provision of Skin Cover.—Mr. F. T. MOORE.

Changing Patterns in Skeletal and Articular Tuberculosis

PRESIDENT'S ADDRESS

By E. STANLEY EVANS, C.B.E., F.R.C.S.

IN this brief survey of orthopædic tuberculosis I shall begin by referring to the changing patterns of skeletal and articular tuberculosis which are now chiefly of historical interest.

Motherby's New Medical Dictionary published in 1775 contains the classification of spina ventosa or caries of bone by Percivall Pott as hydrops articuli, fungous articuli and the enlargement of bone. Treatment was directed towards promoting the absorption of fluid by blisters, by inunction of mercury and antimony and sometimes with advantage following the electric shock. "The third type—enlargement of bone, is sometimes relieved by perforations made through the diseased parts to the marrow, but most frequently amputation is necessary. The friability of carious bones is much augmented by the acrimony of their humours and chiefly by their corrupted medullary oil. Chronic abscesses in the back and loins are generally of the strumous kind, the matter is usually deep seated and the bones are injured by it before a fluctuation can be discovered." I shall return to the problem of the abscess arising from bone and subsequently causing injury or spread of infection into healthy bone. Sea water was popular in the treatment of glandular swellings. It was known that scrofula (from Scrofa—a sow, because the disease occurs in swine) or the King's Evil which kings from Edward the Confessor onwards pretended to cure by the touch, could affect almost every part of the body and that the lymphatic vessels and glands were the immediate seat of the trouble. The fixed immovable white swellings of joints are compared with the strumous swellings of the neck.

Percivall Pott, one of the great surgeons of the oldest London hospital (still on its

original site) wrote a treatise in 1779 entitled "Remarks on that kind of palsy which is frequently found to accompany a curvature of the spine" and a specimen prepared by him to show the diseased vertebræ in such a case was placed in the museum of St. Bartholomew's Hospital. There was no better description of Pott's paraplegia until the outstanding papers in our time by Seddon and Butler and the recent excellent monograph by Seddon, Griffiths and Roaf.

The approach to the problems posed by the strumous disorders in the early part of the nineteenth century can perhaps best be gleaned from a perusal of the excellent lectures delivered by John Abernethy in the medical school at St. Bartholomew's Hospital which he founded. He paid great attention to his lectures and never forgot that a lecture is to be valued not only by what the lecturer puts into it, but by what the hearer can carry away from it. The *Lancet* of 1824 embodies his course of surgical lectures (in which he frequently refers to his debt to the immortal John Hunter) which he delivered to a very numerous and highly respectable class. Abernethy embellished his lectures with graphic descriptions of the patients he attended and perhaps I may be permitted to quote one case. He records: "I was requested to see a young lady, a long way in the country, even in Wales and in a very remote part of the principality too, who had a lumbar abscess. I went and I found that there was a large collection of matter in the fore-part of the thigh, that the spine was much distorted, the countenance flushed, and the constitution altogether in a very irritable state."

As she was then amongst the mountains of Wales Abernethy advised that nothing need be done, but that she be kept in a state of quietude, that some counter-irritation should be made and that the state of the digestive organs be attended to. The young lady continued to get stronger day by day and the disease gradually subsided under this excellent general and local conservative treatment. After about a year, and without consulting Abernethy, a person was sent down from London to fit a machine and the father wrote in eulogistic terms of the spinal stays, which by screwing it up could raise his daughter in height two inches. Abernethy replied: "In the name of common sense, Sir, only consider what a state the vertebral column must be in which will admit of such elongation by any artificial means." He advised that they should lay the machine aside and return to the former plan. Some six years later the young lady was cured of her phthisical complaint in Bristol after taking a course of muriate of lime and Abernethy was aggrieved to find the excellent state of her spine was ultimately attributed to the muriate of lime and not to the constitutional treatment he had advocated.

In dealing with a lumbar abscess connected with a diseased state of the vertebral column he insisted that the patient should be required to be in bed and not allow the diseased parts to move about, and added that the abscesses frequently subsided and diminished in size if attention is paid to the state of the general health. If necessary he lanced the abscess in order "that it never might be opened", and he tried to prevent foul air entering the abscess after puncture by pressure on the abscess and by applying lint and adhesive plaster. He knew nothing of the bacteriology of secondary infection, but his experience had taught him that the abscess should not be allowed to drain openly. After puncturing the abscess two or three times the patient fancies he is almost well, but Abernethy is mindful of the dangers and advises continued rest in bed and "if he could be sent into the country it would do him much good".

He describes how on one occasion he let out four ale-house quarts of matter, "for seeing an ale-house quart in the room I had the curiosity to measure it". He continues: "Now if you have any inflammation occurring in the cyst of an abscess equal to the surface of a gallon measure it must be productive of more considerable effect on the constitution than when it occurs on a surface equal to that of a four ounce measure." I wonder if Abernethy was right in his belief that tuberculous pus or material is harmful to a patient who by its production responds to the chronic infection we know to be present. A patient came to the out-patient department of St. Bartholomew's about one hundred years after Abernethy gave his lecture. This bonny, rosy-cheeked, fair-haired girl of 17 with sad and wistful blue eyes was accompanied by her worried but indignant mother who thought her daughter was pregnant. The girl had complained of a little backache for two or three months, which her mother felt was a just retribution for her daughter's misbehaviour. Apart from the very large belly, which might have housed twins and hydramnios, there was no evidence of pregnancy and the patient was demonstrated to the Fellowship class and others as having a large parovarian cyst, and this being a gynæcological condition, my chief—a general surgeon—was eager to perform the operation of removal himself. Pre-operative general examination revealed a certain stiffness of the back probably due, it was felt, to the impediment of the enormous abdomen, but a check X-ray revealed small areas of destruction in the contiguous parts of D.V. 12 and L.V.1, with a diminished disc space, but virtually no collapse or kyphosis. My chief decided to remove the large cyst before sending the girl away for treatment for the tuberculous spine. He needed little encouragement to insert a needle first and into the syringe as aspirated typical tuberculous material. He left me to carry on and I shall never forget

aspirating and filling the 20 c.c. syringe several hundred times in two and a half hours. We had no ale-house quart pot available, but we had the curiosity to measure the four gallons of tuberculous material removed. When we had finished there was a typical large psoas abscess on the opposite side. That was in 1928 and since then I have never seen a tuberculous abscess approaching this size. This was an example of a relatively early tuberculous spine with little destruction and an enormous abscess with practically no constitutional disturbance. Why is it that we find some patients with extensive spinal caries and no discernible or small abscesses and others with minimal lesions and large abscesses? Can it be due to anything other than the varying individual response to chronic infection? I have dallied at some length with Abernethy and his methods, because it was nearly a hundred years before the conservative treatment of surgical tuberculosis again became widely advocated and practised.

At about the same time in France, Dupuytren expressed similar views on the chronic abscess when he stated: "There was never any satisfactory relation between the amount of disease affecting the bone in caries of the spine and the extent of the external disorder, for when caries affects a vertebra, the suppuration which is at first confined to the affected bone gradually extends itself." He described the case of a woman who at autopsy was found to have an abscess with complete destruction of the body of the eleventh dorsal vertebra with the bodies of D.V.10 and 12 partially denuded and the seat of superficial caries.

Towards the latter part of the century operations on tuberculous joints became all too common with disastrous results. Billroth in 1878 stated: "During the last ten years I have felt less disposed towards conservative operations for caries and should have amputated far more frequently if the patients or their friends had not objected. However, the antiseptic method has one advantage, namely that in operations such as excision of the hip the immediate results after operation are much better than they used to be under the old systems. Still, treat these wounds as you will, sinuses will be left and the ultimate results will be almost as unsatisfactory as they used to be. The treatment of this terrible affection—vertebral caries—consists principally in keeping the patient in a recumbent position and children are kept lying, generally in the prone position, but Thomas' splints are sometimes used." Billroth envisaged the possibility of attacking surgically the vertebral lesion. "Hitherto it has been found impracticable to extract large sequestra from the vertebral column. It might seem possible to make an incision on one side of the curvature and in this way to extract the sequestra and gouge away the carious parts, but the hæmorrhage cannot be readily controlled and the spinal cord will be exposed to injury. Yet with our advanced knowledge of the treatment of wounds and in face of the unfavourable prognosis I should not blame any surgeon for making the attempt. I remember some years ago to have read something about an operation of this kind which was performed in America but I do not recollect what became of the patient." It is clear that at that time Billroth was not aware of what might one day be achieved by Capener, Seddon, Wilkinson, Macrae and others.

Howard Marsh in 1889 delivered a Hunterian lecture on "Tuberculosis in Some of Its Surgical Aspects". He advocated treatment of surgical tuberculosis by means short of the excisions which were then of too frequent daily occurrence. At the Hip Hospital in Queen Square he advocated consistently the advantage of early and prolonged non-operative treatment and of traction for tuberculous disease of the hip and said: "The weight should be as small as is consistent with its purpose of relieving pain and preventing or removing distortion; so that it is desirable to diminish the amount as symptoms subside and not to continue to employ a heavy weight after it has become unnecessary to do so." However, generally, patients were allowed to go to the seaside wearing ambulant splints, suppuration was regarded as a normal and inevitable part of the disease, abscesses were opened and treated by poultices, amputations were common and the patients frequently died of amyloid disease. Those who survived had gross joint destruction with deformity, very limited joint movement, and great shortening of the affected limb.

In 1913 the *Practitioner* published a Symposium on Tuberculosis and the greatest discussion surrounded the use and abuse of tuberculin and of its potential value as a therapeutic agent. Pearce Gould stated "We may say that all cases of tuberculosis must be treated medically and that the need for medical measures is never more urgent than when a case requires some operative interference to complete the cure." He advocated surgical removal of tuberculous foci in bone which had not cleared up with general measures, but a sufficiently free opening must be made and failures would result from attempts to scrape away a large area of disease through a puncture—"it would be as sensible to ask a housemaid to clean out a room through the keyhole in the door!" Robert Jones in an invaluable contribution stressed the necessity for mechanical fixation. He wrote: "In recent years, I have on many occasions been called upon to deal with tuberculous disease of joints and of the spine, in cases in which an enthusiastic believer in the efficacy of tuberculin has entirely omitted any form of protective fixation, and it is therefore necessary to express my strong conviction that this is a serious error. The neglect of protective fixation is unfair to tuberculin treatment, for repeated injuries to the

diseased structures caused by movement delay, if they do not prevent, the beneficial action of the immunizing treatment." Robert Jones made no attempt to scrape out the tuberculous lesions "for I have too great a dread of the terrors of mixed infection and set excision of a joint for tuberculosis is unknown in my practice". Can we not to-day substitute for tuberculin, streptomycin, I.N.A.H. and other antibiotics and say with Robert Jones that the neglect of the protective fixation of tuberculous joints is unfair to treatment by antibiotics?

I need not dwell on the patterns of non-pulmonary tuberculosis nor on the general and mechanical methods of treatment elaborated during the first half of this century for they are well known, and if I pay tribute to the outstanding work of Robert Jones, Gauvain, Pugh, Girdlestone and Brittain in this country, this is not to say that I do not fully appreciate the considerable contributions made by many others. The orthopædic lesion secondary to a primary focus was regarded as a local manifestation of a general bacillæmic disease and demanded both general and local conservative treatment. Patients remained for long periods in special hospitals and when the lesion became quiescent protective surgery was frequently performed. During the past ten years, the outlook and patterns have changed materially with the advent of antibiotics. Penicillin was of some value in controlling secondary infection to a large extent, but it was streptomycin that made a direct assault on the local disease safe and possible. The emergence of resistant strains of tubercle bacilli was avoided to a large extent by a combination of streptomycin, PAS and I.N.A.H., and it is a moot point as to whether or not this therapy should be reserved for critical phases and episodes in the natural history of the disease.

Value of Antibiotics

(1) During the bacillæmic stage to assist the patient in coping with the general infection and thereby avoiding multiple tuberculous lesions.

(2) The centre of a tuberculous lesion may be caseous and, as the result of tuberculous endarteritis, have no blood supply. Systemic antibiotics cannot reach the core of disease, but in the surrounding hyperæmic zone can contain the local disease and limit the local spread of infection and destruction.

(3) Long-standing sinuses may heal soundly following systemic administration and local instillations.

(4) Direct attack on the tuberculous lesion is now possible under the antibiotic umbrella and the dread of dissemination is no longer a haunting spectre.

(5) The length of treatment has been greatly curtailed and is generally half or even less of what it was before. Patients are in and out of hospital far more quickly, the turnover of patients is more rapid and the number of in-patients and the waiting lists have fallen dramatically.

LORD MAYOR TRELOAR ORTHOPÆDIC HOSPITAL

STATISTICS ON TUBERCULOSIS

1932: Twenty-five years ago over 50% of patients were tuberculous—
Admitted 26 spines, 66 hips, 14 knees and 50 other tuberculous lesions.

1937: Twenty years ago about 50% of patients were tuberculous—
Admitted 30 spines, 50 hips, 10 knees and 80 other tuberculous lesions.

1957: *February*. 25 children with non-pulmonary tuberculosis.
" 20 adults " "
Waiting list of 5 patients.

Surgery of the Local Lesion

It is now possible to operate on the infected bone or joint without being unduly concerned about the tuberculous nature of the infection and for example dealing directly with caries of the vertebral bodies, as envisaged by Billroth, has become a reality as the result of strict aseptic technique, superb anæsthesia and antibiotic cover. Tuberculous cavities are curetted, sequestra removed and gross tuberculous lesions can be excised, as in partial synovectomy of the hip. Antibiotics can be applied locally to the exposed tuberculous lesion, and systemic antibiotics become more effective as the result of the reactive hyperæmia following the surgical assault. The processes of repair can be enhanced by the insertion of bone chips ground in streptomycin into tuberculous cavities or denuded joints. Temporary internal fixation of joints by nails can if desired be used with impunity. It is not suggested that radical and difficult surgical procedures should be undertaken lightly, but that surgery has been made safe by antibiotics, by blood transfusion, by expert anæsthesia, and above all by a rigid compliance with the long-established principles of a sound aseptic technique.

The management of the local tuberculous lesion may thus be summarized:

Tuberculosis of the Hip

(1) General constitutional treatment of the patient with bed rest.
(2) Local treatment by immobilization and traction.
(3) Confirmation of diagnosis by biopsy.
(4) Antibiotic therapy—adequate and prolonged.
(5) Partial synovectomy where indicated and local antibiotics. The ideal end-result is a hip with a good and safe range of movement.
(6) Curettage of the juxta- but extra-articular lesion and insertion of bone chips.
(7) Displacement trochanteric osteotomy if response to therapy is inadequate.
(8) Arthrodesis when joint movement is inadequate and not safe. When joint destruction is gross, the tuberculous debris may be removed, iliac bone chips and graft inserted and temporary fixation secured by the insertion of a Smith-Petersen arthrodesis nail. Otherwise extra-articular ischio-femoral arthrodesis using the technique described by Foley. Intra-articular arthrodesis is no more difficult or dangerous than it is in the tuberculous knee.
(9) If the great trochanter is involved, excision of the trochanter and the overlying abscess.

Tuberculosis of the Spine

(1) General treatment and bed rest.
(2) Local immobilization and mechanical treatment.
(3) Confirmation of the diagnosis by Mantoux tests, the bacteriology of aspirated tuberculous material and sometimes by exploratory curettage.
(4) Systemic antibiotic therapy.
(5) In the quiescent stage when consolidated collapse has occurred, posterior spinal fusion if necessary, for example in the cervical spine.
(6) Aspiration of tuberculous abscesses where possible and repeated only as frequently as is necessary.
(7) Drainage and lavage of the perivertebral thoracic abscess. Macrae has stressed that this can only be done effectively by a bilateral approach and through-and-through irrigation. It has been suggested that this procedure may limit the spread of tuberculous disease to neighbouring vertebræ.
(8) Evacuation of tuberculous cavities in the vertebral bodies. Tomograms particularly in the cervico-dorsal region are invaluable in determining whether this procedure is desirable in the absence of paraplegia. In the mid-lumbar region the bodies can readily be exposed by an antero-lateral extra-peritoneal approach, tuberculous debris and the remains of any intervening disc are removed, healthy firm bone is exposed, and bone chips and streptomycin are inserted under compression and an anterior spinal fusion obtained.
(9) The management of Pott's paraplegia is adequately described in the excellent papers and monograph to which I have already referred.

Little need be said of the tuberculous lesions of other bones and joints. When gross destruction occurs in the tuberculous shoulder, intra-articular arthrodesis by joint excision, insertion of bone chips and temporary fixation with a short Smith-Petersen nail may be performed.

In the tuberculous knee a good range of movement may result with or without synovectomy, but if gross destruction is present compression arthrodesis is indicated.

Satisfactory results may be obtained in the tuberculous tarsus, by curettage and excision with the insertion of bone chips.

Relative Merits of Surgery and Antibiotics

(1) Radical operative measures have followed so closely on the advent of antibiotics that it is difficult to assess the value of each. As patients with almost identical lesions differ in their response, it is no answer to treat one patient by antibiotics alone and the next with antibiotics and surgery. However, so far as possible the alternatives should be used on like and strictly comparable cases and not indiscriminately on alternate patients.

(2) Antibiotics may be used without surgery in the hyperæmic lesions, and if surgery is employed its value lies largely in improving the blood supply to the affected part.

(3) Does the perivertebral abscess cause spread of tuberculous disease to neighbouring vertebral bodies or are the radiographic changes seen consistent with the results of intermittent mechanical pressure seen in the aneurysm phenomenon? One or more vertebræ are involved initially due to hæmatogenous or bacillæmic infection. When several contiguous vertebræ become involved, resulting in due course in a severe rounded kyphos, is involvement due to further hæmatogenous infection or to involvement because of the stripping effect of the abscess? Are all the vertebræ showing radiological erosion tuberculous or do some exhibit the aneurysm phenomenon? Does widespread involvement occur without the presence of an obvious abscess? If as is probable the perivertebral thoracic abscess can infect other vertebræ it should be evacuated and irrigated, but does this procedure

prevent an abscess reforming? In the presence of active tuberculous disease is not an abscess evidence of satisfactory tissue reaction? However, whatever its precise pathological effect, I think I am persuaded that the tense thoracic perivertebral abscess should be drained, even in the absence of paraplegia, in order to limit the spread of pathological and radiological changes.

(4) Tuberculous cavities in bone if accessible should be evacuated and the healing process should usually be assisted by the insertion of bone chips.

(5) The only safe end-results of tuberculous joints are freely movable joints or those in which there is sound bony ankylosis.

The Future

(1) In the large cities bovine tuberculosis has been largely eradicated as the result of the production of safe milk.

(2) Mass radiography is resulting in the earlier discovery of patients with open lesions, who are treated more radically, so that the sum total of infective persons is becoming far less in this country if not globally. Sanatoria have empty beds and waiting lists are almost non-existent.

(3) BCG inoculations will protect susceptibles and thereby diminish still further the potential transmitters of disease.

(4) The value of PAS, I.N.A.H. and of streptomycin and its derivatives and associates is outstanding. The danger lies in the emergence of resistant strains and instances have been reported of patients who when discovered initially are resistant to some of the therapeutic agents if not to all. The question must be posed: Should antibiotics be administered to suspected cases without biopsy and adequately and indiscriminately to all proven cases or should they be reserved for critical periods and phases in the natural history of the disease, e.g. in the bacillæmic stage, for operative cases, and for generalized miliary tuberculosis? The present trend to curtail the dose and continue for many months or for a year or longer may prove satisfactory.

(5) The principles of treatment learned and practised laboriously over the years must not be forgotten. General conservative treatment is more necessary now than ever in the past and combined with local treatment is more likely to produce satisfactory end-results. Although the length of hospital treatment is now largely curtailed the need for specialist long-stay hospitals is greater than ever.

(6) Is it too much to hope and expect that non-respiratory tuberculosis will in the foreseeable future become as uncommon in its devastating effects as rickets, chronic osteomyelitis and the gumma?

(7) Historical surveys reveal to us the apparent progress that has been made in the past, but also serve as a reminder of our limitations and as a guide to the future. The historian a thousand years hence will regard our knowledge and practice of orthopædics as very primitive and incomplete. Preventive medicine may be such that orthopædic surgery as we know it to-day may not exist. Crippling diseases may be stamped out, congenital defects and deformities may be preventable and the immediate treatment of accidents and injuries may be so good that subsequent orthopædic care will be unnecessary.

[*June* 15, 1957]

THE Summer Meeting of the Section of Orthopædics took place at Lord Mayor Treloar College, Near Alton, and afterwards at Lord Mayor Treloar Hospital.

Cases were shown and the following papers were read:

The Treatment of the Cavus Foot by Flexor to Extensor Toe Tendon Transplants Combined with other Procedures.—Sq. Ldr. R. W. POVEY.

Dislocation of the Patella and Its Relation to Chondromalacia Patellæ.—Mr. H. H. LANGSTON.

Review of Cases of Genu Valgum Treated by Stapling.—Mr. J. D. WILSON.

Some Observations on the Mechanical Problems of the Artificial Hip.—Mr. E. H. J. SMITH.

Operative Treatment of the Tuberculous Cervical and Dorsal Spine.—Mr. D. E. MACRAE.

Some Radiological Problems from the Middle East.—Dr. R. O. MURRAY.

DISCUSSION: EYES IN GENERAL PRACTICE

Dr. John Fry: A general practitioner finds considerable difficulty in the interpretation of the many intricacies concerning diseases of the eyes and he constantly looks to his consultant colleagues for their help and advice.

These difficulties appear to arise from a lack of adequate teaching on the subject, the only teaching given being a few sessions during the already overcrowded syllabus of the undergraduate; from a lack of material in practice on which to develop one's experience, for eye conditions account for only 4–5% of all work in general practice and the vast majority of these are relatively minor and self-curing conditions. Until recently there has been a sad lack of literature on the subject specifically for the general practitioner. We now have available two excellent books by Perkins and Hansell (1957) and Jackson (1957).

The importance of eye disorders need hardly be stressed both as local affections and as part of a more generalized disease process as in hypertension, diabetes and renal disease. The family doctor should endeavour to acquire experience and proficiency in the standard methods of diagnosis and be able to apply to his findings a basic knowledge of pathology in order to provide a correct diagnosis and suitable treatment.

By way of introduction I shall discuss the proportion and types of eye disorders seen in a typical suburban practice in S.E. London over a period of one year (Table I).

TABLE I.—EYE CONDITIONS IN A PRACTICE IN ONE YEAR

Condition	No.	% of total number of patients	Referred to hospital
Acute infection	136	68%	4
Accident and foreign body	30	15%	2
Inflammations	6	3%	3
Squint	14	7%	14
Others	14	7%	10
	200	100%	33 (16·5%)

These patients suffering from disorders of the eyes represent around 5% of all patients seen during the year. In addition, there were some 50 patients who required certification for the purposes of refraction.

By far the most frequent type of eye condition met with in general practice is some superficial *acute infection* such as conjunctivitis, blepharitis or styes—accounting for 68% of the total. Management rarely presents any major problems since almost all will settle spontaneously without treatment. Antibiotics, either local or systemic, are required in only a minority of cases.

In my suburban practice *injuries* to the eyes accounted for only 15% of all the eye disorders—this figure will probably be greater in industrial areas.

Inflammations of the uveal tract, so common in hospital practice were responsible for only 3% of my cases. Children with *squints* were seen almost twice as frequently.

Others were a mixed group with various degenerative conditions predominating.

In Table I can be seen the proportion of cases referred to the consultant. The family

doctor is able to cope with over 80% of all the eye conditions that he meets and those that he does have to refer do not represent the most common groups.

If the lack of confidence of the family doctor in dealing adequately and correctly with eye disorders is to be remedied steps should be taken to organize and make available suitable simple postgraduate courses designed specifically for the G.P. dealing with such subjects as principles of pathology, diagnostic methods in general practice, principles of therapy and especially the use of antibiotics and the cortico-steroids in eye disorders.

PERKINS, E. S., and HANSELL, P. (1957) An Atlas of Diseases of the Eye. London.
JACKSON, C. R. S. (1957) The Eye in General Practice. London.

Mr. Joseph Minton:

The most common eye conditions referred nowadays by general practitioners to the ophthalmic departments are: (1) Inflammations of the cornea. (2) Episcleritis. (3) Iritis and iridocyclitis.

Since the introduction of sulphonamides and antibiotics conjunctivitis has usually been successfully treated by the general practitioner. Complications following severe conjunctivitis, such as corneal ulcers and superficial punctate keratitis, are often sent for further treatment to the ophthalmologists.

FIG. 1.

FIG. 2.

FIG. 1.—*Herpes Zoster Ophthalmicus.*—This boy, aged 10, was suffering from acute left herpes zoster ophthalmicus with the usual involvement of the left cornea.

Hydrocortisone with chloramphenicol eye drops and ointment were used as soon as the condition was diagnosed. The cornea cleared within a few weeks, leaving no scarring.

The boy now has good vision in the left eye.

FIG. 2.—*Episcleritis.*—This patient is suffering from episcleritis of the temporal part of the right eye. The patient was complaining of severe pain of the right eye. The œdematous patch on the temporal side of the cornea was red.

Hydrocortisone drops and ointment were prescribed and the eye improved two weeks after the commencement of treatment. The patient is advised to repeat the same treatment if the inflammation recurs, which is often the case.

Cortisone, hydrocortisone and other allied anti-inflammatory drugs have been of the greatest value in the treatment of inflammatory eye diseases. The cases in which cortisone or hydrocortisone should be used are:

(1) Episcleritis.
(2) Phlyctenular keratitis and keratoconjunctivitis.
(3) Superficial and interstitial keratitis.
(4) Rosacea keratitis.
(5) Keratitis following herpes zoster ophthalmicus.
(6) Keratoconjunctivitis sicca. (This condition is often associated with rheumatoid arthritis and erythema multiforme.)
(7) Iritis and iridocyclitis.
(8) Choroiditis.

Iritis and iridocyclitis should be treated with cortisone or hydrocortisone at the earliest stage of the disease. As soon as the diagnosis of iritis is made, the patient should be given a subconjunctival injection of hydrocortisone (½ c.c.) combined with atropine. The patient is advised to use hydrocortisone eye drops three times daily and hydrocortisone eye ointment twice daily. It is necessary to continue with these preparations for a long period. The treatment should not be stopped before all the signs of inflammation (iritis and iridocyclitis or keratitis) disappear.

Choroiditis (posterior uveitis) rarely responds to cortisone or hydrocortisone eye drops. In these cases systemic ACTH should be given for at least two or three weeks. Systemic administration of prednisolone (delta-hydrocortisone) in a dose of three 5 mg. tablets daily is nowadays used with great success in the treatment of choroiditis and iridocyclitis. To offset potassium loss, which is usual during the treatment with cortisone or its derivatives, the patient should also take 3·0 grams of potassium chloride daily. The blood pressure is checked twice weekly and the urine should be examined twice weekly to exclude glycosuria. The patient is advised to take a salt-free, high protein diet, and to reduce his fluid intake. The quantity of prednisolone is gradually reduced. In cases of choroiditis or severe iridocyclitis at least six weeks' treatment with prednisolone is necessary.

Herpes Zoster Ophthalmicus is often associated with corneal complications (keratitis with loss of sensation of the cornea). In my experience the early administration of hydrocortisone drops and ointment combined with chloramphenicol or neomycin for at least six to twelve weeks prevents severe corneal complications. Systemic administration of penicillin is most helpful because it deals with the secondary infection of the herpes vesicles.

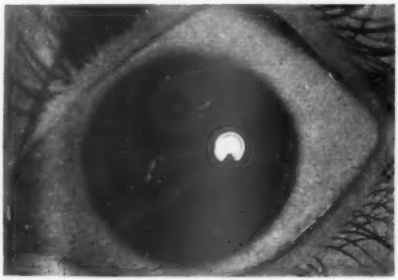

FIG. 3.

FIG. 4.

FIG. 3.—*Uveitis and Keratitis of Left Eye.*—This patient, aged 11, is suffering from uveitis (iridocyclitis and choroiditis) of both eyes associated with Still's disease. Seven years ago she developed uveitis of the right eye. Local treatment with cortisone (subconjunctival injections and drops and ointment) did not improve the vision of the right eye. She can only see shadows of large objects with this eye.

Two years ago she developed uveitis of the left eye which caused loss of vision. She was then treated with systemic ACTH and the vision of the left eye improved to 6/12.

A year ago she developed Still's disease (juvenile rheumatoid arthritis) which again caused acute uveitis of the left eye with loss of vision. Since October 1956 she has been treated with deltahydrocortisone tablets (Prednisolone). This treatment again restored the vision of the left eye to 6/18. Her eyes are now not inflamed. She is still having two Prednisolone tablets daily.

FIG. 4.—*Acute Choroiditis of Right Eye* (*Retinal Photograph*).—This patient, aged 32, was suffering from acute choroiditis of the right eye two years ago. All investigations were negative. He was treated as an in-patient at the Hampstead General Hospital.

Intramuscular injections of ACTH gel 60 units daily were administered for three weeks. The vision of the right eye, which before treatment was very poor (6/36), improved rapidly to 6/6. Exudates disappeared. Vision normal within three weeks. Patient seen May 1957 when no scarring or pigmentary changes could be found in the retina.

Mr. [illegible] A. Williamson-Noble:

Much can be learnt in General Practice by simple methods of examining the eyes.

(1) *External examination.*—Direct the patient to look up, evert the lower lid by pulling it down and examine its inner surface for evidence of conjunctivitis. With the lid still in this position, the inferior lacrimal punctum will be exposed and pressure over the lacrimal sac will cause pus or mucus to escape if infection is present. The sac lies deep to the internal

palpebral ligament and so can easily be located. The upper lid can then be everted by one of the usual methods if a foreign body is suspected and a rough estimate made of the intra-ocular pressure by palpating the globe through the uneverted lid with the index finger of each hand, the middle fingers resting on the patient's forehead.

With the patient looking straight ahead, pupil reactions and ocular movements can be tested. A good idea can be obtained of the integrity or otherwise, of the corneal surface by observing the reflection in it of a window as the patient looks in various directions and noting whether there is any distortion. If uniocular conjunctivitis should be found, a foreign body, misplaced lashes, an inturned lower lid or lacrimal sac may be the cause.

(2) *Functional examination.*—Subnormal visual acuity. If the patient can see further down the test card when looking through a pinhole in a piece of cardboard, an error of refraction can be held partly, if not wholly, responsible.

Visual field. Its extent can be estimated by the confrontation method. In this the examiner stands opposite the patient and directs her to cover say her right eye and look with her left into his right eye. He can then compare her field with his own by bringing in a small white object from the periphery. A white-headed hat-pin is probably the best to use, but failing this, a piece of white paper $\frac{1}{2}$ in. square, impaled between the points of the nib of a pen can be used. The target should be held so that it is the first thing to come into view and is equidistant from patient and examiner.

For central field defects, produced say by some retinal disturbance, Amsler's chart, consisting of squared paper printed in white on black is invaluable; distortion or absence of some of the squares being noted in cases of disease (Neame and Williamson-Noble, 1956).

(3) *Ophthalmoscopy.*—It is a good thing to start with a +12 lens in the sight hole, gradually decreasing its strength until the fundus is visible. In this way, opacities in the cornea (keratic precipitates) lens and vitreous can be detected. In the case of patients with high myopia or astigmatism the fundus is seen more clearly if the patients wear their glasses, tilting them forward slightly to displace the reflection of the ophthalmoscope light.

Much more can be seen through a dilated pupil. If the examiner is unwilling to take the remote risk of precipitating glaucoma by using a drop of homatropine and cocaine, quite good dilatation can occur about half an hour after instillation of two drops of 4% cocaine hydrochloride with a five minutes interval between them. Although diagnosis of eye disease is the more important part of general practice and in this respect, the careful taking of a history can be invaluable, there are at least two emergencies whose treatment should be mentioned.

The first is sudden loss of vision in one eye. The majority of such cases are due to obstruction of the central retinal artery and can be diagnosed by the ophthalmoscope. If seen soon after onset, firm pressure on the eyeball with the fingers over the closed lids for five seconds followed by sudden release, may result in displacement of the clot or embolus from the main artery into one of its branches. The manœuvre should be repeated every ten or fifteen seconds for at least thirty minutes if improvement in vision does not occur before this.

The second is acute glaucoma. In this, a drop of oily eserine 1% should be instilled into the eye every five minutes for two to four hours and then continued four hourly. This should be accompanied by oral administration of diamox 500 mg. followed by 250 mg. four hourly for twenty-four hours and then eight-hourly.

DISCUSSION ON REFERRED PAIN

Dr. G. Weddell (Department of Anatomy, University of Oxford):

Referred Pain in Relation to the Mechanism of Common Sensibility

The neuro-anatomist is faced with unexpectedly difficult problems when he starts to analyse the structural arrangement of the peripheral sensory nervous system in terms of common sensation. To determine, for instance, whether a particular nerve terminal is related to a particular sensation such as pain, appears to be a straightforward question to which it should be possible either to give or to find an answer. But this is not so, for the word pain has many connotations. This constitutes a serious dilemma, for the framework of terminological definition within which the academic neurologist tries to work is quite different from that restricting the clinician. The clinician must necessarily assume a set of definitions which are far less stringent than those employed by the academic neurologist for he has to analyse the symptoms reported by patients.

Advancement of knowledge, however, must ultimately depend upon a convergence, not further divergence, between these two extremes.

When I use the word "pain" in this discussion, I mean the sensations reported by healthy resting subjects when their skin is either severely crushed or burnt. Further I would accept the sensations reported by patients either during an attack of renal colic or following a movement which tears and displaces part of the medial semilunar cartilage in a knee-joint as coming within my definition of pain. By contrast, I do not accept as pain (but only in relation to the restricted definition I have adopted) a sensation reported as agony but engendered solely by grief. By this I do *not* mean that I disbelieve what the patient says but that, for the purposes of this discussion, I do not accept such complaints as coming within my definition of the term "pain", although I am only too well aware that grief may modify the sensations evoked by physical stimuli which are not usually reported as pain.

Having defined pain, I, in the role of a neuro-anatomist, must first ask myself whether or not there is evidence that pain is subserved by a specific set of peripheral sensory nerves and terminals which, in turn, come into relationship with specific neurons and tend to be segregated in specific pathways within the central nervous system. This is the commonly-accepted theory and there are some facts which can be cited in its support. For instance, reports of pain in the hands cannot be evoked by any means whatever from certain patients known to be suffering from syringomyelia; the same is true for the leg following a successful antero-lateral cordotomy. Yet, in both cases the patients usually report that touch sensibility from the affected parts is unimpaired. Observations of the effect on sensibility of infiltrating tissues, in particular skin, with local anæsthetics also seem to support the idea that there are specific pain nerves, for among other things, pain sensibility is apparently abolished before touch.

The facts I have just referred to, however, do no more than support the hypothesis that there are specific pain nerves. Recently a number of new observations have been reported which suggest that this may not be the case. For instance, Sinclair *et al.* (1952), Hagen *et al.* (1953), Weddell, Palmer and Pallie (1955) and Dastur (1955) have shown that in hairy skin which covers by far the greater part of the body, there are no complex circumscribed nerve endings, such as Meissner corpuscles, Krause end-bulbs and so forth. The nerves either terminate in a highly complicated manner in relation to hairs, or in the form of widespread arborizations of fine, freely-ending filaments, which interweave and overlap with one another, i.e. so-called free nerve endings. This observation alone destroys von Frey's theory that the primary modalities of common sensation, i.e. touch, warmth, cold and pain, are each subserved by morphologically specific nerve terminals, at least as regards hairy skin. In hairy skin, free nerve endings must subserve the modes of warmth and cold, for the terminals ending in relation to the hairs do not discharge when the skin is either warmed or cooled. It is, of course, generally accepted that they subserve pain. It can nevertheless be argued that the free nerve endings, if not morphologically specific, are physiologically specific. The evidence in favour of this view (Zotterman, 1953), although limited and of an indirect nature, cannot be disregarded. But the evidence against it is increasing in amount, it is derived from a number of different sources and the new theory which emerges provides a useful and satisfying working hypothesis. None of the evidence is direct, however, and the theory is still, scientifically speaking, just a good idea.

The evidence against the theory that there are specific pain nerves is both of an anatomical and physiological nature and I shall try to summarize it as briefly and succinctly as possible. It has been shown by Lele (1954) that reports of warmth and cold are never evoked when fine quartz[1] needles are inserted through the skin, although reports of touch, prick, itch and tickle were aroused from every subject in due course. This alone suggests that the mechanism of thermal sensibility is more complex than has been suggested. Further, Lele *et al.* (1954) have shown that reports of warmth and cold are dependent upon the transfer of heat to and from the skin respectively; they are not related to the absolute temperature of the skin. Together, these observations suggest that thermal sensibility is in some way connected with the *pattern* of the discharge evoked from the skin and not just due to a discharge from modality specific endings. Another series of observations, in this case quantitative and anatomical in nature, lends support to this idea. It has been shown that in the rabbit ear (qualitatively man parallels the rabbit) the hairs not only form a highly complex and continuously variable pattern but their mode of innervation is equally complex. The striking points which emerged were that every hair is multiple-innervated, being subserved by at least two dorsal root axons of different diameters. The average number subserving a single hair is around six and guard hairs may be subserved by as many as twenty. Moreover, there is no more than one dorsal root axon available for every 20 hairs and the hairs which it subserves may be scattered over a relatively large area. It has also been calculated that each and every dorsal root axon could be caused to discharge simultaneously if a selection of no more than one-quarter of the total number of hairs in the ear was stimulated (Weddell, Taylor and Williams, 1955).

These observations can only mean that messages which, for example, enable hairs to be accurately localized are, as it were, coded for transmission and reach the central nervous system as trains of spatially and temporally dispersed action potentials where they are presumably decoded. There can be no question of each hair having a private and exclusive line along which to pass messages centrally.

I believe that free nerve endings and the nerves subserving them in the skin are arranged in a similar kind of way and I shall now state the evidence in favour of this belief, leaving my readers to judge whether they will accept this new theory regarding the mechanism of pain.

In the first place, the number of sensory nerves subserving free nerve endings in the skin of the rabbit ear cannot be more than about 1,500 and, as regards axon diameter, the fibres are scattered in a random way in the nerve bundles at the base of the ear. This arrangement naturally suggested to me that information from free nerve endings is also coded for transmission to the central nervous system by way of a minimum number of parent axons. Unfortunately, we found it impossible with the methods at present at our disposal to analyse the matter any further in the rabbit ear.

After taking stock, we decided to approach the problem from a fresh angle. We asked ourselves where in man is there an area of integument subserved solely by free nerve endings and which, when appropriately stimulated, evokes reports referable to each of the four primary modes of common sensation? We soon remembered that it is generally agreed and that we had confirmed that the human cornea contains only free nerve endings; incidentally, it is also avascular and free from autonomic nerve fibres. At the same time, we also remembered that it is generally accepted that pain is the only sensation ever reported when the cornea is effectively stimulated. Nevertheless, we decided to reinvestigate this problem for from what we now knew about hairy skin, and from what we read in the literature concerning corneal sensibility, it seemed to us that this belief in its restricted nature was possibly not founded on a firm scientific basis.

Our suspicion proved correct for we have now been able to show that sensations in all four primary sensory modes can be evoked when the cornea is suitably stimulated (Lele and Weddell, 1956). Reports to the contrary we have been able to trace to the fact that few observers in their experiments used appropriate stimuli; for instance, the fact that reports of warmth did not follow stimulation of the cornea with horse hairs which had been dipped in hot water were considered to be conclusive. But hairs have no thermal capacity and could not have transferred heat to the cornea. By contrast, we found (among other things) that a copper rod of reasonable diameter heated to a temperature 1° C. above that of the surface of the cornea was invariably reported as being warm.

Having established that the cornea in respect of common sensibility behaves like the skin, clearly the next step was to record action potentials from single ciliary nerve fibres subserving the cornea, to determine the size and patterned relationship of the free nerve endings to one another and to determine whether individual endings were modality specific. In other words, if stimuli equivalent to those reported as touch, warmth, cold and pain evoked action potentials in specific groups of nerve fibres and not in others.

It has not so far proved possible for us to carry out such an experiment in man. For

[1]Fine quartz needles (20 μ) have a very low thermal capacity.

ately however, as far as we could see, the cornea is a tissue which does not differ fundamentally from species to species (Zander and Weddell, 1951). We therefore carried out the investigations which I have just outlined in the cat. The answer was unequivocal. The free nerve endings are arranged in a complex pattern and those derived from widely separated parent axons overlap and interweave extensively. Moreover, the number of parent axons which supply the cornea of the cat is less than 1,000. Finally, it is clear that free nerve terminals in the cat's cornea can all transduce more than one kind of stimulus. For instance, all of them transduced stimuli reported as either touch or pain when applied to the human cornea and all but two (in more than 200 which have been investigated) transduced stimuli of heat transfer in either direction; some, however, had a lower threshold for heat flux in a particular direction. The activity evoked by brushing, heat transfer and "injury" in the case of a particular ending were of different patterns and time courses but it was not possible to distinguish any significant difference in the case of positive ("warmth") and negative ("cold") heat transfer respectively. However, stimuli which damaged the cornea invariably gave rise to a large number of action potentials which often lasted for an indefinite period (undiminished activity for up to 10 minutes). These observations provide no direct evidence as to the mechanism of common sensation in man but they are highly suggestive and it is tempting to speculate that pain *as I have defined it on page 581* is reported when the number of impulses from any or all the free nerve endings in a given zone rises excessively, is maintained, evokes excessive excitation centrally and reaches the "pain centre", i.e. pain is an excitatory space/time impulse pattern (which reaches the appropriate centre without being blocked *en route*) from terminals which, when suitably stimulated, can give rise to reports of sensations related to other sensory modes.

One of the satisfying things about this theory is that it provides a mechanism which can account for the large number of different kinds of pain about which patients complain and which the doctor uses as a means of diagnosis. In a sense, it makes nonsense of my initial definition for, if you accept the implications of the theory which I have erected, there is no room for such a restrictive practice.

Referred Pain

I have discussed pain at some length, as opposed to referred pain, for I felt that it was impossible to ignore any work which may lead us to modify our views concerning the nature of the activity reaching the central nervous system from the periphery which consistently evokes reports of pain.

The literature is full of speculation as to the mechanism of referred pain and the phenomena associated with it; i.e. cutaneous hyperalgesia, superficial and deep tenderness and a local muscular spasm. However, the numerous shades of opinion which have been expressed are usually resolved into two opposing theories, each of which is manifestly supported by a number of verifiable facts; curiously enough, no one seems willing to accept the possibility that more than one mechanism is involved in any particular case.

One theory is that the phenomena of referred pain are due to events taking place in the periphery and the other, that the mechanism responsible is located in the central nervous system. Neither theory, however, can be regarded as exclusive on the facts available.

The evidence in favour of the theory that the phenomena of referred pain are due to events taking place in the periphery was set out fully by Sinclair *et al.* in 1948 but even they were persuaded that it was desirable to construct yet another hypothesis based on a single mechanism to account for the divergent views which had been expressed previously. They were, however, careful to state that their hypothesis might well require extension and amplification, and, in particular, to account for the reference of pain and associated phenomena to distal segments. Their chief objective was to emphasize that no theory that is put forward can afford to ignore the possibility that axon branching in the sensory (particularly peripheral) pathways is responsible, at least in part, for the phenomena of referred pain.

The theory they put forward (which is in fact an extended and amplified version of, and includes, those which have been put forward previously) rests on a basis of currently accepted anatomy and physiology and it is certainly capable of explaining many of the numerous, sometimes divergent, observations which have been made on the reference of pain from both somatic and visceral structures. They envisage a mechanism based on the existence of a small percentage of parent dorsal root axons having a number of peripheral branches, one passing up from the site of origin of the disturbance, i.e. gut or deep somatic structures, another from the area of skin to which the pain is referred, yet another arising in adjacent somatic musculature and so on. The theory is summarized in its simplest form in Fig. 1.

Such an arrangement, it is suggested, could operate in two ways: first, by leading to a misrepresentation by the central nervous system of the true origin of the pain impulses; second, by the liberation of chemical substances (Lewis, 1942) at the terminals in the region where the pain is experienced, which would in turn stimulate interweaving and overlapping terminals

subserving neighbouring parent axons, thus giving rise to secondary pain impulses actually having origin in the periphery. In any given case, both mechanisms might be concerned. To explain cutaneous hyperalgesia, the first is considered as being initially more important than the second, but the second as increasing in importance with time and in the later stages preponderating.

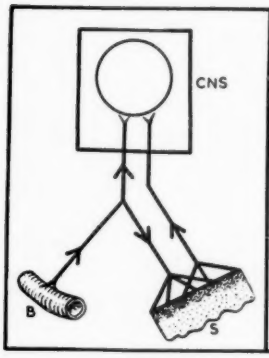

FIG. 1.

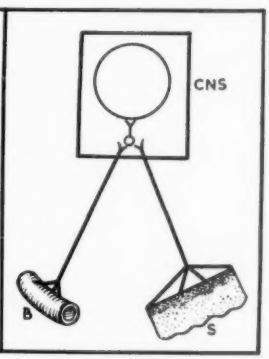

FIG. 2.

The phenomenon of misreference is explained as follows; the nerve terminals at B (Fig. 1), which may be either in the gut or any deep somatic tissue, lie in positions where they are protected from stimuli which impinge on the surface of the body and thus seldom, if ever, discharge any impulses. Moreover, there are very few of them and each is spread over a very much larger area than the terminals in S which represents the cutaneous site of reference; this suggests that a relatively extensive disturbance would be necessary to discharge them (Feindel *et al.*, 1948; Schofield, 1957). These two factors ensure that, under normal circumstances, the preponderance of impulses reaching the spinal cord will arise (together with impulses from neighbouring axons) in the skin arm of the axon. Hence the brain comes to refer all impulses reaching the cord along the parent axon to the skin. It can likewise be argued that antidromic impulses, passing down other arms of the axon, when the skin is stimulated, would be spread over such wide areas that the local concentration of chemical substances liberated would not normally be high enough to give rise to any signs or symptoms. Incidentally, this would perhaps explain why, in counter-irritation, it has been found necessary to resort to skin blistering in order to obtain an effective response.

Perhaps the greatest weakness of the theory is that, although parent axons, having two peripheral limbs, each passing along a different nerve trunk, are known to exist in amphibia (Adrian *et al.*, 1931), in fish (Wernoe, 1925, 1927) and probably also to exist in mammals (Dogiel, 1896; Lloyd, 1944), the position with regard to man is just unknown.

In my view, another weakness is the explanation which is put forward to explain referred tenderness, for it is necessary to assume that antidromic impulses produce chemical substances which, at first, stimulate the nerve endings and later *damage* them, if reports that pain can sometimes be relieved by anæsthetizing the area of reference are to be explained. In other words, it has to be assumed that pain and tenderness in the area of reference are, at first, as it were, an illusion, but rapidly become a reality which may persist independently for some time after the original cause has been removed.

You will probably have noticed that the theory as formulated by Sinclair *et al.* in 1948 assumes the existence of a specific set of pain nerves operating more or less within an all-or-nothing framework. If, however, you adopt the hypothesis that it is the pattern of discharge from free nerve endings which determines the report which is evoked, the particular objection to which I have just been referring loses some of its force for it is then only necessary to assume that pain will be reported when the total number of impulses passing along the parent axon rises excessively. The abolition of pain by anæsthetization of the area of reference is then explained on the basis that in some instances this reduces the total impulse frequency in the common parent axon below the threshold necessary to evoke pain, in other cases it does not. On this score, it is no longer necessary (in particular to explain referred tenderness) to assume that terminals in the area of reference are either damaged or that the original cause has ceased to operate.

Thus, it is possible to make out a case in favour of the view that the phenomena of referred pain are at least *in part* explicable on the basis of mechanisms taking place in the periphery. But one must face the fact that it is still not known whether axon branching actually takes place in man in the manner which has been conjectured. Moreover, the hypothesis does not account for the reference of pain to regions supplied by distant segments (Theobald, 1941; Lewis, 1942; Wolff and Hardy, 1947). Finally, I find it hard to believe that such well-known phenomena as summation, inhibition and irradiation operating centrally have no part in the explanation of phenomena such as referred tenderness, which it seems to me put an

unnecessarily severe strain on the hypothesis that peripheral mechanisms alone are involved.

For this reason, I shall now discuss the theory that the phenomena of referred pain depend upon some mechanism located in the central nervous system. Fig. 2 illustrates the simplest mechanism for which there is some anatomical and physiological evidence and which I believe can also account for referred pain and the phenomena associated with it.

It assumes that a proportion of cutaneous and visceral (or deep somatic) afferent fibres each converge on to one and the same neuron in the central nervous system. In other words, I have now placed the point of convergence not only away from the periphery but in particular in a region where the principles of summation, inhibition and facilitation are applicable. Such a mechanism not only accounts for referred pain, which is approximately segmental in distribution, but if (as is usually assumed) pain ascends in the antero-lateral column of the cord, to the thalamus and thence to the "pain centre" in the brain via a chain of neurons, it can also be made to account for pain referred to distal segments. For, to explain such observations, it is logical to assume that convergence may take place on to any neuron in the course of a particular chain. In other words, that pain may be referred to the distribution of C.N. V by impulses arising from the heart (Lewis, 1942; Wolff and Hardy, 1947).

This theory reveals its most attractive aspects if one also adopts my suggestion that pain is related to the particular spatio-temporal pattern of activity which is transmitted by certain nerve fibres to the spinal cord and not to the fact that the nerves in question merely happen to be active. I can perhaps best illustrate this point by reference to experiments on tickle recently reported by Ebbecke (1957).

Briefly, he has shown that a sensation of tickle is reported when the *skin* anywhere over the body surface is suitably stimulated. Moreover, subjects find that they can evoke a sensation of tickle by stimulating themselves, provided they are given an appropriate stimulus object and told what to do. Tickle can be evoked most easily in zones of acute tactile sensibility by the application at suitable intervals of a rapid series of stimuli which, when delivered singly, are reported as very light contact. It is also of considerable interest to note that tickle evoked in this way cannot be aroused from the skin in subjects in which the antero-lateral tract in the spinal cord has been divided, although their touch sensibility may still appear to be normal.

The most convincing series of experiments, which illustrate the particular points I want to make, can be done on oneself. Take a tuning fork (of the kind used by otologists), attach a fine bristle to it, start the fork vibrating and apply the bristle anywhere on the lower lip near the junction of the skin and mucous membrane for half a second or so, at intervals of about 5 seconds. Almost at once there is an intolerable tickling sensation which persists for as long as a minute if one refrains from wiping the lip to get rid of it, for the sensation is immediately abolished if the lip is wiped. If one stimulates the lip repeatedly in this way and at the same time refrains from wiping it, both the strength of the sensation and the length of time for which it persists will increase. Moreover, adjacent areas of skin from which a single train of stimuli previously evoked no sensation of tickle will now be responsive to a single light touch stimulus. Indeed, the sensation can be made to irradiate for some distance in this way. The affected area, however, is not uniformly sensitized, the stimulated zone remains the most sensitive, while the sensitivity falls towards the margin which is indistinct. By contrast, one can also stimulate the lip with the same object in such a way as to prevent a sensation of tickle being aroused in the manner I have just described; furthermore, this inhibitory state can be made to spread in exactly the same way as the state of excitation was made to spread. All that is necessary to evoke a state of inhibition for tickle is to stimulate one's lip in exactly the same way but to reduce by 50% or more the interval of time between the application of the trains of stimuli.

Here, then, is clear-cut evidence that the pattern of activity impinging on the cord from one and the same set of endings determines the kind of sensation which is reported. There is no question here of the liberation of a chemical substance in the periphery (particularly in view of the effect of cordotomy on tickle) by stimuli evoked elsewhere in the body. Furthermore, the experiments of Rensch and Franzisket (1954) and Franzisket (1955) suggest that this mechanism (which is presumably the sensory arm of the scratch reflex) is primarily located in the spinal cord and not in the brain. It is also clear from these experiments that irradiation, excitation and inhibition have a role in the reports which are evoked when the skin is stimulated.

Thus, it seems clear that, provided in man peripheral axons from different regions such as the gut and deep tissues converge on to a neuron which also receives impulses from the skin, the phenomena of referred pain can be satisfactorily explained on the basis that the mechanism is situated in the central nervous system. The central mechanism I have suggested provides for the possibility that impulse patterns entering the spinal cord can not only be modified

at the segmental level at which they enter but also at other positions on their way to the "pain centre."

Having started with a definition of pain in my quest for the mechanism of referred pain, it seems that I have fathered theories which abhor a rigid definition of pain in terms of anatomical arrangements and physiological mechanisms. Indeed, the theories I have discussed are most acceptable when it is assumed that there will be as many pains as there are patients reporting them. Fortunately this also implies that there are almost as many and diverse ways of treating them.

The facts concerning the mechanism of referred pain and the phenomena associated with it are too few to allow of any one theory being wholly acceptable. It should, however, be possible to design experiments to put some of the suggestions which I have made to the test.

Dr. G. Gordon (Laboratory of Physiology, Oxford):

The Physiological Basis of Referred Pain

Dr. Weddell has made my task easier by presenting clearly the two general hypotheses put forward to explain the phenomenon of referred pain—that of the branching of peripheral nerve fibres and the more traditional one of central synaptic convergence. What I must do now is to examine each of these from a physiological point of view, asking first whether each, as a hypothesis, will explain the hyperalgesia, the muscular rigidity and the actual reference of pain, and then asking whether either is supported by objective physiological evidence.

It is clear, I think, that each hypothesis can explain the facts in a purely diagrammatic sense. In each case the false reference of pain is the result of the confluence of a visceral or deep somatic path with a cutaneous path, such confluence forming an inevitable part of any hypothesis which proposes an objective basis for the phenomenon. In each case muscular rigidity is a form of reflex activity akin to the flexion reflex, readily reproduced in the spinal animal by mishandling deep somatic or visceral structures (*see* Lewis and Kellgren, 1939). Cutaneous hyperalgesia, on the peripheral hypothesis, is the result of impulses running antidromically to the skin and there setting up an excitable state which lowers the threshold of neighbouring cutaneous nerve fibres which mediate pain: on the central hypothesis it is explained by visceral impulses lowering the postsynaptic threshold at the site of convergence, so that cutaneous impulses more easily excite the secondary common pathway. It is worth noticing that, on the central convergence hypothesis, the cutaneous fibres concerned need not be "pain fibres" in the sense that pain is felt when they alone are stimulated: pain may be felt only when a deep sensory path is simultaneously active. It is a fact that the results of anæsthetizing the cutaneous area of reference have been extremely conflicting, some having abolished visceral pain in this way and some having failed to do so; but this conflict has been resolved to some extent by showing that the efficacy of cutaneous anæsthesia can depend on the strength of the visceral stimulus (Doran and Ratcliffe, 1954), and it is known moreover that on occasion pain can even be referred to phantom limbs (Cohen and Jones, 1943). These

facts can be explained on either hypothesis: in each case the effect of cutaneous anæsthesia will depend on the quantity of visceral impulses and hence their capacity to "fire" the central pain pathway on their own account without summation with cutaneous impulses.

In examining these two hypotheses in the laboratory one must remember that there is no *a priori* ground for assuming that all the curious subjective phenomena which we group under the heading of referred pain have in fact a single common physiological basis, and one must not reject out of hand a hypothesis which offers only a partial explanation. No crucial evidence exists at present which causes either hypothesis to be rejected; but some probabilities arise from the evidence. There is, in the first place, perfectly clear proof of the confluence of cutaneous pathways in the central nervous system with deep somatic and visceral pathways. Many examples of this confluence have been recorded in the last few years, the evidence usually taking the following form: an electrical record is made of the activity of a single central neurone (or of a group of neurones), and it is shown that activity in this neurone can result from stimulating either a cutaneous nerve or a deep sensory nerve. It is important to prove that it is really the same neurone which responds in either case, and this is done by showing that after the neurone has been excited from one peripheral source a period of time elapses (the "unresponsive period", a term analogous to "refractory period") during which it cannot be excited from the other peripheral source. It has been shown in this way that in the cerebral cortex and subcortical white matter of the cat interaction occurs between cutaneous and deep somatic pathways (Mountcastle *et al.*, 1952), between cutaneous and splanchnic pathways, and even between pathways from two related skin areas (*see* Amassian, 1952). It has to be emphasized, however, that this extremely interesting information is not necessarily relevant to the question of referred pain. Clearly it will always be impossible to prove that any purely objective evidence from animals does give the actual basis for referred pain; but the likelihood of the evidence being relevant will be enormously increased if one shows not only the confluence of the central connexions from the two peripheral sources, but also that this occurs in the main cerebral projection system for sensory fibres which could reasonably be expected to mediate pain in man. From now on I shall confine myself to evidence which conforms to these criteria.

Data from many sources have contributed to the view that the peripheral elements concerned in mediating pain and nociceptive reactions are particularly concentrated among the smaller myelinated and the unmyelinated fibres of sensory nerves: the former have a mean diameter of about 4μ and are responsible for the Aδ wave in the compound action potential of the nerve. I shall call them *delta* fibres. When recording the electrical responses of a central cell to stimulation of a peripheral nerve, one can control the peripheral stimulus by recording also how the nerve responds to it, so that one knows whether the *delta* fibres are being stimulated or not. Gaze and I (1954), using this technique, were able to show that in the main cutaneous relay nucleus of the thalamus (*n. ventralis postero-lateralis*) of the cat and monkey there were cells which seemed to be excited specifically by stimulating cutaneous *delta* fibres and by applying noxious stimuli to the skin. This seemed a promising situation in which to look for interaction between visceral and cutaneous paths, and this was done by my colleague McLeod (1956), using the splanchnic nerve as the source of visceral impulses. This nerve has a group of large myelinated afferent fibres, which probably do not concern us here, and also a group of *delta* afferent fibres which have been shown to be concerned in responses to noxious stimuli (Gernandt and Zotterman, 1946). McLeod found many cells in and around *n. ventralis postero-lateralis* of the thalamus which responded to stimulating one or other of these fibre-groups in the splanchnic nerve: they were mainly to be found in the part of the nucleus which receives impulses from the skin of the trunk, though some were found in the limb regions. The interesting point is that the majority of these cells responded also to stimulating the skin—usually the skin of the trunk, but sometimes that of the limbs or tail. Cells such as these were found in both the ipsilateral and contralateral thalamus.

These facts seem to me to provide us with at least a plausible experimental basis for referred pain of visceral origin. Undoubtedly one would be more convinced if it had been shown that the same systematic basis existed in the cerebral cortex also; and it is to be hoped that it will be looked for. Does the evidence now allow us to choose between the two hypotheses with which we started out? Strictly it does not, because the hypotheses do not exclude one another. There were certainly some features of these particular experiments (McLeod, 1957) which made it seem unlikely that the confluence of pathways was due to branching of peripheral fibres. If it were due to branching, it is extremely difficult to explain why the "unresponsive time" of the pathway should invariably depend on which of the peripheral fields was stimulated first, or why the response to stimulating one of the two fields should sometimes be intermittent whereas that from the other field should be regular and consistent. Only an improbably elaborate argument can reconcile these facts with the hypothesis of branching fibres. Even if these particular facts cannot be explained in this way, a few peripheral fibres may branch in the suggested manner nevertheless; and this could be investi-

gated fairly readily by seeing whether stimuli applied to visceral nerves do, in fact, cause action potentials to run antidromically in cutaneous nerves of related segments.

Whatever other factors may be concerned, then, it seems that there is a synaptic convergence mechanism present in mammals, at the thalamus or at a lower level, which is capable of explaining the reference of pain, usually to neighbouring parts of the skin surface, sometimes to more remote parts. We do not know the level at which this convergence occurs, or even whether it is confined to one level. Certainly some such convergence may occur at a spinal level, as Widén's (1955) results have shown; but it has not yet been discovered whether the interaction seen by Widén is occurring in the main spino-cerebral sensory pathway. Finally, let me say that although the experimental evidence which I have described is probably the right kind of evidence to bring to bear on this problem, the question of its actual relevance to the problem of referred pain is nevertheless pure guesswork.

Dr. R. M. Mason (London Hospital):

I propose to speak primarily from the clinical aspect of referred pain and to limit myself to the beginning and the end of the anatomical pathways and physiological mechanisms dealt with by the two previous speakers, i.e. the effect of pain on the patient at one end and the pathology of the lesion causing the pain at the other.

Our first clinical problem is the difficulty of assessing the severity of the pain. It seems clear that even for the trained investigator the translation of sensory experience into words may be extremely difficult (Kellgren, 1949). How much more difficult is it for the average hospital out-patient, especially where the emotional component may be high, since, as Medvei (1949) pointed out, pain is "close to the centre of personality" and cannot be separated from the emotional quality of the individual. All we can really say of the character of any pain is that it is unpleasant; nor indeed does the English language contain a word to describe the effects of the relief of pain (Critchley, 1934). Epicurus apparently took the view that the absence of pain is in itself a pleasure, but as Medvei rightly said pleasure is not the correct word, and the physiological and psychological gratification following immediately on the relief from pain is perhaps regarded only by lunatics as equal to pleasure. It is all too easy for us to be misled into false estimates of the severity of the patient's pain and we have to remember that a trivial lesion can give rise to severe pain and a serious lesion, constituting a major threat to the patient's survival, may give rise to no, or to only trivial, pain. Some bone conditions are easy to miss.

Case I.—A 22-year-old salesman was referred to the Orthopædic Department of the London Hospital with a four-and-a-half-year history of obscure pain in the left leg. It was mostly situated in the adductor region of the left thigh but had extended to the left knee. He had been to another hospital where no derangement of the knee had been found and he had been reassured but the pain continued, aching in the knee, calf and ankle, intermittent but becoming more severe and eventually extending round the iliac crest and across the groin. Osteopathy failed to help. Physical signs amounted to no more than a slight wasting of the left leg but an X-ray showed an area of sclerosis just below the left lesser trochanter, containing an area of rarefaction, and within this area of rarefaction a further ring of sclerosis. This was osteoid osteoma, the cause of his pain.

This curious condition of osteoid osteoma is just the sort of pathological lesion which can give rise to referred pain, in which serious mistakes can be made in discounting the severity of the pain simply because no physical signs are found, and the pain is relieved by one aspirin.

Case II.—A 70-year-old woman was referred complaining of pain in the left knee and leg of three months' duration. Clinically there was some thickening of the lower leg. She had a sedimentation rate of 125 mm. in the first hour (Westergren) and a hæmoglobin of 65%. X-ray of the left tibia showed the characteristic appearance of syphilitic periostitis and her quantitative W.R. was positive in serum diluted at 1 in 1,600. Further skeletal survey showed similar changes in the forearm but these were quite painless illustrating the discrepancy between the severity of the pain and the pathology of the lesion.

Then, of course, there are the more frequent sources of error.

Case III.—A young woman of 36 was referred by her doctor "I think this patient has a spinal lesion with referred pain in the right calf. It is now preventing sleep and I would be grateful for your advice and treatment". This had developed three months previously with pain in the right calf on getting out of bed. Her doctor had examined her at that time and found tenderness in the calf and thought she had a muscle strain. She had recovered but two months later had returned with an "uncomfortable feeling" in the back of both thighs worse in bed at night. This had been ascribed to sitting on a hard chair at work—she was a medical secretary—but by the time I saw her she had limited straight leg raising and limitation of spinal flexion with a scoliosis. X-ray of her spine showed secondary deposits in L.3 and 4 and further skeletal survey showed multiple bone deposits. On re-examination there was a firm tumour in the upper medial quadrant of the left breast with enlarged axillary glands. Biopsy showed this to be an adenocarcinoma and a bilateral oophorectomy and adrenalectomy was carried out. Post-operative X-rays showed rapid resolution of the secondaries and she completely lost her pain. The basic pathology of the lesion was unchanged and the loss of pain does not alter the ultimate prognosis.

The next patient illustrates the other common mistake.

Case IV.—A 59-year-old butcher was referred to Medical Out-patients complaining of substernal pain with a diagnosis of ? angina. He was there noted to have a dorsal kyphosis but ECG was normal. X-ray of the dorsal spine was interpreted as showing osteo-arthritis and he was therefore referred to the Physical Medicine Department. We took the precaution of taking a better quality X-ray, however, and this now showed collapse of the dorsal vertebræ. Sedimentation rate was 140 mm. in the first hour (Westergren), hæmoglobin 64% with abnormal plasma proteins. Marrow biopsy showed large numbers of plasma cells characteristic of myelomatosis.

On the other side of the coin there is the occasional patient who presents with what should be a painful condition but without pain.

A congenital indifference to pain is recognized as occurring in children giving rise to a characteristic picture of a severe arthritis of the ankles and tarsus (Murray, 1957). In these children fractures may only attract attention because of the resulting deformity and osteomyelitis is a common complication.

Case V.—A 58-year-old decorator was seen recently complaining of weakness of the limbs for twelve months. His main complaint was of loss of strength of his arms and loss of grip, making it difficult for him to work. He did agree that his joints had become swollen but he had not been off work at all. X-rays showed severe rheumatoid changes. His central nervous system was completely normal except for loss of pain sensation.

I think that this problem of assessing pain with these varying factors is a most important one. Measurement of pain thresholds is difficult and at least 82 methods have been devised (Goetz *et al.*, 1943), these being mechanical, electrical, chemical and thermal which suggests that none of them are really satisfactory. Perhaps the simplest is that described by Libman (1934) who found that pressure in the direction of the styloid process is painful in some individuals and not in others. He classified people into three groups—hypersensitive, normosensitive and hyposensitive—on their response to this test. Keele (1954) reintroduced the pressure algometer which had been used in the last century for assessing analgesia in tabetics. Whatever method is used it is necessary to distinguish clearly what is being measured, distinguishing, that is to say, the point at which pain is felt—the pain perception threshold—from the pain reaction threshold, what I would call the "Ow!" point, and the point at which the pain becomes intolerable which is the maximum pain tolerance. I suspect that many of our patients have low "Ow!" points, even if their pain perception thresholds are normal. So far as I know we have no data on this. Keele has provided us with data on normal controls in which he has shown that the pain perception threshold by his criteria is distributed as follows—23% were hypersensitive and 15% were hyposensitive. I think a similar study on the out-patients in one of our departments would be of great interest. It seems to me that unless we can tell to which group the patient belongs when we are trying to assess his symptoms we must be in difficulties in determining the amount of pain, quite apart from any anatomical considerations. There are, however, many difficulties such as the variations produced by changes in the skin temperature to which Beatty and Woodmenay recently drew attention (1955).

We have to remember that pain whether referred or not may become "an old friend". Tic douloureux lends itself particularly to a study of the effects of relieving pain, for the pain is severe and complete anatomical block of the sensory root of the trigeminal nerve is possible. Penman (1954) found that some 22% of his patients showed subsequent neurotic symptoms after such relief. As he says the transformation from a patient in frequent severe pain but not weeping, to one out of pain but weeping, could not by any feat of reasoning be called improvement. How often does that not apply in lesser degree to our patients. I can well recall one whose chronic backache referred from multiple disc degeneration was relieved by a month of strict bed rest, and of having had the foresight to warn the general practitioner that I hoped we would not altogether cure the patient for I anticipated disaster if we did. Shortly after her return home cured of her backache, she had to be readmitted in agitated depression and required electric convulsant therapy.

Even where a careful history and physical examination will give us the anatomical site of the lesion giving rise to referred pain, it is of even greater importance to us clinicians to identify the pathology. I have already mentioned two or three cases of this kind but the pathological nature of the lesion gives rise to some unexpected surprises. I think one can learn from these experiences and that they bear repetition.

Case VI.—An Assistant Matron of 24 came up to Out-patients recently complaining of attacks of acute low backache and left sciatic pain, the first attack having been at the age of 17, putting her to bed for three weeks. She still complained of occasional bouts of pain down the left leg. Initial examination revealed no physical signs. An X-ray showed bilateral sacro-iliitis.

Case VII.—Another surprise was a male Indian of 34 years who was referred by his doctor for advice on the treatment of his low backache after a radiological diagnosis of ankylosing spondylitis had been made. He gave a six years' history quite characteristic of ankylosing spondylitis, of morning stiffness in the low back relieved by getting about, and there was occasional stiffness in the groins and the neck. Examination revealed a moderately limited lumbar spine. His chest expansion was 1½ in. The X-rays showed a diagnostic picture of ochronosis of the spine with frayed thinned disc spaces and his urine contained large amounts of homogentisic acid.

These two cases represent fairly simple surprises. I would like to describe two more rather more complex problems of referred pain.

Case VIII.—A motor cycle agent of 46 was referred to Mr. H. Osmond-Clarke with a three years' history of vague lumbar and sciatic pain on the right side after he had lifted a motor cycle. He had not responded to plaster jacket, &c., and when seen by Mr. Osmond-Clarke was also complaining bitterly of pain in the right knee. No abnormality could be found in this joint and it was considered that it was a referred pain from the low back. X-ray of the spine showed definite forward slip of L.5 on S.1 and the oblique view showed quite clearly a defect in the pars inter-articularis. When he came into hospital he developed a considerable effusion into the knee-joint and when I saw him his sedimentation rate was 43 mm. in one hour (Westergren). X-ray of the right knee showed subchondral cystic changes in the patella with a patchy osteoporosis which was attributed (wrongly) to osteo-arthritis. He went rapidly downhill and after various complications, interpreted as embolic phenomena in the lungs, he developed symptoms of a severe transverse cord lesion in the lower cervical and upper dorsal region and died. Post-mortem revealed diffuse carcinomatosis with a primary carcinoma of the lower lobe of the left lung. He did have a spondylolisthesis of L.5 on S.1 but the bodies of both vertebræ were infiltrated by growth of osteolytic deposits, and there was "considerable erosion and partial destruction of the right patella, the central portion of its articular surface being replaced by soft greyish growth". Nearly every other tissue of the body was also infiltrated with secondary carcinoma.

Case IX.—A man of 32 with a diagnosis of Tietze's syndrome. He complained of pain in the region of the right trapezius and in the low back with a dull aching pain in the left loin, and of a tender swelling over the left third costal cartilage. His history was that he had cut his left thumb some three years previously whilst working in a slaughter house and the healing of this wound had been delayed for about a year. Six months after the injury he had developed a sharp pain in the left side of the chest and shortly afterwards this swelling had appeared. It had given rise to a constant dull aching pain. Later he had developed pain in the right shoulder region and left loin and had been readmitted to hospital where full investigations had failed to reveal any significant findings. He had continued to lose weight—about 4 st.—and was obviously in pain. On examination, apart from a tender hard swelling over the costochondral junction of the left third rib, he was very tender over the third and twelfth dorsal vertebræ and all his spinal movements were much limited. The only positive pathological or radiological finding was a little collapse of D.12. A further biopsy was carried out by Mr. Vernon Thompson revealing a secondary carcinoma consisting of trabeculated polygonal squamoid cells with a few giant cells. He was treated with radiotherapy with some symptomatic improvement but subsequently died. Post-mortem showed a small white tumour in the left kidney, ¼ in. in diameter, which proved to be a hypernephroma, and secondary deposits were found in the third and twelfth dorsal vertebræ as well as in the third left rib and elsewhere.

Conclusion

I have tried from these examples to show the clinical application of the basic sciences of anatomy and physiology which have to be coupled with pathology, and are sometimes complicated by psychiatry, to make up the complex problems of referred pain which form our daily lot.

I am grateful to Mr. H. Osmond-Clarke for permission to publish Cases I and VIII.

The Pattern of Australian Medical History

By BRYAN GANDEVIA, M.D., M.R.A.C.P.

Wunderly Travelling Scholar in Diseases of the Chest, Royal Australasian College of Physicians

"... the writer (of a history of medicine) may be tempted to exaggerate the importance of great discoveries and to lay great stress on the lives of famous men. It should be remembered that this is only one aspect of history, a survey of the peaks and not of the valleys, a study of the milestones rather than of the miles between."—DOUGLAS GUTHRIE, *Int. Rec. Med.*, 1956, **169**, 700.

The history of medicine in Australia is a small valley in the vast realm of medical history, but in some respects it is a fertile one.

The introduction of new concepts and techniques amply repays careful study in Australia. I shall draw attention to some of our medical pioneers, in the forefront of whom are those with the courage and initiative to try new ideas, whether original or not, and those whose foresight and planning contributed to subsequent development. In Australia the first penal settlements had their own peculiar problems; the factor of distance led to the development of the "flying doctor" service and significantly influenced the character of general practice.

The basic pattern of Australian medical history is readily defined. There was first an era of exploration, before settlement, limited to the coastline, and with this may be classified, from the medical viewpoint, many of the subsequent voyages and expeditions of exploration in the half-century or more after the first settlement. Secondly, there was the early colonial era (1788–*c.* 1850), which includes the penal era and a short ensuing period of economic and legislative dependence upon the United Kingdom, somewhat euphemistically termed the romantic era. Thirdly, there was the late colonial era, extending from about 1850 to the turn of the century. The special significance of this period lies in the fact that it coincides not only with the advent of modern scientific medicine but also with the achievement of independence by the several colonies and with the social consequences of increasing population and prosperity and in particular of the discovery of gold. The fourth era, of clinical science, in which we now live, is as yet young in Australia. The only reference which I wish to make to it is to observe that the modern development of Australian medicine as a national enterprise, based largely upon graduates of her own universities, is due chiefly to a small group of doctors of the latter part of the nineteenth century. Most of them were emigrants from Great Britain, and in them our countries may jointly take considerable pride.

THE ERA OF EXPLORATION

It was not until the seventeenth century that visitors to Australia were in any sense numerous. One must be mentioned because he was the first medical man known to have set foot on our shores. In 1629 the *Batavia*, commanded by Francis Pelsart, was wrecked off the coast of Western Australia. About 180 people landed on a near-by island. Pelsart sailed 400 miles up the inhospitable coast in the ship's boat looking for water. Finding none, he simply went on to Batavia and came back with a rescue ship. Meanwhile, the apothecary or surgeon aboard the wrecked ship, Jerome Cornelis, who had in any case planned to mutiny and forsake medicine for piracy, had taken the liberty of murdering most of the survivors, except for a few women. On the return of Pelsart, in unexpected strength, Cornelis had his hand chopped off and was then hanged. So much for tradition.

The most notable voyage of exploration connected with Australia was that of Captain James Cook (1768–71). At the request of the Royal Society, the voyage was undertaken to observe the transit of Venus from Tahiti, after which Cook was to investigate New

Zealand and to seek confirmation of the existence of a great Southern Continent. All this Cook did, and in particular he mapped the east coast of Australia. The scientific side of the expedition, under the personal direction of Sir Joseph Banks, was also an outstanding success. The medical interest of this voyage lay in the striking freedom of the *Endeavour*'s company from serious illness of any kind, and from scurvy in particular, prior to the arrival of the ship at Batavia late in 1770. Banks wrote proudly in his journal that "our people . . . might truly be called rosy and plump. For we had not a sick man among us." Indeed, this was the first trans-Pacific voyage to be completed without the development of serious scurvy. Captain Cook himself has usually been given sole credit for this, notably because of the cunning ruse which he adopted in order to entice his crew to eat sauerkraut: he allowed the men to see that the officers ate it daily but he left it optional for them—within a short time he had to ration it all round. Cook is known to have taken great care in the selection of his crew, and some of the credit may be due to his two surgeons, Monkhouse and Perry. The Admiralty, which took no official notice of Lind's work until 1796, sent detailed orders to use malt wort, together with two books on this subject by a Dr. MacBride. Perhaps more important, Dr. John Fothergill, the Quaker physician, sent concentrated orange and lemon juice to Joseph Banks, and this was accompanied by a long letter of instructions from Dr. Nathaniel Hulme, an influential naval surgeon and a foundation member of the Medical Society of London. Finally, some credit may be due to Dr. Carl Solander, who was a member of Banks' entourage. Whoever or whatever was responsible, Cook's voyage was a remarkable feat; scurvy remained a major problem on the Australian run well into the nineteenth century, and was recorded as late as 1867.

The Early Colonial Era

We may now consider the conditions of convict transportation, with special reference to the first three fleets to arrive at Sydney Cove, Port Jackson. The first, under Arthur Phillip, arrived in January 1788, and consisted of eleven ships bearing over a thousand souls. Only 45 of 756 (6%) convicts died on the seven months' voyage, and 3 of the remaining other personnel (the difference is statistically significant); Phillip was a good commander and he was ably supported by his senior surgeon, John White (1750–1832). White's "Journal of a Voyage to New South Wales" (1790) is the starting point of Australian medical literature. Many of the prisoners were carriers of disease, if not actually ill, at embarkation. The mortality was probably no more than could be expected in view of the overcrowding (which existed on board long before the ships sailed), and the inevitable restrictions on food, fresh air and exercise. The second fleet arrived in June 1790. Of approximately 1,800 prisoners, rather less than a third died *en route*, and almost as many again were put ashore sick and dying. The Rev. Johnson described their arrival: ". . . great numbers were not able to walk, nor to move hand or foot; such were slung on the ship's side in the same manner as they would sling a cask. . . . Upon their being brought up to the open air some fainted, some died upon the deck, and others on the boat before they reached the shore. When come on shore many were not able to walk, to stand, or to stir themselves in the least . . . . Some creeped upon their hands and knees, and some were carried upon the backs of others." In the crowded conditions the prisoners had found it easy enough to conceal corpses, until the stench gave them away, in order to gain the deceased person's share of the rations. Dysentery, scurvy and probably typhus and typhoid fevers were the specific diseases responsible. However, the tragedy of the second fleet lay not only in its own pitiable state but also in the inability of the original settlement to succour them. For months it had been on the brink of starvation itself, for it was far from self-supporting. The chief factors contributing to this were the lack of experienced farmers, the failure of the crops and gardens, and the death or loss of much of the livestock. The strain on the tiny hospital had been great throughout; on its arrival £1,400 worth of surgical equipment and supplies, found to be of inferior quality, had to be thrown away. The sudden influx of 500 patients was a calamity to the settlement; perhaps the major factor in its survival was the dogged, determined leadership of the ailing Governor Phillip. In the third fleet, which arrived in 1791, the mortality was down to about 10%, but a month after its arrival Phillip reported that nearly 600 convicts were under medical care and constituted a "deadweight on the stores".

Having described these conditions, it is necessary to refer briefly to the measures taken to ameliorate them. It must be remembered that in the years which followed the first settlement England was beset with the economic and military problems associated with the Napoleonic wars, and that even granted every facility medical science was not yet ready to cope with the problems involved in the mass transportation of a convict population. In 1800, among other changes, the £23 per convict, dead or alive, paid to the transportation contractors, was replaced by £18 per head, with a bonus of £4 10s. 6d. for each one safely landed. Despite some improvements, mortality and morbidity remained high until the

adoption of recommendations made in a report, described as a model of its kind, prepared by William Redfern, a colonial surgeon and ex-convict, in 1815. Redfern's advice regarding fresh air, diet, personal cleanliness and clothing is obvious to-day. He advocated the appointment to the transports of naval surgeons; previously these appointments had been made by the shipowners, and the appointees were usually "students", derelicts or failures. Subsequently surgeons-superintendent were appointed and given wide powers. Over the years their responsibilities grew, and ultimately we find them responsible even for the religious and general education of the convicts on the voyage. Later, they were employed as immigrant agents, recruiting immigrants in England and travelling out in medical charge of the ships which brought them; somewhat modified, this service continued through most of the nineteenth century, long after the transportation of convicts had ceased.

The health of the tiny settlement, perched precariously on the edge of a vast continent, during what have been called the "hungry years", was much as might be imagined. Injuries, snakebite and sunstroke were common, but the major problems were dysentery, typhus and typhoid fevers, tetanus and venereal diseases, aided and abetted by scurvy and malnutrition. For over two years there was no fresh meat, butter or milk, and only very little in the way of vegetables. White and Considen, one of the assistant surgeons, found that the native sarsparilla was a valuable antiscorbutic agent, that the gum of the native myrtle was astringent and that eucalyptus oil had useful properties. Of venereal disease, Governor Phillip wrote in 1789 " . . . it has gained such a footing in the Settlement that I now doubt if it will ever be done away with. The Precautions I ordered to be taken in England have been rendered ineffectual by the infamous conduct of some of the Magistrates, in sending on board the transports those who have [*sic*] been turned out of the Hospitals as incurable". The first legal order relating to public health, promulgated in 1795, was one to prevent contamination by pig ordure of the stream from which the colony drew its water supply; curiously enough, we have no knowledge of the means of disposal of human excreta. The acute infectious diseases made inroads upon the relatively "non-immune" population from time to time. Trachoma was described in 1794. In the subsequent history of Australia it was always to appear on the advancing edge of civilization, disappearing as civilized living became established. Its wide distribution and curious behaviour seem to exclude causation simply by dust, heat or bacteria, and a nutritional basis has been postulated. By 1803 the colony could be described as "very healthy"; a decade earlier (1792) the mortality had been over 10% of about 3,400 inhabitants, but it had then fallen to about 2% per annum. About this time government-sponsored free settlers began to arrive; by the second decade of the nineteenth century settlers were arriving with capital, and these emigrants must have influenced the social and hygienic standard of the community for the better. By this time the degenerative diseases were beginning to replace the enteric diseases and syphilis as causes of morbidity and mortality; so too was alcoholism.

An epidemic of very severe smallpox decimated the native population in 1789, but spared the entire European colony, with one exception. The disease had not previously been established on the Continent, as far as is known; it has been suggested that the infection was introduced by Malay or Macassar fishermen, and that the colonists were immune. Variolous matter brought out with the first fleet, a conceivable source, was not apparently responsible. Vaccination was introduced by surgeons Savage and Jamison in 1804, and this led to the first signed medical paper to be published in Australia. Entitled "General Observations on the Smallpox", it was published by Jamison in the *Sydney Gazette* of October 14, and drew attention to the new "infallible preventative". Calf lymph was not manufactured in Australia until 1881.

The medical officers who ministered to the community during its early years provide a fascinating study. Their social background varied widely and their professional skill was no doubt equally variable. They were deeply involved in the scandalous traffic in rum, which largely took the place of currency, and in which the officers of the New South Wales Corps established a vicious but profitable monopoly; some of them were directly concerned in the successful plot to depose Governor Bligh, of *Bounty* fame; two of them fought a duel after a dinner party at the Governor's house. It would be unwise to judge this behaviour by modern ethical standards, just as it would be unfair to judge their professional skill by the vital statistics of the colony in the hard cold light of modern medical knowledge. They were overworked, underpaid, and administered in a clumsy and frustrating fashion which predisposed to conflict. One of the more interesting and important surgeons was William Redfern (1778–1833), whose excellent report on convict transportation we have already mentioned. Redfern was 19 and had recently passed the examination of the London Company of Surgeons when he was sentenced to death for offering advice and encouragement to the mutineers at the Nore (1797). Because of his youth, the sentence was commuted to one of life imprisonment, and he was transported

to Australia in 1801. After a year's work as assistant surgeon at the subsidiary settlement at Norfolk Island he was granted a free pardon by Governor King. By 1808, when he went to Sydney, he owned both land and houses there. Unable to produce documentary evidence of his qualification, he passed an examination set by a specially constituted board of examiners, and thus became the first person to hold an Australian medical diploma. On this board he was later to serve himself. Redfern's worth seems to have been immediately recognized. He is said to have attended the family of Governor Bligh, then a prisoner in his own house, and certainly he rapidly became a personal friend of Bligh's successor, Macquarie, to whom he was physician for many years. About this time Macquarie invited tenders for a new hospital, to be built on the grand scale which characterized public buildings during Macquarie's term of office. The result was the famous "Rum Hospital", opened in 1816, later to become the Sydney Hospital. The contractors received a virtual monopoly on the importation and distribution of 60,000 gallons of rum over several years, together with the labour of some bullocks and convicts. For a governor who had been sent out with the express orders to quell the rum traffic, it was a fantastic contract to have signed, especially without prior reference to England. Another curious feature was that one of the three contractors was the Principal Surgeon, an Irishman of uncertain medical qualifications, once allegedly implicated in some highway robbery, who may have been added to the original two contractors to give the firm financial stability. When the hospital was built Dr. Arnold recorded that "it perhaps might make a good barrack but certainly must be a very bad hospital . . . a preposterous building". Arnold doubtless kept his view from Mrs. Macquarie, who may well have been responsible for its design. Occupying a fine site in Macquarie Street, the buildings are still in use, only part of them at present forming the hospital. As an assistant surgeon in the colonial medical service, Redfern was the first medical officer to the hospital, where he worked conscientiously and well every morning. He was assisted by his apprentice, William Cowper (1800–?1855), the first student of clinical medicine in Australia, the first Australian to become a Member of the Royal College of Surgeons, and the first surgeon to the Moreton Bay (Queensland) Settlement, where he was concerned with the foundation of the Brisbane Hospital. Redfern's private practice grew to be the largest in the colony, and his work must have been of a high standard. In 1818, Macquarie recommended him for the vacant post of Principal Surgeon, "being a man of very eminent talents and an excellent scholar and possessing universal knowledge". This promotion of an ex-convict was too much, however, and Redfern's claim was overlooked. He resigned, and after some years of private practice devoted himself solely to his extensive agricultural interests. The recognition of Redfern's ability, his championship of the emancipist cause in later years, his philanthropic and social activities, his personal friendship with the Governor, all reflect a significant change in the colony over the first two decades of its existence, namely, the commencing evolution of a free, progressive settlement from the original purely penal establishment. With Redfern must be linked William Bland, another emancipist surgeon, and an even more prominent figure in political, philanthropic and educational spheres. He is also remembered as the first surgeon in Australia to ligate the innominate artery for aneurysm (1832), his case report being the seventh in the world literature. Had nearly a gallon of blood not been taken from the patient during the post-operative days there is a possibility that this might have been the first successful case.

Lest at this stage we grow too optimistic about the progress of the colony, I would quote the views of John White, written as the first Principal Surgeon was becoming embittered by the hardships and heartbreak of the early days: " . . . a country and a place so forbidden and so hateful as to only merit excretions and curses; for it has been a source of expense to the country and of evil and misfortune to us . . . there is not a single article in the whole country that can prove the smallest use or advantage to the mother country or the commercial world."

The Late Colonial Era

Unlike Sydney or Hobart, Port Phillip, or Melbourne as it became, was formed as a free and voluntary settlement in 1835; as part of Victoria, it became a separate colony, independent of New South Wales, in 1850. Almost immediately its population was swollen by the gold rush migration, rising from 100,000 to over half a million in eight years. During the 1880s there was a further influx of relatively young adult emigrants. Victoria has been chosen to illustrate the pattern of Australian medical history over the latter half of the nineteenth century partly because of these well-defined social influences, and partly because it is well-documented. The continuous publication, since 1855, of a regular medical journal, a direct ancestor of the present *Medical Journal of Australia*, and the existence of the minutes of medical societies in almost unbroken succession since 1847 have provided an invaluable basis for historical study, without compare in other states.

The epidemiology of the period is of considerable interest. Healthy young adults looking

for gold, camping without sanitation in small areas, provided ideal conditions for the spread of enteric diseases. From 1854 to 1861 typhoid fever was extremely common. From 1861, when conditions became more settled, until about 1890 it remained a common disease, but thereafter its prevalence decreased. Acute progressive tuberculosis in young adults decreased after 1861, prior to which it had been a major cause of mortality. About fifteen years later the mortality rate from the same type of disease in "non-immune" young adults rose again; these were in large part the children of the period 1850–1865, which was not unnaturally associated with a high birth rate. Towards the turn of the century, the age distribution of fatal cases assumed a more usual form. Incidentally, the practice of sending consumptives to Australia to take the cure had long been well established, and indeed among the survivors of this arduous treatment were some noted medical practitioners.

Another sequel of the increased birth-rate of the gold rush period was a high mortality from acute infectious diseases in children in the subsequent decade (1861–1871); in fact, whole families were lost in this way. Diphtheria burst upon Melbourne in 1858, the year in which it first assumed epidemic proportions in England; it is remarkable that by the time the third, if not the first, case appeared in Melbourne the disease was correctly diagnosed and distinguished from non-diphtheritic croup. The third patient, the child of Mrs. Dewar, has the distinction of undergoing the first tracheotomy for this condition in Australia. It was performed by Edward Barker (1818–1885), former dresser to Liston at University College Hospital and later first lecturer in surgery at Melbourne University, and James Rudall. It was unsuccessful, but Rudall later performed the first successful tracheotomy for diphtheria in 1865—an interesting reflection on the relative importance of toxæmia and respiratory obstruction. After the world-wide epidemic of 1858, Victorian epidemics of diphtheria were unrelated to epidemics in England. Measles appears to have behaved differently, for in this case fluctuations in English mortality rates tend to be reflected in the Victorian figures, suggesting that the disease may have been successively reimported. There were several sharp epidemics with high fatality rates prior to 1900, when transition to an endemic disease was shown by a more or less constant death-rate a little above that of the interepidemic periods of the previous era. A similar phenomenon occurred with whooping cough. Scarlet fever, with malignant sore throat, occurred in several vicious epidemics, but, as overseas, its severity declined about the turn of the century.

It is apparent that for all these conditions the period 1890–1900 was a critical one; several factors were involved in the changes which took place. One was the approaching stability of the age constitution of the population with the elimination of large groups of susceptible individuals. A second was the introduction of sanitation and improved water supply. Public interest in hygiene was fostered in Victoria by a violent controversy on the role of contagion in the ætiology and spread of all these conditions, as opposed to their propagation by effluvia from cesspools and the like. Erysipelas and wound infection—"hospitalism"—were so common at the Melbourne Hospital that casualties feared nothing so much as going there. These and other matters received much local publicity, and indeed it was the useful age of lay "medical journalism" the world over. Politicians and others were also conscious of the passage of the Public Health Act 1875 in this country. It is gratifying, although in the circumstances not surprising, that a Royal Commission on Sanitary Reform was set up in Melbourne at this important time; its valuable report was largely the work of Sir Harry Allen.

William Thomson (1820–1883), from the Andersonian School of Medicine in Glasgow, was in the forefront of the battle for the contagionists. He published sound work on typhoid fever, but his most interesting books—he was a prolific author—deal with tuberculosis. He inveighed against the practice of sending consumptives to Australia, not only because this had no influence on the course of the condition, but also because these people served as a source of germs, spread as dried sputum particles, which were the cause of the disease. He supported his contentions mainly by careful epidemiological studies, but in 1876 he published a notable book "The Histochemistry and Pathogeny of Tubercle", in which he analysed the pathology and histology of pulmonary and intestinal tuberculosis, reviewed current knowledge of biochemistry and bacteriology, and concluded that the disease was due to a living micro-organism. He clearly affirmed the principle of chemotherapy when he looked forward to a "(chemical) means of killing parasitic particles in living tissue without at the same time destroying its own integrity". I am sorry to say that he regarded Koch, who identified the tubercle bacillus seven years later, not as the great man who had brilliantly confirmed his views, but rather as one who had merely done what he was told, and that without acknowledgment. He was an interesting personality; he wrote a book which showed that Bacon wrote Shakespeare, and he wrote "blackguards" across a notice, still preserved, from the Medical Society of Victoria, and returned it. The incident indicates why his more elaborate literary compositions failed to meet with the reception which they undoubtedly deserved even in his own country.

A more influential man in his day was J. T. Rudall, F.R.C.S. (1828–1907), who has already been mentioned in connexion with tracheotomy. Rudall went to Melbourne in 1858, having graduated from St. Thomas's Hospital, and having spent some time on an expedition in search of Sir John Franklin. He was a competent pathologist and microscopist; he prepared a section of the diphtheritic membrane from Mrs. Dewar's child and showed it to the Chief Justice, among others. He is best known as "the father of Australian ophthalmology", a title to which his numerous publications, his operative skill in this field, and the fact that he was the first person known to have used the ophthalmoscope in Australia, all give justification. He was also the first in Australia to perform amputation through the hip-joint (1868), and the first to do the operation of gastrostomy (1867), assisted on this occasion by W. C. Rees, one of the first Melbourne graduates. Prior to the latter operation, he passed an œsophageal bougie in an attempt to overcome the obstruction, and he examined the material on the end of the bougie for cancer cells. This must be a very early attempt at diagnosis by means of "exfoliative cytology". Incidentally, the result was a "false negative". His sound consistent work, which included much for medical organizations and public hospitals, spans almost the whole half-century which we are considering, and he may well be chosen to epitomize the progress in surgical practice in Australia over this period. He is notable also for his restraint in controversy in a medical community where this quality was not always to the fore, and where, as Osler remarked "differences and dissensions seem lamentably common".

Earlier, reference was made to the men who made it possible for Australian medicine to stand "upon its own feet" at a comparatively early stage of national development. Two of these men must serve as representative of a much larger group. Seven years after the establishment of a University, little more than a decade after Victoria became independent of New South Wales, the Melbourne medical school began its work. The project was undertaken at a time of comparative economic depression after the surface and alluvial gold had been exhausted and before more extensive mining operations were producing any profits. Ambitious and courageous from the start, it rejected the advice of James Paget for a three or four year course, and adopted one of almost unheard of length—five years. On the advice of Richard Owen and James Paget, the first professor of anatomy and of physiology and pathology to be appointed was G. B. Halford (1824–1910), formerly of St. George's and Westminster Hospitals, and then lecturer on anatomy in the Grosvenor Place School of Medicine in London, where we also find Benjamin Ward Richardson and Spencer Wells. Halford, among other qualifications, was an outstanding experimental physiologist, and his monograph "The Action and Sounds of the Heart" (1860, when Halford was 36) was an outstanding contribution to experimental cardiology. With this work he became the first man to apply comparative zoological studies to the elucidation of the relationships between function and structure in man. His fascinating and scholarly Inaugural Address (1863) seems to have been written in blank verse, such was the visionary grandeur of his prose—and indeed it well might have been, for he left his audience with a famous quotation from Henry's speech to the English Army on the field of Agincourt. He at least played his part in ensuring that men should "stand a tip-toe" when that day was named. In Melbourne the influence of his teacher led him to support Owen in his battle with Huxley, in which controversy he was most violently opposed by William Thomson. He also erred in some of his contentions in regard to the pathology and treatment of snakebite, but these observations do not detract from his outstanding work in the formative years of the first Australian medical school. How easy it would have been, in a small, remote colony, more rudely practical than cultural or academic in its outlook, to have permitted a lowering of standards and a tradition of easy degrees, such as existed at that time in many famous centres. From such a catastrophe it might have taken decades to recover.

In 1882, a second great man, H. B. Allen (1854–1926), destined to render even greater service to Australian medicine, was appointed to the new chair of anatomy and pathology, Halford retaining the chair of Physiology. Allen was in every sense an Australian for he was born in Geelong (Victoria) and educated at Melbourne Grammar School. He graduated in medicine at Melbourne University in 1876 at the age of 22. It is difficult to summarize the career of a man with such wide interests and activities and such an immense capacity for work. His contribution to questions of public health and hygiene were vital in the closing years of the nineteenth century; his pathological studies on syphilis evoked world-wide interest; his editorship of the *Australian Medical Journal* for a time, his successful efforts to unite the two factions of the profession at one time represented by the Medical Society of Victoria and the Victorian Branch of the British Medical Association, and his work for a host of congresses and committees testify to his interest in medicine and the medical profession as a whole. Although universally acknowledged a great teacher and the personal creator of a great museum of pathology, he will be remembered most for what can only be described, quite inadequately, as his administrative work for the University and the medical

school. It is only to be regretted that after this auspicious beginning, Australia's first medical school had to wait almost a century before it had chairs in medicine and surgery. Australian medicine was amazingly fortunate to have Allen in Melbourne, Edward Stirling and Archibald Watson in Adelaide, and in Sydney T. P. Anderson Stuart, with his Edinburgh colleagues R. Scot Skirving and Alexander MacCormick, and also J. T. Wilson (later professor of anatomy at Cambridge).

In illustrating the pattern of Australian medical history by reference to the medical conditions of one penal settlement and to public health and medical education in a voluntary settlement much of importance has had to be omitted. In particular, little has been said of Australian contributions to medicine, and of the Australian reactions to new ideas abroad. The random observations which follow are intended to provide a little balance in these respects. Anæsthesia was rapidly introduced, despite a hostile reception in the medical press. W. R. Pugh, a Launceston surgeon, administered ether in 1847, and was closely followed in Sydney by C. Nathan and J. Belisario, and in Melbourne by D. J. Thomas. Thomas read one of the first scientific papers to be presented in Victoria to the recently formed Port Phillip Medical Association, and the manuscript of this is still extant ("On the Inhalation of the Vapour of Æther, with Cases"). Within a few months of the publication of Lister's epoch-making work, William Gillbee, an Edinburgh student, reported from the Melbourne Hospital a series of cases of abscess and compound fracture which clearly demonstrated the value of the new method. The Minutes of the Medical Society of Victoria record that the paper was "very instructive", but none the less it was to be some years before "Listerism" became generally accepted in Melbourne. Richard Tracy, one of the founders of the Women's Hospital (1856) in Melbourne, working from written instructions furnished by Spencer Wells, similarly obtained excellent results with the early cases of ovariotomy in Victoria; the first Australian ovariotomy was performed in 1852. J. H. Webb accurately described the point of maximum tenderness in appendicitis in 1884, five years before McBurney; he also advocated laparotomy for this condition, but the first Australian appendicectomy was apparently not done until 1893. The publications of J. Davies Thomas on hydatid disease, presented in book form in 1884, "remained as classics in English" until the monograph of H. R. Dew (1928). Davies Thomas is also memorable for his assertion, supported by statistical evidence, that ether was a safer anæsthetic than chloroform, but it was about thirty years before the contrary findings of the Hyderabad Commission were refuted for good by E. H. Embley's exhaustive researches on the pharmacology of the two agents. This work was done at Melbourne University, and Embley, with C. J., later Sir Charles, Martin, was responsible for the development of the heart-lung preparation which was later employed so successfully by Starling and by Anrep. Other outstanding observations up to the early years of the twentieth century were Joseph Bancroft's discovery of the parent worm of filariasis and J. A. Thompson's fundamental studies of the epidemiology of plague during the Sydney epidemic of 1900.

Finally, it remains to mention the outstanding contributions made by medical men in Australia in two fields, politics locally, and natural history internationally. As they were among the best educated people in the colonies, and as they probably outnumbered the lawyers and parsons, it is perhaps not surprising that doctors should appear so frequently playing leading roles in community life. Among them were James Palmer, editor of Hunter's works, and W. L. Crowther, Premiers of Victoria and Tasmania respectively during the formative years, but there were many others. Of the doctors' achievements in the field of natural history, where they were presented with a virgin field, suffice it to say that the breadth of their knowledge is rather awe-inspiring to a graduate of modern times.

The Study of Medical History in Australia

We may conclude by referring briefly to the study of medical history in Australia. One of the first historical papers was an admirable survey of the history of surgery by Edward Barker in his Inaugural Address as Lecturer in Surgery at the University of Melbourne. The first paper on the history of Australian medicine, by G. T. Hankins, appeared in 1891. I have recently found it possible to list about 500 papers published since that date which are relevant to this theme, and in this remarkable achievement no small credit is due to the generous policy of the *Medical Journal of Australia*, edited by Dr. Mervyn Archdall, which has published the bulk of this material. I am aware of only one society concerned solely with medical history (Section of the History of Medicine, Victorian Branch of the British Medical Association, reformed at the time of Dr. Douglas Guthrie's visit to Australia four years ago). There is a Readership and a Lectureship in Melbourne and Sydney Universities respectively. A most pressing need is for the development of a museum of medical history which covers the period coincident with our national history. A start

has been made within the Victorian Branch of the British Medical Association but progress will be slow. A second need is for manuscript material relating to Australian medicine, and I would be very grateful to learn of the existence of any relevant diaries or letters in this country so that they may be listed in the museum's files.

ACKNOWLEDGMENT

Almost all of this paper is based upon the work of others and I wish to acknowledge this debt. In the particular circumstances of this address I have chosen to give a classified list of references rather than intersperse them throughout the text; the list is not to be regarded as a selected bibliography, since it contains only papers consulted in the preparation of this review.

History of Excision of the Rectum [*Abridged*]

By R. P. WARREN, F.R.C.S.

I PROPOSE to outline the history of excision of the rectum for cancer from 1820, at which time no planned operation was performed, to 1920 when the stage was set for what might be termed the modern era.

In the pre-anæsthetic era Jacques Lisfranc (1790–1847) of Paris was the first to perform a planned operation for cancer of the rectum. Lisfranc's operation was a limited excision of the lower end of the rectum from a perineal approach and was first performed in 1826. A few years later in a paper read before the Académie Royale de Médicine, he reported the results in 9 patients, 6 of whom survived and were more or less continent. This type of operation was performed in England by Hubert Mayo (1796–1852) of the Middlesex Hospital in 1833, and James Wardrop (1782–1869) in 1834, but the reported cases are few compared with those on the Continent. In Berlin Johann Dieffenbach (1792–1847) performed a similar operation in some 30 cases and in his textbook of operative surgery states that all survived the operation and remained well for a year.

With the advent of anæsthesia the circumstances of the operation became easier, but the risk of complications remained, particularly hæmorrhage and sepsis. The écraseur was introduced by C. M. E. Chaissaignac (1805–1879) of Paris to reduce hæmorrhage, but sepsis was formidable until the teachings of Lister gained ground. In 1874 Theodore Kocher (1841–1917), of Berne, introduced excision of the coccyx to improve the exposure and promote freer drainage. (This modification had already been used by A. A. S. Verneuil (1823–1895) in France for operation for imperforate anus.) Richard Volkmann (1830–1889) of Halle described improved results using the antiseptic methods in 1878.

While these advances were occurring on the Continent the position at home seems to be best summed up in the words of Thomas Curling (1811–1888), surgeon to The London Hospital and sometime President of the Royal College of Surgeons. In 1876 Curling wrote: "Excision of the carcinomatous rectum was practised formerly by Lisfranc and Dieffenbach and is resorted to in the present day by several German surgeons. I am unwilling to discourage any attempt to relieve so dire a disease as cancer of the rectum, but knowing the danger that must be incurred from hæmorrhage in the operation, the misery likely to ensue from incontinence of fæces as well as the prospect of early return of the disease, I cannot think that a chance even of a prolongation of life is worth acceptance on the terms offered of such an operation." Henry Smith (1823–1894), assistant surgeon to University College Hospital, was more dogmatic. Writing a few years earlier in a popular textbook of the day he states: "Some surgeons were a few years since in the habit of performing excision of the lower end of the rectum for cancer, but this proceeding must be looked upon as barbarous and unscientific and is now happily exploded from the catalogue of surgical operations."

However, a change was imminent and in 1876 the Royal College of Surgeons set as the subject of the Jacksonian Prize Essay "Treatment of Cancer of the Rectum, particularly as regards curing or relieving the patient by excision of the affected part". The prize was awarded to Harrison Cripps (1850–1923) then aged 26 and Demonstrator of Anatomy at St. Bartholomew's Hospital Medical School. His essay was based on 53 collected cases between 1826 and 1875. The mortality was 20% and the survivors were shown to have their lives prolonged. There was not a high proportion of incontinence. Sepsis, particularly peritonitis, was the main cause of death. All but 3 of the cases were from the Continent. Cripps was subsequently appointed to the staff of St. Bartholomew's Hospital and became a leading exponent of excision of the rectum. His operation is described in his textbook published in 1884, when he had treated 42 cases.

Perhaps unknown to Cripps, William Allingham (1829–1908) had performed his first excision of the rectum in 1874, ten years after he joined the staff of St. Mark's Hospital. Allingham described his operation in his textbook published in 1888. The operations of Cripps and Allingham held the field in England for the next twenty years. Although the technique of the operation was different, the scope was similar, and only suitable for growths in which the upper limit could be reached with a finger.

To return to the Continent, where we left Kocher and Volkmann showing improved results, Paul Kraske (1851–1930) a former assistant of Volkmann and later Director of the Clinic at Freiburg, had used the Kocher operation, but wanted a better exposure to reach higher growths

and to control hæmorrhage more easily. To do this, he made a new posterior approach removing the coccyx and part of the sacrum. The results were read to the 14th Congress of the German Society of Surgeons in Berlin in 1885. The new factor in the Kraske operation, which was based on 2 cases, was the posterior approach, but the Kraske operation does not exist as a set technique, nor did Kraske always do it the same way. This new approach was rapidly taken up by various Continental surgeons who added their own modifications. Julius Hochenegg (1849–1940), later to become Professor in Vienna, brought out the upper cut end as a sacral anus for which he designed an ingenious colostomy belt. Later he modified the operation further; after mobilizing the upper cut end he brought it through the anus, from which the mucosa had been removed. This "pull-through" method now goes by his name.

In 1892 W. H. Maunsell (1847–1895), Senior Surgeon at Dunedin, introduced a new approach to excision of the rectum. In his operation, designed for growths of the upper rectum, the rectum was mobilized through an abdominal approach, and then invaginated through the anus. The growth was excised and the cut ends anastomosed. Robert Weir (1838–1927), Professor of Surgery in Columbia University and an Honorary F.R.C.S., described a modification of Maunsell's operation in 1901. Weir excised the growth through the abdominal incision and then drew the cut ends through the anus, where the anastomosis was done.

Progress at home remained slow. The Kraske operation was performed in 1888 by F. T. Paul (1851–1941) of Liverpool, but even in 1897 the largest series to be recorded consisted of only 14 cases. It was at this time that Ernest Miles (1869–1947) appeared on the scene. Miles had been house surgeon at St. Mark's in 1895, and later was appointed Assistant Surgeon at the Royal Cancer Hospital. After a few years' trial, he considered that the recurrence rate following the various operations then practised for cancer of the rectum was too high. He decided that removing the rectum "as a tube" was insufficient, and that attention should be paid to the field of lymphatic spread. Miles performed his first abdomino-perineal excision fifty years ago, and published the first results in 1908. Two years later he gave a further account of his new operation at the Annual Meeting of the British Medical Association.

Mr. J. P. Lockhart-Mummery, Senior Surgeon to St. Mark's Hospital, had introduced various modifications of the existing operations, and was one of the earliest to perform the abdomino-perineal excision. However he considered that the operative mortality of the Miles operation was too high, and introduced an extended perineal excision which he first performed in 1915. Details of this operation were published in 1920.

At the Section of Surgery of the 84th Annual Meeting of the British Medical Association, both Miles and Lockhart-Mummery read papers describing their particular operations. Another speaker was George Grey Turner (1877–1951), later Professor of Surgery at Newcastle, who described the sacro-abdominal operation, which he had then done seven times. This operation has since been perfected in the hands of Mr. W. B. Gabriel, and is now known as the perineo-abdominal excision.

The year 1920 is a suitable date to conclude this history of excision of the rectum. The abdomino-perineal, the extended perineal and the perineo-abdominal operations had all been evolved. Later years were to see improved results from these operations and the introduction of the synchronous combined excision, and various modifications of the conservative resection and abdomino-anal operations.

Benign Strictures of the Colon

By Peter Boreham, M.Chir., F.R.C.S.

Introduction

In June 1956 an old lady was admitted as an emergency to the Whittington Hospital with large bowel obstruction of some days' duration. She was treated initially by blind transverse colostomy to relieve the obstruction and recovered. Subsequent investigation showed a benign stricture of the colon near the splenic flexure, and this was resected with end-to-end anastomosis and the colostomy closed later. She has done well since then (Case 1). The specimen showed a stricture at the left end of the transverse colon, the rest of the bowel being normal. There was no clue to the ætiology of the stricture either on gross appearance or on microscopy, and her previous history and subsequent course are featureless. After a search, 4 similar cases were found to have been admitted to the Whittington Hospital under Mr. Neville Stidolph in the past six years, and Mr. O. V. Lloyd-Davies has kindly given me the details of a case, making 6 in all. They have the same features, suggesting that they may have a common ætiology: All occurred in females, the youngest being 59, and the eldest 73. None of them had had any history of diarrhœa or other bowel symptoms until the onset of the illness, which had lasted only a few days or weeks before they came to hospital. Each presented as an acute illness, usually with colicky abdominal pain and collapse at the onset, and with diarrhœa and vomiting and, in the case of 3 of them, the passage of blood *per rectum*.

Four cases were treated by resection of the affected colon, one of them in two stages, owing to the presence of obstruction. Another case had a laparotomy, but no resection, and the sixth case was treated conservatively. In each there was a localized stricture of the colon, which appeared to be inflammatory in nature and the outside diameter of the colon was decreased, there being no hypertrophy or thickening of the walls.

The strictures were either in the left end of the transverse colon, in the lower descending colon, or at the recto-sigmoid junction, all places where the colon normally has a small lumen. 2 cases had two strictures each, but in the others there was a single stricture. The longest stricture was about 6 in. (15 cm.) in length but most of them were less than 3 in. (7·5 cm.) long.

There was no question of malignant disease causing the stricture in these cases, 4 of them being proved by resection and histology, 1 by laparotomy and inspection of the stricture and its subsequent resolution; in the last, the stricture disappeared on conservative treatment, as shown on subsequent barium enemata.

Inflammatory strictures of the colon are known to occur in certain granulomatous conditions, notably regional colitis resembling Crohn's disease of the ileum, tuberculosis of the bowel and in ulcerative colitis. In all these there is always a longer history than there was in the cases now presented, there is more general upset and the results of resection are poor.

Crohn's disease of the large bowel is notoriously liable to recur at the anastomosis or elsewhere, giving rise to early or late complications. Neuman, *et al.* (1954) in reviewing 201 cases of regional colitis give a figure of 42% recurrences after resection. Tuberculous strictures of the large bowel are usually associated with long-standing tuberculosis elsewhere, and respond poorly to local resection of the bowel, unless full supportive and chemotherapeutic treatment is given at the same time. Similarly, ulcerative colitis gives poor results when treated by local excision of a short affected segment, the disease usually recurring in the remaining bowel within a few months.

So that clinically, these non-malignant strictures of the large bowel differ from the known inflammatory conditions which give rise to such strictures, both in the absence of previous symptoms and in their smooth convalescence, and subsequent freedom from trouble.

One of the cases died from a carcinoma of the bronchus two and a half years after resection, but had had no bowel trouble in the meantime. The 3 cases that were resected are well and free of bowel symptoms five years, three and a half years, and six months after the resection. The fifth patient remains well, with no bowel symptoms two years after the onset of symptoms from the stricture, which was not resected. The sixth case is well, with no bowel symptoms six years after laparotomy when her two strictures were inspected but not resected.

Case 1.—Female, aged 77.

Admitted in June 1956 with large bowel obstruction. Previous laparotomy elsewhere in March 1956 for acute dyspepsia showed no abnormality. Emergency transverse colostomy performed. Subsequent barium enema showed an inflammatory stricture near the splenic flexure (Fig. 1). This was resected in July 1956 and the colostomy closed later. Uneventful recovery and now free of

FIG. 1.—Barium enema of Case I showing a stricture in the left end of the transverse colon.

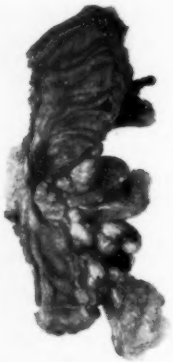

FIG. 2.—The specimen excised from Case I.

bowel symptoms. The excised specimen is shown in Fig. 2. Section showed ulceration of the mucosa with inflammation and fibrosis of all coats of the bowel.

Case II.—Female, aged 73.

Admitted in September 1953 complaining of abdominal pain and vomiting for five days, with diarrhœa for two days. No previous history of bowel trouble. Barium enema showed a stricture in the descending colon. Left hemi-colectomy in October 1953. Uneventful recovery. No further bowel symptoms until she died in January 1956 of carcinoma of the bronchus. Section of the colon showed ulceration of the mucosa with inflammatory changes in all coats of the bowel.

Case III.—Female, aged 73.

Admitted in January 1953 with seven weeks' diarrhœa and colicky pain of sudden onset. Barium enema showed long inflammatory stricture in the descending colon. Left hemi-colectomy in March 1953. Uneventful recovery with no bowel symptoms since. Section showed ulceration of the mucosa with plasma cell infiltration of all coats of the bowel.

Case IV.—Female, aged 62.

Admitted to Middlesex Hospital June 1948 with incomplete large bowel obstruction. Left inguinal colostomy performed for an inflammatory stricture in the sigmoid region. Barium enema confirmed the presence of a benign stricture. Refused operation until September 1953 when the stricture was still present and was resected by Mr. O. V. Lloyd-Davies. Section showed fibrosis only. Further laparotomy required 3 months later for small bowel obstruction due to adhesions, but thereafter uninterrupted recovery and no further bowel symptoms.

Case V.—Female, aged 64.

Admitted in September 1951 with forty-eight hours' colicky pain, vomiting and diarrhœa with melæna. Barium enema showed two strictures, one on either side of the splenic flexure, both appearing to be inflammatory in nature. Laparotomy showed two areas of narrowing and fibrosis of the colon with petechial hæmorrhages. Rest of bowel normal. No suggestion of malignancy. No resection. Recovered; no bowel symptoms since.

Case VI.—Female, aged 68.

Admitted in July 1954. Colicky pain, vomiting and diarrhœa with streaks of blood and mucus for three weeks. Barium enema showed two strictures, one in the lower sigmoid and one near the splenic flexure, each being 3–4 cm. long with tapering ends. Symptoms rapidly improved on conservative treatment, and she has had no bowel symptoms since. Two further barium enemas have been quite normal.

DISCUSSION

Clinical.—All these cases were comparatively fit for their age before the onset of the acute illness which brought them to hospital. There was no history of major tuberculosis in any of them, and none of them had had previous diarrhœa or intestinal upset. One of the cases was anæmic on admission and required transfusion, but although three of them had passed blood *per rectum* immediately before admission, there was no evidence of a long-standing blood loss.

Rectal examination was normal in all cases, but unfortunately not all of them were sigmoidoscoped. The rectal mucosa was normal, however, in the 2 that were, and in the other cases, the mucosa was seen to be normal in the colon either side of the stricture after resection.

X-rays.—The X-ray appearances of these strictures as shown on barium enema, have several features in common. The length of the strictures varies from a few centimetres to a few inches, and most of them would be considered rather longer than is usually seen with a carcinoma, and certainly longer than the short, narrow strictures usually seen in cases of healed tuberculous and ulcerative colitis.

The lumen of the colon at the stricture is, in most cases, between a half and one centimetre in diameter, and it is remarkable that in only one of these cases was an emergency operation required for complete obstruction. The ends of the strictures are, in most cases, clearly tapering and in none of them is there any well-marked shoulder deformity or filling defect, as usually seen with a malignant stricture. As noted above, they all occurred in portions of the colon which are normally narrow. In 2 of the cases small diverticula were present, but in neither case did they seem to bear any relation to the stricture. In all the cases, the colon away from the region of the stricture was normally haustrated and showed none of the "lead-pipe" appearance usually seen in ulcerative colitis.

Pathology.—In the 4 cases that were resected and also the stricture that was inspected at laparotomy, but not resected, the colon at the site of the stricture was reduced in its outside diameter and the wall of the colon was thinned and fibrous and showed no signs of thickening or hypertrophy. The serous coat was reddened and inflamed in each case, and the changes merged gradually into the normal colon on either side. In none of the cases was there much hypertrophy of the colon proximal to the stricture, suggesting that the stricture had not been present for any great length of time. None of the strictures was adherent to neighbouring peritoneal surfaces, and in no case were there more than a few small mesenteric glands.

On histology, the common features were ulceration of the mucosa, infiltration of the submucosa and muscle coats by polymorphs and small round cells, and a variable amount of fibrosis. The vessels were engorged but in all cases there was a striking absence of histological features which would give a clue to the ætiology. There were no giant cells to be seen or any giant cell systems with endothelial cells suggestive of either Crohn's disease or tuberculosis. There were no polypi or pseudo-polypi associated with the strictures in any of the cases, nor any diverticula in the neighbourhood of the stricture. In one case there was a considerable infiltration of all coats of the colon by plasma cells and in another case there is a complete disruption of the muscularis mucosa suggesting that the condition may be traumatic in origin.

On reflection, it seems possible that these cases may have a traumatic origin, certain other features, besides the histology, being in keeping with this. Chief among these is the sudden clinical onset, with colicky pain, vomiting and collapse, followed by diarrhœa and the passage of blood. I think the trauma could be caused by a scyballus passing through the narrower portions of the colon under a greater-than-usual stimulus, either from a purgative or an attack of gastro-enteritis.

Another possible form of trauma in one case was the passage of a gallstone through the narrowed colon, but there is no direct evidence obtainable to confirm this. The benign course of the disease, again, is suggestive of a traumatic stricture rather than a specific inflammatory disease, and so is the lack of surrounding adhesions or signs of associated localized peritonitis.

These arguments are not entirely convincing, however, but in the absence of other obvious ætiological factors, it seems conceivable that such a mechanism may account for these strictures.

Literature.—A search of the literature for reports of similar cases has not been very rewarding. Butler (1953) reported 3 cases similar to mine, which he called "Segmental colitis". 2 of these were treated by resection and 1 had a laparotomy only. All made a good recovery with no recurrence. Thompson (1950) reported one case, in which there was an inflammatory stricture in the proximal end of the transverse colon. The stricture was 5 in. (12·5 cm.) long and presented as an acute illness. Histologically he remarked on the absence of fibrosis in the wall of the bowel.

At the January 1957 meeting of this Section, Mr. Rupert Corbett (1957) reported the case of a labourer, aged 36, who developed a stricture of the colon looking very much like my cases on X-ray, but extending from the splenic flexure to the sigmoid. This portion of the colon was resected with an uneventful recovery and no further bowel trouble. It followed some weeks after a fall on to his left side from a height of 14 ft. There had been generalized collapse at the time, with bleeding from the rectum, and later, he complained of passing ribbon-like stools. It was suggested that this stricture followed either an indirect injury to the colon at the time, or possibly a traumatic thrombosis of the vessels in the mesocolon.

Mr. R. V. Cooke reported two similar strictures, one following six months after reduction

of a hernia, and another after reduction of an intussusception, and he suggested that they were due to venous thrombosis following the trauma.

There is a very large literature on the subject of "Segmental inflammatory disease of the large bowel", and this was well reviewed by Professor Charles Wells in 1952. He distinguishes three conditions, namely regional ileitis, ulcerative colitis and segmental colitis, and he compares the latter to Crohn's disease of the ileum, and remarks on the presence of a "cobblestone" appearance of the mucosa of the colon. He emphatically states that this is not a variant of ulcerative colitis.

Brooke (1954) in his book on "Ulcerative Colitis", and in his numerous other writings on the subject, refers to a right-sided disease, "ileo-colitis", which may occur segmentally; but he lays no great emphasis on segmental disease in the left side of the colon. He says that strictures following ulcerative colitis are most common in the rectosigmoid, and all his cases with strictures similar to those that I am presenting had long-standing diarrhœa, with loss of weight and other systemic upset, and, in fact, all the general symptoms associated with generalized ulcerative colitis.

Neuman and Dockerty (1954) reviewed the pathology of regional segmental colitis. They described it as "a non-specific granulomatous condition, with ulceration and thickening of the wall, occurring both in the colon and in the ileum, and characterized histologically by the presence of tubercles and giant cells".

Neuman *et al.* (1954) reviewed 201 cases of regional segmental colitis, and found that 14 of them had strictures; but each of these cases had signs of generalized disease, namely fever, diarrhœa and loss of weight.

There are numerous other papers reporting large numbers of cases and reviewing the subject of colitis, some of them presenting obvious features suggesting an ætiology similar to that of Crohn's disease and others resembling more closely the usual generalized type of ulcerative colitis. Many of them refer to the occasional occurrence of strictures of the colon, and I have made no attempt to review the whole of this literature. Of those referring to strictures or stenosis of the colon, however, only the 3 cases reported by Butler (1953) the 1 case reported by Thompson (1950) and those mentioned in our January 1957 meeting have, in common with my cases, the absence of any general upset, an acute onset of the disease, localization of the disease to a short segment of the colon, the rest of the colon being quite normal, and absence of complications after resection.

I wish to express my gratitude to Mr. Neville Stidolph for allowing me to operate on Case I and report his other cases, and to Mr. O. V. Lloyd Davies for giving me details of Case IV. Also to Dr. S. Robinson who reported on most of the specimens and Dr. Gordon Osborne who did the barium enemas. I am also very grateful to Dr. Basil Morson of St. Mark's Hospital for much helpful advice and criticism.

Pelvic Abscesses: Diagnosis and Treatment

By HAROLD DODD, Ch.M., F.R.C.S.

SINCE the war, the paradoxical term, "a dying disease", has come into the medical vocabulary. It applies to tuberculosis, osteomyelitis, pneumonia and rickets. Impressions are often erroneous and I was tempted to regard pelvic abscess as a dying disease, until I looked up my records and found that whereas before the war (i.e. before antibiotics and sulphanilamides were available) I saw four a year; to my surprise, since the war I have treated three such abscesses a year. Thus, pelvic abscesses are still with us in general surgical practice. Further, they are missed often enough by registrars and residents for your Council to believe that they merit review in a short paper. There are few operations more satisfactory than that of draining a pelvic abscess through the rectum.

Collections of pus in the pouch of Douglas or in the rectovesical pouch occur after any abdominal condition, especially infected ones, with or without operation. They especially follow a ruptured appendix, less often a perforated peptic ulcer, partial gastrectomy for a penetrating ulcer, salpingitis, hysterectomy or suppurative diverticulitis, and very rarely after infective arthritis of the hip. Of every 4 cases, 3 are caused by suppurative appendicitis with peritonitis, while the fourth is due to one of the other causes, especially perforated or

penetrating peptic ulcer. Rarer cases are after anterior resection of the recto-sigmoid, and infection from Crohn's disease tracking down from the terminal ileal peritoneal fold.

A pelvic abscess may follow appendicitis, treated by operation or medically. One large abscess treated contained three pints of pus; it complicated appendicitis treated by aureomycin and terramycin. The temperature was swinging, the abdomen distended, and the patient had a moderate degree of diarrhœa which was thought to be due to the antibiotic. The period of three weeks and three days which passed without it rupturing is noteworthy; he had been ill four days before admission to hospital (Fig. 1).

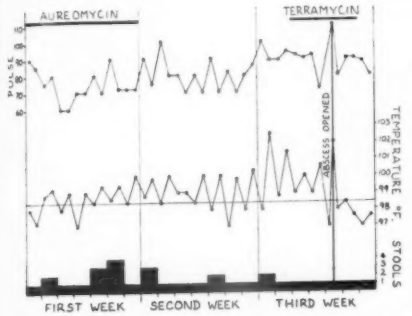

FIG. 1.—The chart of a man with appendicitis treated medically. The opening of the appendix abscess resolved his attack.

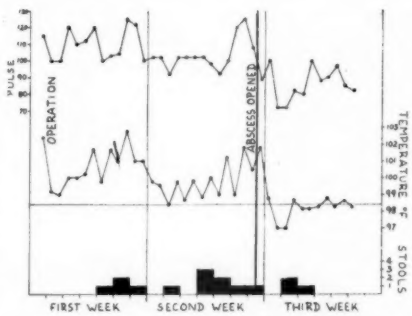

FIG. 2.—A pelvic abscess following appendicectomy. It ruptured spontaneously on contact with the examining finger.

Diagnosis.—The diagnosis of a pelvic abscess is based on the awareness of its possibility after any infected abdominal procedure, the temperature, diarrhœa and the rectal findings. The symptoms at first seldom direct attention to the rectum. The usual story is as follows:

After an infected abdominal operation, the chart shows a raised pulse and pyrexia for three to seven days. Then a normal temperature for one to three days, after which it starts to swing again. The pulse is in the 80 to 100 bracket and the respirations are unaffected, which tends to negative a subphrenic or respiratory infection, which are possible causes of pyrexia. The patient looks toxic. The tongue is moist, pointed and often shiny and bright red; a glossitis, which I have learned indicates undrained pus.

The bowel action.—After two to three days of further pyrexia, tenesmus and frequency and looseness of the bowels appear—perhaps two to four actions daily of fluid fæces, usually with an excess of mucus. This is regarded as satisfactory, as it follows the constipation usual after an abdominal operation. Occasionally the bowels continue inactive, or act once a day.

The abdomen is slightly distended in the lower half, and muscle tension is a little increased. The respiratory excursion below the umbilicus is absent, or even reversed. There is tenderness in the right iliac fossa, and the wound is often infected. As the pelvis fills, pus ascends on the left side, and tenderness appears here. In a thin patient, visible peristalsis is sometimes observed, which raises the possibility of post-operative subacute intestinal obstruction; this suspicion is strengthened when, as occasionally happens, the patient vomits. I think, however, that if there is the possibility of "pus somewhere", this should be sought before considering an organic intestinal obstruction.

Frequency and dysuria.—In the male it is readily understandable that with the bladder forming the boundary of an abscess, uneasiness, frequency, urgency and difficulty of urination will occur and may be the main complaint.

Rectal examination.—The diagnosis of a pelvic abscess is clinched by a rectal examination. The findings are according to the development of the abscess when the examination is made. Three stages may be found:

First stage: "The early and suspect phase." The rectum is empty, dilated, warm, and the mucous membrane is smoother than usual. At the tip of the finger, the rectal wall anteriorly and laterally is hard and indurated. There is no fluctuation, and the impression formed is that the dilated rectum is "set in felt".

Second stage: "The abscess is declared." A day or two later, a significant addition appears; it is the first sign of softening of the rectal wall, and the abscess will point through it. At the tip of the examining finger on the anterior wall, a dimpling or fluctuant spot is felt.

The sensation to the pulp of the finger is identical with that of palpating the tip of the nose, where there is a soft spot between the cartilages. The abscess is drained through this dimpling spot. The reflection of the peritoneum is a finger's length from the anus and it is necessary to press up firmly over the swollen valve of the rectum to reach the abscess.

Third stage: "The abscess is obvious." The fluctuating mucous membrane is bulging into the bowel lumen and there is an obvious abscess pointing into the bowel.

Fourth stage: The abscess may rupture. Spontaneous rupture of the abscess should rarely occur (it should be detected clinically before this). The pus bursts into the rectum, and is passed into the bed-pan after an urgent call to stool. Rupture, however, may not occur for two to three weeks.

Unusual presentations.—There are three unusual presentations of pelvic abscesses: First, a gluteal abscess: as the abscess points into the rectum it infects the pelvic cellular tissue. Ordinarily this is so indurated that spread is limited, but in a debilitated patient pus may track outwards and downwards through the sacro-sciatic foramen and point at the fold of either buttock. The process is a painless one, and in a patient who is not progressing and who obviously has "pus somewhere" vigilance is necessary to detect such a collection. I have seen this twice.

The second possibility is the abscess which tracks along the round ligament or the vas deferens and points in the groin at the pubic tubercle. I have had 3 patients with this presentation, and the abscess needed opening three times in one.

The third route is through the vaginal fornix. I have seen two in thirty years, and both followed a ruptured ectopic gestation.

Treatment: opening a pelvic abscess.—It is *in*advisable to open the abscess in bed, although occasionally one's finger penetrates the bowel wall effortlessly (Fig. 2). The patient is anæsthetized, placed in the lithotomy position and catheterized. I once mistook a full bladder for a pelvic abscess and withdrew urine with the aspirating needle.

The operation.—A duckbill speculum is inserted into the anus taking care not to tear the anal mucosa. The rectum is usually empty, but if not, it is cleansed of fæces. The dimpling or fluctuating spot on the anterior wall is located with the tip of the left index finger, and a long wide-bore needle attached to a 20 c.c. syringe is thrust resolutely through this softened area in the rectal wall; pus appears on aspiration. A hesitant approach may impale the mucosa on the needle point and fail to enter the abscess. If no pus is found, the point of insertion of the needle is checked to see that it really has penetrated the rectal wall at the fluctuating area. If no pus is withdrawn, the operation is stopped. When pus is located, the syringe and needle are kept in position. A pair of uterine dressing forceps, whose points are grooved on the inside, are slid along the needle through the rectal wall and into the abscess cavity. Pus emerges, often considerable in volume and smell. As the flow slows, the forceps are opened in a north-and-south and east-and-west direction, making a generous hole in the rectal wall. I no longer insert a drain, and patients have done well. I once used a pair of Mayo scissors to open an abscess, and a gross hæmorrhage followed which exsanguinated the patient, and required a second operation and a transfusion two hours later. I think I cut a vessel in the rectal wall while opening and closing the scissors. No incidents have occurred since using the uterine dressing forceps.

After-care.—A glycerin suppository is inserted into the rectum daily for four days. The pus is cultured for its sensitivity and if necessary the appropriate remedy is given; very rarely actinomycosis will be found, but as a rule, the temperature falls immediately the abscess is drained. Hæmoglobin estimation often reveals a surprising degree of anæmia and this is corrected. No patients have died.

DISCUSSION

In the ensuing discussion instances were given of pelvic abscesses rupturing into the bladder, following the psoas sheath in the thigh, and penetrating levatores ani and pointing in the ischio-rectal fossa.

The President recounted 2 patients with undetected pelvic abscesses complicating carcinoma of the ovary and uterus. Examination under an anæsthetic is valuable.

The development of acute intestinal obstruction with pus in the pelvis was cited.

The use of antibiotics in preventing and treating residual abscesses was discussed but opinion favoured drainage whenever pus was detected.

MR. A. LAWRENCE ABEL and Mr. H. GORDON UNGLEY
showed a coloured talking film entitled:
Hæmorrhoids or Piles and the Early Detection of Rectal Cancer.

Section of Dermatology

President—LOUIS FORMAN, M.D., F.R.C.P.

[*March* 21, 1957]

Dermabrasion

By J. S. PEGUM, M.D., M.R.C.P.

DERMABRASION is a technique of considerable if not of respectable antiquity. As Burks (1956) points out the Ancient Egyptians probably used pumice and alabaster for this purpose. The modern form of dermabrasion was introduced and developed by Kromayer (1905) in Germany. In the United States abrasion became popular after Iverson (1947) had introduced the sandpaper technique; later Kurtin (1953) revived and popularized the Kromayer technique of using rotating machinery to produce what Kurtin described as "Corrective Surgical Planing of the Skin". In England, on the other hand, dermabrasion has lagged behind and tends to be treated with suspicion.

I started planing in 1954 after the technique had been introduced at the London Hospital by my senior colleague Dr. Brian Russell. In all I have done 41 planings on 24 patients. These are small numbers compared with those of Kurtin and of Burks in America, both of whom have reported series of 1,000 planings. The apparatus which we use consists of an electric motor capable of 18,000 r.p.m., the speed of which can be varied by a foot-operated rheostat. The drive is through a flexible cord and a ball-bearing mounted handpiece, which carries the abrading instrument, a toothed wheel made of steel (Eller and Eller, 1956). The skin is frozen with a spray of Arcton (or Freon) to produce local anæsthesia and a firm surface for abrasion. Arcton (or Freon) is a mixture of fluorinated hydro-carbons; its local effects are similar to those of ethyl chloride but it has the advantage of being non-inflammable and non-toxic.

Conditions for which I have used this technique are as follows:

Artistic tattoos (3 *cases*).—Two were on the forearms and were removed satisfactorily. The cosmetic results although acceptable to the patients were far from perfect because the flexor aspect of the forearms does not re-epithelialize nearly so elegantly as the face and also because the tattoo material was deeply ingrained. The third case was a dark-skinned West African with a tattoo-mark on the forehead. After planing the skin re-grew quite white; later the pigmentation appeared to be spreading out from the mouths of the hair follicles at which stage unfortunately the patient defaulted. This case, although incompletely reported, illustrates the dangers already well recognized of producing dyschromias in dark-skinned persons.

Accidental tattoos (4 *cases*), produced by the entry of road or coal dirt into breaches of the skin. The tattoos were removed adequately but two cases developed keloids which required further treatment.

Post-acne scarring (6 *cases*).—This is one of the principal indications for dermabrasion. The results show improvement rather than cure. The improvement is gratefully accepted by the patient.

Other scars (1 *case*).—A woman of 50, who had a scar with bridgework on the neck at the site of previous lymph-gland suppuration. The treatment produced improvement.

Nævus flammeus (3 *cases*).—The results are promising but vary from patient to patient and from area to area in the same individual.

Adenoma sebaceum (2 *cases*).—The lesions treated were flattened by dermabrasion.

Lichen sclerosus et atrophicus (1 *case*).—The early result here is distinctly promising. If local cure can be effected by abrasion, it may be a useful treatment in sites where leukoplakia is likely to follow.

Infected sebaceous cyst (1 *case*).—The cyst was unroofed or "marsupialized", the floor becoming part of the external skin. This appears to be a useful treatment. It is similar in principle to using dermabrasion in the active phase of cystic acne.

Chronic discoid lupus erythematosus (1 *case*).—A lesion was planed twice and on each occasion healed well and became covered with normal skin. Unfortunately relapse occurred promptly after each treatment.

Linear nævus (1 *case*).—A lesion was planed twice and on each occasion recurred.

Alopecia areata (1 *case*).—Planing produced no improvement.

Other conditions in which dermabrasion is reported to be of value include rhinophyma, rosacea, freckles, vitiligo and shagreen skin.

I have encountered the following complications: milia, keloids, dyschromia, atrophy of the skin, and (in 1 case) hæmorrhage (fortunately not severe in degree).

On the basis of a limited experience it is not possible to assess accurately the value of the procedure. Probably, however, dermabrasion will remain as a useful treatment for a limited number of conditions and will take its place beside the other physical methods now used by the dermatologist.

Dermabrasion

By PATRICK CLARKSON, M.B.E., F.R.C.S.

THE value of dermabrasion, by wire brushes or by other methods, is disputed. Thus Dr. George V. Webster (1956) of California, in a lecture at Guy's Hospital, stated that the effect of dermabrasion depended on the length of the time of the follow-up; the longer the interval after operation, the worse the result. My own view, based on over three years' use of Kurtin's wire brushes and Eller's abrasive wheels and a longer experience of abrasion by the cruder, now generally abandoned, method of sandpaper is more optimistic (Clarkson, 1949). I believe the failures and adverse results which have been widely seen in the States and elsewhere have been largely due to indiscriminate use of the method under inadequate surgical conditions.

In particular it should be remembered that this technique for the improvement of appearance is only one of a number of techniques which can be used for the same end. The best result can often only be obtained by a combination of abrasion with excision of some lesions, or more often by a general tension of the cheek (as is provided by the standard ridectomy techniques). The question of diagnosis of depth of ingrained dirt, or tattoo pigment, also affects the proper choice of technique. Depth can sometimes only be assessed accurately during the course of planing through the affected area of skin. It not infrequently happens that the whole depth of skin has to be removed. The operator then has to make a decision whether to use a surgical method of closure or to allow healing by marginal ingrowth with a risk of keloid or other formation of gross unsightly scarring. What I would like to plead is that for the great majority of lesions where wire brush abrasion can be of value the operator must be technically capable of supplementing the method by such additional plastic methods as may be necessary for the best results. It is for these reasons that I plead that the method be used only under full operating theatre conditions, not in the inadequate arrangements of consulting rooms.

The use of Freon (Eller and Eller, 1956) and other freezing agents as the anæsthetic also raises important points for debate. Freezing (Smith, 1954) causes intracellular dermal rupture, and Pomerat and Lewis (1953) have shown by tissue culture methods the added burden that this causes to normal healing. Nor do English patients take well to the freezing of large areas of the face; nor can freezing be considered really safe for use near the eyes. For these and other reasons I prefer local analgesia for small areas; a general anæsthetic is preferable for the most extensive cases. I would especially stress the need for repeated abrasion for many of the acne cases. Nor is it necessary to await the disappearance of acute lesions before proceeding to abrasion in acne scars. Indeed the abrasion appears to accelerate the resolution and disappearance of the active lesions. But I must stress that my experience is limited to abrasion of acne scars in the presence of only a few active lesions, not when any diffuse severe reaction is present.

There are also reasonable matters for debate about almost every aspect of the abrasive techniques at present used, about the type of abrasive wheel, the rate of revolutions per minute of the wheel, the type of post-operative dressing, as well as about the range and scope of method. My own view is that dermabrasion is capable of dramatically successful results in a minority of patients (such as small superficial angiomata), and can give a very reasonable margin of improvement to many other patients (such as girls with acne scars, provided it is repeated two or three times); but it can be harmful and has some special complications of its own. This especially holds if it is not used with technical skill.

While minor areas can be successfully abraded under local anæsthesia on an out-patient basis, extensive facial operations can I believe only be safely done under general anæsthesia in an operating theatre with adequate post-operative nursing as an in-patient for two or three days. If these precautions are not observed, the method is likely to fall into the disrepute in England that prevails for it in many parts of America.

Tuberculides.—O. L. S. SCOTT, M.R.C.P.

This is an otherwise healthy young woman aged 26 with a papular, erythematous rash on her face and forearms. The rash has been present on the face for more than six years, and is getting worse. Biopsy taken when she was first seen two years ago showed (Dr. Ian Whimster) "tuberculosis, with the lesions apparently arranged about the hair follicles".

The Mantoux test was positive at a dilution of 1 : 1,000 Old Tuberculin. X-ray of chest showed multiple, small, well-defined opacities in both middle and lower lobes, consistent with a diagnosis of sarcoidosis.

A diagnosis of miliary sarcoidosis was considered, and she was given intensive treatment with streptomycin, isoniazid, calciferol, prednisone and chloroquine. (The last was given since she is extremely sensitive to actinic light.) All these drugs failed to help, and some of them made her feel ill. No improvement in skin or lung has been noted.

In view of the increasing erythematous background to the eruption, a diagnosis of micropapular tuberculide (rosaceous tuberculide of Lewandowsky) was made and approved at another dermatological clinical meeting. Her condition remained unchanged until six weeks ago when she developed a crop of papules on the forearms which resemble papulonecrotic tuberculides. Histology of one of these papules is consistent with this diagnosis (Dr. Henry Haber).

The sudden appearance of these lesions at least five years after her original facial eruption is unusual. I have been unable to find any evidence in the literature of micropapular tuberculides associated with subsequent papular necrotic lesions elsewhere.

Dermal Leishmaniasis.—R. G. HOWELL, M.R.C.P.

Mr. S. T., aged 23, an Indian national from N.W. India, resident in England twelve months. Eight months ago he developed a papule on the dorsum of the left wrist which has increased in size. Five weeks ago a similar lesion began on the left internal malleolus.

On examination.—General health good. On the dorsum of left wrist a raised red-brown granulomatous lesion 3 cm. × 5 cm. On the left internal malleolus a similar papular lesion 1 cm. in diameter.

Investigations.—Hb 106% (16·2 grams/100 ml.). W.B.C. 15,000 (polys. 74%, eosinos. 0%, lymphos. 23%, monos. 3%). Blood W.R. and Kahn negative. Chest X-ray: No abnormality. Scraping: No Leishman-Donovan bodies seen. Leishmanin intradermal test: At 48 hours: papules 3 mm. in diameter; surrounding erythema 10 mm. in diameter.

Biopsy (Dr. H. Haber).—Chronic granulation tissue consisting of tuberculoid structures and diffuse round cell and endothelial infiltration. No organisms or L-D bodies seen.

Comment.—This patient has been resident in an endemic area and the Leishmanin test is positive. No *Leishmania tropica* have been found in scrapings or sections from the wrist lesion. It appears that in older lesions where tuberculoid granulation tissue has replaced the initial reticulo-endothelial cell response to the parasite, *Leishmania tropica* may be difficult to find.

He is being treated by mepacrine injections (0·1 gram mepacrine in 1 c.c. distilled water) into the lesions, which are beginning to resolve.

The **President:** The organism should be demonstrated in section from the soft granulomatous type of dermal leishmaniasis.

Dr. **H. Haber:** I think another biopsy will reveal it from a non-ulcerated area.

Dr. **C. D. Calnan:** I saw quite a large number of these cases in Northern India during the war. I accept the fact that in some cases it is difficult if not impossible to find the organism. The leishmaniasis lesions are sometimes divided into the ulcerative variety, in which organisms are found easily, and this small granulomatous form in which they may be absent.

Sarcoidosis with an Unusual Arthritis.—C. M. RIDLEY, B.M., M.R.C.P. (for J. S. PEGUM, M.D., M.R.C.P.).

H. L., female, aged 26.

This patient was well until 1951. At that time and again in 1952 and 1954 she had febrile illnesses with pain and swelling of the joints and glandular enlargement. Between the attacks she felt well and the glands became smaller; there was residual stiffness in some joints. During the first illness the spleen was felt once. That in 1954 was associated with a dental abscess. Each attack settled within a few weeks without treatment. In 1953 she had a normal pregnancy. Since 1951 she has also had occasional urticaria.

Investigations (1951).—Chest X-ray normal. Hb 67%. W.B.C. 12,200 (polys. 84%, lymphos. 13%, monos. 3%). E.S.R. 64 mm. in the first hour (Westergren). Sternal marrow normal. Paul Bunnell test negative. Wassermann reaction and gonococcal fixation test negative. Agglutination tests for *B. typhosus* and *paratyphosus*, salmonella and brucella negative. Blood culture negative. Plasma proteins: Total 6·9, albumin 4·5, globulin 2·4 grams%.

Biopsy of cervical gland. Marked hyperplasia of lymph node with development of active germinal centres. An intense proliferation of reticulum cells and immature lymphoid cells is present in the pulp of the node. This proliferation is of uncertain nature and might represent either the start of a neoplastic lymphadenopathy or the early proliferative response of normal immunity.

Investigations (1952).—X-ray of feet normal. Hb 80%. W.B.C. 19,400 (polys. 81%, lymphos. 15%, monos. 3%, metamyelocytes 1%). Gonococcal fixation test and meningococcal fixation test negative. Blood culture (4 times) negative. Culture of axillary lymph gland for acid-fast bacilli negative.

Biopsy of axillary lymph gland. Lymph node showing hyperplasia of germinal centres, proliferation of sinus endothelium and of reticulum cells and histiocytes of pulp. Scanty infiltration with eosinophils. This suggests a non-specific chronic inflammatory reaction.

Investigations (1954).—X-ray of hands: Early erosion and sclerosis of articular surfaces. Hb 76%. W.B.C. 11,200 (polys. 82%, eosinos. 2%, lymphos. 10%, monos. 6%). E.S.R. 74 mm. in the first hour (Westergren). Rose's test negative. Agglutination test for brucella negative. Plasma proteins: Total 7·1, albumin 4·2, globulin 2·9 grams%. No L.E. cells found in the blood.

At the end of 1956 a rash appeared on the trunk. The last menstrual period was in January and she is probably pregnant.

On examination.—Looks well. C.V.S., R.S., A.S.—n.a.d. Eyes—n.a.d. L.S.—no glands felt. Joints—limited dorsiflexion of the wrists.

Skin: Keloidal scar at the site of sternal puncture; biopsy scars not keloidal. Back, and to a lesser extent on the abdomen, buttocks, arms and thighs: densely scattered red papules, smooth surfaced, showing a faint brownish discoloration on diascopy and some surrounding diffuse erythema. No dermographism.

Investigations (1957).—Chest X-ray normal. X-ray of hands: Loss of cartilage in the wrist-joints. X-ray of feet normal. Hb 86%. W.B.C. 8,800 (polys. 68%, eosinos. 1%, lymphos. 28%, monos. 3%). E.S.R. 22 mm. in the first hour (Westergren). Plasma proteins: Total 7·6, albumin 5·0, globulin 2·6 grams%. Mantoux test negative. Beryllium patch test negative.

Skin biopsy.—Dermal granuloma consistent with sarcoid. Compact aggregates of large epithelioid cells. No necrosis. Occasional lymphocytes. No doubly refractile material. No acid-fast bacilli seen.

Comment.—At the time of her first two admissions the diagnosis of a reticulosis was made; since the admission in 1954, however, it has been considered more likely that she has either rheumatoid arthritis or systemic lupus erythematosus. She now has sarcoidosis which seems to be limited to the skin.

It may be that the conditions are unrelated, but a connexion between them is possible.

It seems agreed by writers on the subject—for instance Longcope and Freiman (1952) and Cowdell (1954)—that the joints are rarely affected in sarcoidosis apart from the joint pains accompanying associated erythema nodosum. Cases of sarcoidosis and arthritis have, however, been reported. Burman and Mayer (1936) described a case with a synovial biopsy; Castellanos and Galan (1946), Myers *et al.* (1952), Gendel *et al.* (1952) and Laroche *et al.* (1955) described others. All these cases have, however, had evidence of concurrent sarcoidosis elsewhere, whereas in this patient sarcoidosis has appeared in the skin six years after the onset of the illness involving her joints.

It is likely therefore that she shows only an interesting chance association of sarcoidosis and an unusual arthritis.

JOINT MEETING No. 4

Section of Neurology with Section of Psychiatry

Chairman—D. W. C. NORTHFIELD, M.S., F.R.C.S.
(President of the Section of Neurology)

[*May* 2, 1957]

DISCUSSION ON THE TOXIC EFFECTS OF DRUGS USED IN NEUROLOGICAL AND PSYCHIATRIC PRACTICE

Dr. Hugh Garland (Leeds):

Drugs Used in the Management of Epilepsy

It would be of some interest to know how many patients are being treated for epilepsy at any one moment, the incidence of epilepsy, very broadly defined, in Great Britain usually being considered to be about 250,000 persons. Through the kind co-operation of the Leeds Executive Council a group of general practitioners was circularized and information obtained relating to a population of about 300,000. 800 epileptic patients were reported to be under treatment, an incidence of 2·5 patients per 1,000 population. This suggests that the number of epileptics under treatment in Great Britian (population approx. 50,000,000) is about 125,000, which is perhaps only half of all epileptics.

My personal figures relate to a survey of over 2,000 epileptic patients seen in the Neurological Department of the General Infirmary at Leeds, and in private practice, between the years 1948 and 1956. The dominant problems arose in connexion with the hydantoins, the bromides, primidone and the diones. In this group only two examples of barbiturate intoxication were seen, which illustrates the wide margin of safety between the therapeutic and toxic doses of the barbiturates.

The hydantoins.—During the initial stages of treatment the signs and symptoms of intoxication with sodium phenytoin are the result of gastric irritation, giving rise to anorexia, nausea and vomiting, or to individual idiosyncrasy reflected in the skin by rashes which may resemble those of measles or scarlet fever. The former may be avoided by giving the drug after meals, whilst, if small doses are given initially and later increased, the incidence of dermatological complications is said not to exceed 5% (Tullidge and Fox, 1942; Symonds, 1950) and in my experience the incidence has been even less.

The most important toxic phenomena are referable to dysfunction of the cerebellum with resulting dysarthria, nystagmus and ataxia, with or without disturbance of mentation and behaviour. In 31 patients symptoms and signs of this nature occurred and were of sufficient severity to warrant admission to hospital. It was possible in only 4 to incriminate overdosage and in another 3, who developed their disability within the first few days of treatment, individual hypersensitivity seemed to be the predominant factor. The greater proportion, however, had received sodium phenytoin and phenobarbitone or phemitone (Prominal) for many years in unvarying quantities and had developed evidence of toxicity for no apparent reason. This would seem to indicate that either detoxication or excretion varies from time to time in any one individual and may occasionally lead to the accumulation of an excessive quantity of phenytoin. In others it is clear that there is a very narrow margin between the therapeutic and the toxic doses, and 6 patients developed toxic symptoms after their daily intake was increased from 3 to 4½ grains. More rarely the addition of primidone may provoke phenytoin toxicity although the dose of the latter drug is not altered.

Mental disturbances may accompany the cerebellar dysfunction or may occur independently. These vary from drowsiness which is rapidly controlled by amphetamine sulphate, to a confusional psychosis necessitating withdrawal of the drug. One of my patients developed an acute mania and had to be forcibly restrained; this was later followed by prolonged and severe depression, but fortunately such examples must be exceptional.

Spongy hypertrophy of the gums is usually a late complication and though superficially this may resemble scurvy it is probably unrelated to deficiency of ascorbic acid (Hawkins and Meynell, 1956). Symonds (1950) estimated the frequency of this toxic manifestation to be in the region of 15% but my impression is that the incidence is less than that. It may be that a lower figure has resulted from improvement in dental hygiene in recent years, since it has been claimed by Nattrass (1949) that hypertrophy may be associated with dental sepsis; in my experience, however, this is certainly not always true. Gum hypertrophy is reversible and may largely result from œdema; it rarely if ever occurs after the administration of other hydantoins and for this reason Mesontoin may be substituted for sodium phenytoin when gum hypertrophy proves troublesome.

Perhaps the most interesting late toxic effect, and the last to be recognized, is a megaloblastic anæmia. The first example of this was described by Badenoch in 1954. In a recent survey of the subject Gydell (1957) reviewed the problem of megaloblastic anæmia in patients being treated with diphenylhydantoin and primidone; 3 personal cases are described and 14 others mentioned from the literature between 1954 and 1957. All 17 were taking one of the hydantoins with the exception of 3 who were taking primidone alone. The duration of treatment had varied from thirteen years to nine months and the ages of the patients from 17 to 52, 12 being females. It was striking that the 14 quoted from the literature all came from England. What interests me still more is that I find that I first recognized this condition, without appreciating its importance, in 1948.

A woman of 28 had suffered from major epilepsy since the age of 3. For eleven years she had been taking sodium phenytoin grains 4½ and phenobarbitone grains 1½ daily; at one point Mesontoin was substituted for phenytoin because of gum hypertrophy but because of drowsiness the former treatment was resumed. One month before admission to hospital in 1948 she had complained of increasing lassitude. She was found to be anæmic, with Hb 58%, R.B.C. 2,900,000 and C.I. 1·0; a blood film showed macrocytosis, anisocytosis and poikilocytosis, the reticulocytes being less than 1%; the sternal marrow was actively megaloblastic. The gastric juice contained free hydrochloric acid and the split and unsplit fæcal fats were normal. Treatment with Anahæmin 4 ml. intramuscularly every day was without effect. Folic acid 30 mg. by mouth daily was followed by a reticulocyte response and both the peripheral blood and sternal marrow were rapidly restored to normal. Phenytoin had been withdrawn when the results of gastric analysis indicated that we were not looking at pernicious anæmia but six months after leaving hospital phenytoin treatment was resumed and has been maintained, without folic acid, up to the present time without any hæmatological relapse.

Since that time I have had three other examples of anæmia of a similar character resulting from phenytoin, though one of these has also received primidone, and my experience adds nothing, except numbers, to that of Gydell and others (Hawkins and Meynell, 1954, 1956; Chalmers and Boheimer, 1954; Rhind and Varadi, 1954; Webster, 1954; Berlyne *et al.*, 1955; Ryan and Forshaw, 1955). In a few of these recorded examples extensive investigation has shown that the serum B_{12} level and the absorption of folic acid were normal; all have responded to folic acid by mouth and only four to vitamin B_{12} by injection, though in the case of two of the latter the withdrawal of phenytoin may have been responsible for the improvement (Webster, 1954; Ryan and Forshaw, 1955) whilst one other (Chalmers and Boheimer, 1954) may have had coincidental pernicious anæmia.

Girdwood and Lenman (1956) and Girdwood (1956) described a similar anæmia attributable to primidone. They pointed out that phenytoin, primidone and phenobarbitone all have in common with folic acid a pyrimidine ring and they suggested that drugs with this structure might act as competitive inhibitors for some enzyme system involving folic acid as a co-factor. It is therefore important that Hobson *et al.* (1956) have described a patient who developed a megaloblastic anæmia attributable to large quantities of the two barbiturates Amytal (amylobarbitone) and Seconal (quinalbarbitone). In addition, Hawkins and Meynell in 1956 surveyed 159 epileptic patients from a colony and found that only one had a frank megaloblastic anæmia but 36% showed the mean corpuscular volume increased to between 94 and 114 cu.μ; the sternal marrow was megaloblastic in 5 and probably so in 1 other. The highest incidence of macrocytosis occurred in those taking phenytoin and phenobarbitone (45%) but when either phenobarbitone or phenytoin alone had been taken the figure was still in the region of 30%. Since reading their paper I have been carrying out routine blood counts on all patients taking these drugs but my figures at the moment are not significant.

The bromides.—It may cause some astonishment that the bromides should be invoked as a major cause of intoxication in the year 1957 but there is little doubt that many examples of bromism are overlooked as was emphasized by Spence (1957). This condition has been proved in 2% of epileptics seen in private practice though it amounted to less than 0·1% of hospital patients, many of whom were seen by doctors who did not entertain the likelihood of bromism and had in all probability never recognized an example. I have shown elsewhere

(Garland and Parsonage, 1951) how the consumption of bromide in the General Infirmary at Leeds fell from 2,297 lb. in the triennium 1939 to 1941 to only 10% of that level in 1948 to 1950, a trend which was accompanied by a proportionate increase in the use of barbiturates.

Although the bromides have rightly fallen into disrepute in the treatment of epilepsy they are still widely employed in combination with other drugs such as chloral hydrate and gelsemium for a supposed sedative or analgesic effect, which is a fallacy. It is interesting that in the General Infirmary at Leeds the consumption of bromide has remained stationary for the past seven years (100 lb. per annum) but I find that its use is strictly limited to the Department of Dermatology.

It is generally accepted that blood levels of 50–100 mg.% are necessary to produce a therapeutic action and since a dose of more than 50 grains provokes vomiting this level cannot be achieved by a single dose. It has been known for twenty years that repeated small doses of bromide are dangerous. The kidney excretes halogens without discrimination and retention of bromide at the expense of chloride steadily develops. Mental symptoms may appear with blood levels of 160–200 mg.% so that the margin of safety is too small for there to be any therapeutic value in prescribing the drug. Symptoms of intoxication are predominantly mental and consist of a dull headache with depression and slowing up of intellectual processes which may be erroneously attributed to psychoneurosis, and indeed it has been estimated that up to 10% of the inmates of certain American mental hospitals were suffering from no other illness than bromism. It is important to remember that the characteristic bromide rash is found in less than 25% of those suffering from intoxication. Less commonly with more profound bromide poisoning there may be manic psychosis, hallucinosis, dysarthria and ataxia. I have seen 29 examples of bromide intoxication between 1949 and 1957 and only 5 of these were epileptics, suggesting that the uselessness of bromides in the treatment of epilepsy is now fairly widely recognized, though their bogus position in other realms is still unknown or ignored.

There is a lessening of tolerance to bromide with increasing age. One of my patients, a woman of 60, had complained of headache and loss of weight for a month, and had become tearful, abusive and later deluded. The highest level of serum bromide recorded was only 160 mg.% yet when she was given a high salt intake and ceased taking her "medicine" her mental state rapidly returned to normal. This may be compared with a boy of 16 who had taken 15 grains of potassium bromide for several months on account of epilepsy; his mother complained that he was rather "dopey" though otherwise well. His serum bromide level was 225 mg.%, a much higher level than in the first patient but associated with only mild symptoms, as usually obtains in the young. It has generally been considered that levels of much over 400 mg.% are incompatible with life, but I saw one elderly woman who had taken a "nerve" medicine containing 10 grains of bromide for over twenty years and her blood level, at a time when she seemed to be dementing, was 505 mg.%; she made a rapid and complete recovery. It would seem that in the treatment of epilepsy, insomnia or tension states bromides share an equal status with their old contemporaries the leech and the seton.

Primidone (*Mysoline*).—The majority of the toxic effects of primidone, unlike those of the other anti-convulsants, occur during the first few days of treatment and indeed often after the first dose. Anorexia, nausea and vomiting are fairly common, especially if the drug is taken while fasting. Drowsiness is also complained of in about one-fifth of the patients and for this reason it is best to give the first dose in the late evening. Whitty (1953) reported drowsiness in 48 of 70 epileptics treated with primidone, but in only 12 was this sufficiently severe or lasting to necessitate withdrawal of the drug. Fortunately, both the gastro-intestinal symptoms and the drowsiness usually subside within a few days when therapy is maintained and the main problem is to convince patients of this, since many refuse to accept such a prognosis.

Whitty (1953) and Sharpe (1954) have reported acute confusional psychosis, with paranoid features, as a complication of primidone therapy. This is undoubtedly a valid observation but the advent of a psychopathy may not always be attributable to primidone alone. There is a high incidence of psychiatric deviation in patients with lesions of the temporal lobe, with or without epilepsy, and a fortuitous association in such patients treated with primidone must be expected. Hill and Falconer (1953) described 13 patients with epilepsy and psychopathy and in 11 of these there was EEG evidence of a focus in one temporal lobe. A second factor to consider is the phenomenon of convulsion dependence. It has been recognized for some time that psychotics who have occasional fits may obtain benefit from electric convulsant therapy and it is not uncommon to see pre-ictal irritability and tension relieved by the advent of a fit. Under these circumstances the suppression of fits may lead to a worsening of the mental state irrespective of the nature of the drug employed. However, bearing these considerations in mind, a few patients are totally unable to take primidone even in homœopathic doses. One patient, a woman of 22, had suffered from major convulsions, often with rotation of the head and eyes to the right, since the age of 3. She had been

treated with a number of drugs including Mesontoin, phenytoin, phenobarbitone and phemitone, with a very inadequate control of her fits. EEG showed a widespread abnormality without focal features and all other investigations, including air encephalography, were normal. She was given a single dose of primidone 0·25 gram and within a matter of hours developed a confusional psychosis with paranoid delusions; this resolved in thirty-six hours and she remained mentally normal until a second dose of 0·125 gram of primidone was administered, when the previous experience was repeated. In this case the time relationship made it clear that the psychopathy had been provoked directly by the drug. However, after a year in which she had no primidone she became permanently deluded and is now a certified psychotic. One other patient, also a young woman, developed a similar psychopathy with primidone which was not related to fit-suppression.

Many patients become very drowsy when a barbiturate is given with primidone and there seems to be a synergistic effect between these drugs in this respect. Skin rashes of morbilliform type have been reported by Whitty (1953) and Briggs and Tucker (1954) but they are uncommon. Acute primidone poisoning in a child has been reported by Morley and Wynne (1957), the child having swallowed at least fifty tablets. An interesting feature of this case was the appearance of crystalluria and recovery of consciousness was accompanied by temporary ataxia.

The diones.—The strange symptom of visual "glistering", was first described by Lennox in 1947, affecting about 2% of epileptics treated with troxidone (Tridione). This seems to be peculiar to troxidone and when troublesome may be relieved immediately by changing to another dione. It is exceptionally rare in children under the age of 6, perhaps because of their inability to describe the symptom. Another occasional complication is the appearance of acneiform papules over the forehead and face, and more rarely a generalized morbilliform eruption (Lennox, 1947).

By far the most important drawback to the use of the diones is their effect on the bone-marrow. Two distinct forms of blood dyscrasia occur. The first, which is not uncommon, consists of a slow downward drift of the neutrophil count, sometimes associated with a mild increase in the total eosinophils and lymphocytes (Davis and Lennox, 1947; Greaves, 1946; Briggs and Emery, 1949). This, provided it is detected in time by serial blood counts, is not dangerous and the normal white cell count is restored when diones are withdrawn. The second, which fortunately is rare and which I have not yet seen, is the sudden development of an aplastic anæmia with a rapid diminution of the circulating red cells, polymorphonuclear white cells and platelets (Harrison *et al.*, 1946; Mackay and Gottstein, 1946; Braithwaite, 1948; Forster *et al.*, 1949). I believe that all the recorded cases of aplastic anæmia have died of secondary infection and multiple hæmorrhages, together with one example of exfoliative dermatitis, and energetic therapy with hæmatinics, transfusion, antibiotics and the withdrawal of diones seems to be of no avail. Moreover, the condition develops too rapidly for serial blood counts to be of any value. Although only a few examples of this kind have been reported the hopeless prognosis has naturally served as a deterrent to those who would otherwise use the diones. However, I feel that in view of the large number of patients who have taken diones without ill-effect the dangers have perhaps been overemphasized. Often patients with *petit mal* may be treated with other drugs such as Diamox or amphetamine with a measure of success, and other mild cases frequently require no treatment at all, but when fits interfere with the education of a child or later with employment it may be essential to effect control with one of the dione group.

Some authorities (Lennox, 1945; Whitty, 1949; Symonds, 1950) have indicated that the suppression of *petit mal* with diones may provoke major seizures. My registrar has recently made a survey of 70 epileptics in whom EEG showed a rhythmic, bisynchronous, 3 per second, spike-and-wave abnormality. In over half of these, classical *petit mal* was associated with some other seizure pattern. These latter may either precede in time the onset of *petit mal* or alternatively follow after varying intervals and there would seem to be no statistical evidence for the belief that diones are responsible for the major fits that so often occur.

Conclusions.—Bromides should no longer play any part in the treatment of the epilepsies, being the least effective of all anti-convulsants and carrying a high toxicity rate, with lethal possibilities. The barbiturates are the least toxic of all anti-convulsant drugs and are still the first choice in the treatment of major, temporal lobe and other focal seizures. The hydantoins and primidone, alone or in combination, may succeed when the barbiturates have failed but they produce toxic reactions, though these are usually not serious if recognized early. The diones are perhaps the most valuable drugs in the treatment of *petit mal* but their toxic complications are serious and sometimes fatal and their use should probably be restricted to those patients having large numbers of minor attacks daily. Finally, it would seem that hæmatological changes of major or minor import are probably much commoner than has yet been suspected when using any of the modern anti-convulsants.

Dr. David Stafford-Clark (York Clinic, Guy's Hospital):

Bromides.—In psychiatric practice most of the indications for which bromide is given—and these include states of acute grief and agitation on the one hand, and chronic disturbances of sleep rhythm on the other—are likely to be made worse rather than better, if the administration of this drug is continued for any length of time. This is particularly true when it is given to old people; and I would endorse a categorical veto on the exhibition of bromide to anyone over the age of 60, for any purpose whatever.

At the Maudsley Hospital we used to make serum bromide estimations as a routine on all patients admitted to the hospital, regarding a level above 200 mg.% as potentially toxic. Certainly, concentrations at and above this level can produce a state of confused drowsy irritability by day and disturbed paranoid and hallucinatory alarm and apprehension at night, in just those old people whose early senile dementing changes may have led to the administration of what was believed to be a safe and mild sedative over a period of several weeks.

Barbiturates.—Another stand-by whose use in psychiatry threatens to be equally abused is phenobarbitone. My own view is that there are only two really justifiable indications for phenobarbitone in psychiatric practice; the symptomatic alleviation of anxiety by small doses, regularly spaced; and the selected exhibition of a single 1 grain dose at 9 p.m. every evening for a month, as a trial therapeutic measure in the control of migraine, when this is allied to persistent emotional or environmental tension. It is only fair to add that this latter indication is borrowed from what was standard practice at the National Hospital, Queen's Square, when I was a registrar there.

All other occasions on which phenobarbitone is apt to be prescribed would probably be better met by an exhibition of other drugs. In particular, phenobarbitone should be rigorously avoided in all cases where there is an element of depression, since it undoubtedly tends to make depression worse, and can occasionally exacerbate it to the point of suicidal intensity. The dosage in anxiety states should not exceed ¼ grain t.d.s., and if phenobarbitone in this modest quantity is not sufficient to control symptoms, other drugs such as Sodium Amytal or Equanil should supplement or replace it. The practice of prescribing doses of ½ grain t.d.s. or even 1 grain b.d. in psychiatric conditions is in my view obsolete and essentially unprofitable.

Quick-acting barbiturates are of course extremely useful in psychiatric practice, and are

also reasonably safe, provided that they are not prescribed in undue bulk. Their chief toxic effects include:

(1) The risk of addiction, never to be overlooked, since addiction to barbiturate is by now probably the most common form of dependence on drugs in Western civilization.

(2) The additive effect when barbiturates are taken at the same time as alcohol; this has been suggested as a potentiating or synergistic effect, and has on occasion proved fatal when the dosage of barbiturate has not exceeded 9 grains of Sodium Amytal, and of alcohol, two large gins.

(3) Disturbance of glucose metabolism, both in the direction of hypo-and hyper-glycaemia, with a concomitant disturbance of vitamin B metabolism; both of which can be corrected by giving large doses of vitamin B when any barbiturates are prescribed for any length of time.

Amphetamine derivatives.—The wide use of Benzedrine, Dexedrine, and other amphetamine derivatives has made most of us familiar with the common clinical toxic effects which these very useful preparations can produce. They include anorexia of pathological degree, a tendency to hypertension, and once again the risk of addiction. This latter is perhaps less well recognized than the corresponding risk with barbiturates, but may not be much less common. One patient who was taking between 500–700 mg. of Dexedrine every day developed this addiction after being successfully weaned from alcohol, to which he had formerly been addicted, and put on to Dexedrine by his family doctor. Curiously enough, the only untoward symptom which this colossal dependence seemed to produce was a spontaneous tendency to fall asleep if he was without the drug for more than an hour or two.

However, there are other and far more ominous toxic effects which may be observed from time to time. Acute confusion and disorientation can occur when large doses of Dexedrine are combined with alcohol in purely social proportions; and Dr. P. H. Connell (1955) of the Maudsley Hospital has made some extremely interesting observations on acute psychotic episodes arising in the course of Dexedrine addiction and overdosage. Our own experience of toxic psychoses of this kind at Guy's has included 3 cases of acute paranoid delusions and hallucinations, with a marked strain of outright terror, and a constant urge on the part of the patient to escape from the delusional and hallucinatory pursuers. It is of some interest that 2 of these 3 cases were doctors' wives, and the third was a nursing sister. Psychotic reactions of this kind tend to settle down very rapidly once the drug is completely withdrawn, but produce sufficient disturbance during the withdrawal phase to require expert supervision, preferably in hospital.

The tranquillizers.—The number and complexity of drugs recently put on the market with the general object of producing varying degrees of subjective calmness, tranquillity, and detachment from sources of emotional stress, whether endogenous or exogenous, but without producing drowsiness or sedation in normal dosage, is legion. We have tried most of them in my Department, and while it would be invidious to mention those which appear to have no beneficial action whatever, and to produce in fact nothing but toxic side-effects, it may be helpful to mention some of the more generally useful preparations, whose toxic effects are usually avoidable provided effective supervision is maintained over dosage. These include:

(1) Largactil (chlorpromazine), Notensil (acetyl promazine), Sparine (promazine)—all phenothiazine derivatives.

(2) Rauwolfia, and associated alkaloids, including reserpine and *Rauwolfia serpentina.*

(3) Equanil (meprobamate) a propanol derivative.

(4) Frenquel and Meratran, two useful benzhydrol derivatives.

The first group of drugs are well known for their proven tranquillizing effects, particularly in states of excitement following withdrawal of other drugs; their clinical toxic effects include drowsiness, tachycardia and postural hypotension in moderate excess, with jaundice and Parkinsonism as more serious signs of overdosage or sensitivity. Less well-known complications can include an induced hypersensitivity to ultraviolet light, making sunbathing potentially dangerous in patients saturated with these drugs, and a lowering of the levels of vitamins B and C in the serum. This latter complication, like that attendant on barbiturate administration, can be prevented by concomitant administration of adequate vitamin supplements.

The toxic effects of the rauwolfia derivatives also include jaundice and Parkinsonism, the latter appearing relatively early; but the single most important clinical disadvantage is that drugs of this group are extremely depressing, and have certainly precipitated suicide in already depressed patients on more than one occasion. This complication can only be effectively avoided by careful selection of patients in the first instance, constant supervision

of response, and occasional concurrent administration of Ritalin, a piperidine derivative with a similar action to amphetamine preparations, but without their hypertensive effect.

Equanil is singularly free from toxic effects, although the possibility of blood dyscrasias in sensitive patients has been raised. I have never seen any; and in my own experience this drug, properly used, is without disadvantages.

Meratran has a similar effect to amphetamine compounds, but is certainly capable of increasing anxiety; it does not belong among the tranquillizers on its own account but is included because of its very close structural relationship with Frenquel. Frenquel is the gamma-isomer of Meratran and is of interest in being the first commercially available substance which can be used to block the hallucinatory effects of known hallucinogenic drugs, when given before their administration, or in some cases even when given afterwards. In the light of the theory put forward by Hoffer *et al.* (1954), the possibility that Frenquel might mitigate or control comparable symptoms of schizophrenia has held out hopes which remain as yet unfulfilled. No toxic effects have been reported from it.

Hallucinogens.—These include such substances as mescaline, lysergic acid diethylamide (L.S.D.), cannabis indica, and adrenochrome, and have been used chiefly in the investigation of the temporary psychoses, which can be induced by their administration. Two of these, cannabis indica and L.S.D., are currently in use as therapeutic agents; cannabis indica in some work we are doing at Guy's in the treatment of depersonalization, L.S.D. in some recent studies of the relief of chronic mental conditions at Powick Hospital. It is possible that all these drugs have in common a capacity to affect synaptic transmission throughout the central nervous system, but particularly in the cerebral cortex, and may produce their toxic effects by an extension of the physiological mechanism whereby adrenaline is presumed to produce changes in levels of awareness and interpretation of reality, by direct effect upon the brain.

Dr. M. Weatherall (Department of Pharmacology, London Hospital Medical College):

I shall consider mainly some less well-known toxic effects of certain barbiturates, and the principal effects of the most recently introduced central depressants, the tranquillizers of various kinds. The relation between barbiturates and porphyria has often been put forward but never well supported, and it has been suggested that there is no connexion, or that barbiturates are capable of precipitating attacks in persons who were in any case porphyrics or that some cases of porphyria were a consequence of unusual sensitivity to barbiturates. Experiments in animals have generally yielded negative results, but recently Goldberg (1954) has shown that certain barbiturates are particularly potent in promoting the excretion of coproporphyrin and uroporphyrin in rabbits and that the chemical structure of the individual barbiturate is important in this context. Activity is much greater in barbiturates containing an allyl group, as in quinalbarbitone (Seconal) and allylisopropylbarbituric acid (Alurate), and still greater when two allyl groups are present, as in allobarbitone (Dial). This observation brings the effect into line with the porphyria which may be precipitated by the hypnotic Sedormid, also an allyl compound, but it does not lead to any correlation between activity on the nervous system and porphyrin metabolism, because allylisopropylacetamide is as potent as Sedormid and allobarbitone in disturbing porphyrin metabolism, but is devoid of hypnotic activity. The available evidence suggests that the excess porphyrin is produced in the liver and that the effect is in no way neurotoxic.

Another toxic effect, both of barbiturates and of most of the tranquillizers, is a drug rash. Skin eruptions of various kinds have been reported after chlorpromazine (Lehmann and Hanrahan, 1954; Lomas *et al.*, 1955), reserpine (Sariver-Foner, 1956), meprobamate (Selling, 1955; West and Fonseca, 1956), mephenesin (Wolf and Pinsky, 1954), and even methylpentynol (de Lamater, 1952). The incidence of such rashes is usually between 2 and

3%, and they commonly appear at the beginning of medication. It seems important to note that they have also been observed after administration of placebo tablets, containing such a pharmacologically innocent material as lactose. Thus Wolf and Pinsky (1954) treated 31 patients with various kinds of anxiety state alternately with lactose and mephenesin: the trial was a properly conducted double-blind in that neither physician nor patient knew when the dummy was being given, and it yielded three toxic reactions including an angioneurotic œdema and a skin rash, diagnosed as a characteristic dermatitis medicamentosa, both precipitated by the administration of lactose. The series is rather small, and more observations of this sort are most desirable, but it suggests that, particularly with the kind of patients to whom sedatives are commonly administered, caution is desirable in the interpretation of symptoms suggestive of a toxic origin. It does not, of course, mean that skin eruptions occurring after any of these drugs are never directly related to the drug administered, but it limits the value of estimates of the incidence of toxic effects, since they will be much affected by the kind of patient being treated. Just as the therapeutic value of a drug requires to be demonstrated by a blind therapeutic trial, unless the effect is very striking, so estimates of the incidence of toxic effects are liable to be misleading except when they are based on observations properly controlled by the administration of dummy tablets to a sufficient proportion of the group being treated.

All these reactions to barbiturates, however, make a very small contribution to the total loss of life caused by these drugs, which accounted for over 500 deaths in 1954 (Brooke, 1956) and perhaps ten times as many hospital admissions (Locket, 1956). Most of these deaths and intoxications were suicidal, but they were only possible because sufficient amounts of barbiturate had been made available on prescription to these patients. It seems impossible to assess whether all or any of these deaths would have occurred by other means if barbiturates had not been available to the persons concerned, but it is reasonable to suppose that the ease of this method of suicide contributed to the incidence, and to regard less liberal prescribing as desirable. In some of these cases, ethyl alcohol has been regarded as a contributory agent, and the term potentiation commonly appears. It is convenient to distinguish between potentiation and simple addition or summation of the actions of two drugs. If the dose of one drug necessary to produce a given effect is A, and the corresponding dose of another is B, and if the effect can be produced by a total dosage less than $\frac{1}{2}A+\frac{1}{2}B$, then potentiation has occurred; if the effect is just produced by $\frac{1}{2}A+\frac{1}{2}B$, the drugs are additive, and if more than $\frac{1}{2}A+\frac{1}{2}B$ is required, the drugs are to some extent antagonizing each other. Alcohol, like barbiturates, depresses the respiratory centre and in acute poisoning by any of these drugs death occurs from respiratory failure. There is no evidence that the agents either potentiate or antagonize each other, and half a lethal dose of alcohol and half a lethal dose of barbiturate are together lethal (Ramsey and Haag, 1946). Reported cases of death occurring after ordinary therapeutic doses or not greatly excessive doses of a barbiturate have generally been accompanied by very high concentrations of alcohol in the blood (Fisher *et al.*, 1948).

As alternatives to the barbiturates for some purposes there are the so-called tranquillizers of various kinds. Their appearance has coincided with much activity in studying the pharmacology and biochemistry of the central nervous system, and new facts are being discovered so rapidly that it is not easy to make a coherent picture about them. At present, the tranquillizers are a very unhomogeneous group of substances which differ in potency, and chemically, and pharmacologically. The most potent, and most complicated, are reserpine and chlorpromazine. Both, and particularly chlorpromazine, have a variety of dissimilar actions, mainly in the central nervous system. It is unusual for a drug to have fundamentally more than one or two actions, and this suggests that they act on some mechanism common to a variety of nervous pathways.

In the peripheral nervous system the synapses are particularly susceptible to the effects of drugs, and it is tempting to regard reserpine and chlorpromazine as drugs which modify transmission at central synapses of some kind. There is not much convincing evidence about the identity of central transmitters, but there are grounds for including acetylcholine, noradrenaline, and 5-hydroxytryptamine among the possible agents, as all these substances have characteristic localizations in the brain and show some fluctuations in concentration in relation to different physiological states. 5-hydroxytryptamine is particularly interesting because most of the hallucinogenic drugs, such as lysergic acid diethylamide, antagonize it, and reserpine liberates it from most of the sites in the body where it occurs. Some of the effects of reserpine may be due to the liberated 5-hydroxytryptamine, which can itself act as a central depressant, or to impaired function of the cells which have been depleted; but it is relevant that reserpine liberates other pharmacologically active bases from tissues as well. In the same way it is possible that chlorpromazine, and indeed all the antihistamines with central depressant effects, act on synapses where, perhaps, noradrenaline is the transmitting agent; but considerably more evidence is necessary than is at present available to justify such a hypothesis. From the point of view of toxic effects, the main dangers of chlor-

promazine lie outside the central nervous system, in causing jaundice and agranulocytosis, and there is little explanation of the way in which these events occur.

Of the milder tranquillizers, meprobamate (Miltown, Equanil, Mepavlon) and mephenesin (Myanesin) act by depressing polysynaptic reflexes (Berger, 1954) perhaps in a manner like but opposite to the effect of strychnine. There is no reason to relate their action to any known chemical transmitter. They are characterized by a very wide margin of safety, and there are individual reports of doses up to 40 grams in twenty-four hours being tolerated; so it does not appear that they affect any particularly vital mechanism.

Methylpentynol (Oblivon) is one of the higher alcohols, and its effects are much less specific and are closest to those of ethyl alcohol and the barbiturates. Probably it acts in the same way as ethyl alcohol, but it is more rapidly metabolized and small differences between it and ethanol in the rate at which the concentration rises and falls in different parts of the body may be responsible for the appearance of different symptoms. In view of its usually rapid inactivation it is curious that many of the toxic effects which have been described (May and Ebaugh, 1953; Marley and Chambers, 1956) have followed the intake of only moderately large doses (1–2 grams per day) for a few days. The symptoms are not very specific: Marley and Chambers describe nystagmus, diplopia, ptosis and muscular incoordination, and variation in mood, usually towards depression: the symptoms abate fairly rapidly on withdrawal of the drug. At the normal rate of inactivation, cumulation of methylpentynol would not be expected in these conditions, and estimations of its concentration in the blood when these symptoms occur would be useful in understanding how they arise.

The question arises as to whether harm may result from prolonged use of these drugs, particularly when they are self-administered. The matter has received considerable public attention because some of the tranquillizers have been, or are, freely available and are evidently being consumed somewhat indiscriminately. It is very difficult to decide what harm is accruing in this way. So far little direct physical damage has been reported, and the problem of control would be simpler if all the tranquillizers caused agranulocytosis as often as does amidopyrine: but the passage of time may bring more evidence of this sort. Some disturbances of behaviour have been reported, such as driving cars into buses, or motor cycles into walls or submitting to seduction by strangers (Pratap, 1956), but controlled studies are particularly lacking in these circumstances and it is very uncertain whether some of the events described would not have occurred without the intervention of a tranquillizer. On the face of the evidence behavioural disturbances are no worse than those produced by alcohol, and alcohol is almost certainly responsible for more road accidents than all the tranquillizers put together. And the possibility of dependence, habituation or addiction is an unassessed risk. Addiction has been reported, for instance, to meprobamate (Lemere, 1955) but mostly in patients who were receiving treatment for previous addiction to alcohol. The risk of addiction depends on the drug and the patient: the milder the central depressant action of the drug, the more important is the personality of the patient, and drugs which have no more powerful action than one of producing tranquillity are likely to be addictable only to a limited section of the community. Whether these risks taken together are great enough to make more stringent control appropriate remains a somewhat debatable question, but there is a good deal to be said against any encouragement of their wider consumption.

BOOK REVIEWS

Schizophrenia 1677. A Psychiatric Study of an Illustrated Autobiographical Record of Demoniacal Possession. Psychiatric Monograph Series No. 2. By Ida Macalpine, M.D., and Richard A. Hunter, M.D., M.R.C.P., D.P.M. (Pp. ix+197; illustrated. £6 10s. Limited edition.) London: William Dawson & Sons Ltd. 1956.

Freud's explanation of paranoia was in some measure forced upon him, in that it had to be reconciled with the theoretical system he had already built up. He was well aware of the disability resulting from his neurological training and lack of mental hospital experience; and explicitly commented upon this himself. It was thus with enthusiasm that he analysed, in 1911, the autobiography of Daniel Paul Schreber, a sufferer from paranoid schizophrenia who made a remission good enough to permit him to write his own memoirs with insight and undisturbed by thought disorder. In 1923 a second opportunity presented itself when the autobiography of Christoph Haizmann came to his notice. Haizmann was a destitute painter who sold his soul to the Devil in the seventeenth century, and was clearly suffering from paranoid schizophrenia at the time of the sale. In addition to the patient's diary, we have nine paintings, and the statements of priests who observed his illness.

For a long time the Schreber memoirs were unavailable and in 1955 Macalpine and Hunter translated and published them. They have now, in the book under review, presented the full Haizmann manuscript which was written partly in Latin and partly in German, together with a translation and reproductions of Haizmann's paintings. The importance of these two very considerable achievements lies, as the authors stress, in the fact that Freud's theory of the paranoid states stems from his study of these memoirs. The theory has never been seriously challenged, partly because the Schreber analysis acquired too soon the immunity from criticism which belongs to a classic.

The authors have given in the book a fair and very readable summary of Freud's work—his investigation into the unconscious and the subsequent elaboration of a theoretical superstructure. With all the evidence before them, they have attempted to look through Freud's eyes and to demonstrate that the evidence in these memoirs did not justify the interpretation placed upon them. In this they have in your reviewer's opinion succeeded completely. Their views are summarized when they point out that the main objection to the Œdipus theory is that there is no indication in the memoirs that Haizmann was homosexual, and there is no mention at all of his father!

Chronic Illness in the United States. Volume II. Care of the Long-Term Patient. Prepared under the auspices of the Commission on Chronic Illness. (Pp. xiv+606. 68s.) Cambridge, Mass.: Harvard U.P. (for Commonwealth Fund). London: Oxford University Press. 1956.

A Commission on Chronic Illness was set up by the American Hospital Association, American Medical Association, American Public Health Association and the American Welfare Association to review all the problems relevant to chronic illness, and to advise on the means of integrating efforts to achieve their prevention and minimize disability. This book is the report of the Commission.

The first chapter deals with the patients and points out that "every long-term patient has one major need: to be looked upon as an individual, whole person". This unexceptional, if somewhat platitudinous statement is followed up by the recording and analysis of a large amount of relevant information. The broad issues in the care of long-term patients whether in their homes, those of others or in institutions or nursing homes, are supplemented by detailed enquiry into, for instance, the dental care of these patients, or the effect of poor housing on their condition. Anong the many interesting facts which emerge is the economic aspect of rehabilitation and the very great saving in cost which results from it.

The Commission conclude that most long-term patients are best cared for in their own homes, and this no one would dispute.

It appears, however, that there are in the United States, as in this country, deficiencies in the various services which are required if this is to be done satisfactorily. In fact, throughout the whole report there is a clear parallel between our difficulties and theirs, and thus a study of this book will repay those interested in the most pressing problem of the care of the chronic sick.

The Social Problem of Mental Deficiency. By N. O'Connor, M.A., Ph.D., and J. Tizard, M.A., B.Litt., Ph.D. (Pp. viii+182; illustrated with a number of diagrams. 30s.) London and New York: Pergamon Press. 1956.

This book is inspiring in its optimism about mental defectives who only too frequently are regarded as beyond human aid. The authors have set out the experiments which guided them in formulating successful principles of training and the book should be read by all those responsible for the care and after-care of mental defectives. They have criticized many legends about defectives which tend to be perpetuated in successive editions of textbooks.

Thus, while half the adults certified as being feebleminded in Greater London have intelligence quotients of more than 70, the authors point out that their social incompetence derives from deficiencies amenable to training—occupational ineptitude, illiteracy, and bad behaviour. Neurotic traits in defectives have been found to be treatable and to improve with increasing years. The great majority of educationally subnormal school leavers can take their places with other adolescents at the work bench and at the counter, and large numbers of imbeciles can work in sheltered workshops. Finally, the authors note, the correlation between defect and delinquency has been over-exaggerated.

Some very useful criticisms are made of the type of training in mental deficiency colonies. Too much training is devoted to the filling in of time without consideration of the usefulness of the work done; and too much use is made of obsolete equipment. Defectives, like the rest of us, need incentives to work, and in particular they should be paid, and learn to use money. Much closer contact with industry is required. The whole question of the comprehensive colony as opposed to specialization on the London principle is considered. The authors state the arguments for and against the comprehensive colony. Many will not agree with their conclusions and indeed your reviewer does not, but the discussion is most interesting. This admirable book ends with a plea for further research, more extensive community services, and a revision of the law.

The Practice of Medicine. Edited by Jonathan Campbell Meakins, C.B.E., M.D., LL.D., D.Sc. 6th edition. (Pp. 1916; illustrated. £6.) London: Henry Kimpton. St. Louis, U.S.A.: The C.V. Mosby Co. 1956.

This edition of Meakins' textbook of "The Practice of Medicine" has now over 80 contributors and the Editor has delegated responsibility to a number of associate editors who, in their turn, have invited specialists in their subjects to contribute to the various sections.

The disadvantage of so many contributors (preponderantly American) to special sections is the risk of re-duplication. It is, however, true to say that the associate editors have succeeded in the main in producing an integrated and co-ordinated work. On the whole the anatomical, physiological, pathological, emotional and environmental factors have received due recognition throughout the text. There is an excellent chapter under "The Allergic States" on the systemic collagen diseases, and one feels that polyarteritis nodosa would be better placed in this section than under "Diseases of the Blood Vessels". The section on chemotherapy is good. It seems a pity, however, that Aureomycin and Terramycin, for example, should not be given under their pharmacopœial names.

The sections on diseases of the respiratory and cardiovascular systems are on the whole comprehensive but the significance of the pneumoconioses merits more space than is accorded to it in this section. By way of contrast one is pleased to note the attention accorded to "the psychosomatic aspects of medicine" in a special section.

The limited but useful number of references at the end of each section is to be commended.

The illustrations throughout the book are excellent and the book is beautifully produced. It can be strongly recommended to the student of medicine.

Medical Guide to Vocations. By René Biot, M.D., and Pierre Galimard, M.D. Translated and adapted by Robert P. Odenwald, M.D. (Pp. xx+303; 18s.) London: Burns & Oates. 1955.

The word "Vocations" in this title is used in the strict sense of the "call" to the religious life. The authors tabulate the principal hereditary factors and temperamental constitutions which are medical contra-indications to admission to the seminary or the novitiate. Paranoia, hypochondriasis, hysteria, cyclothymia and schizoid and emotional reactions are described, and the difficulties in practising chastity are very fully considered. In the second half, devoted to the "Years of Formation", such problems as asceticism, hygiene, dispensation from vows and obligations, and readaptation to lay life for those who have to be rejected, are sympathetically discussed. There is a good deal of repetition, but the book may be recommended to any practitioner invited to assume the medical care of those intended for the priesthood or conventual life. The translation is excellent.

Section of Pathology

Some Observations on the Effect of Fats on Blood Clotting

By J. D. BILLIMORIA, EUNICE LOCKEY and N. F. MACLAGAN

Department of Chemical Pathology, Westminster Medical School, London

THE effect of lipids on blood coagulation has recently become of great interest in relation to the theories of the pathogenesis of coronary atheroma. The early observations of Macfarlane, Trevan and Attwood (1941) and Fullerton and Anastopulos (1949) that certain samples of lecithin were accelerators of blood clotting were followed up by Robinson and Poole (1956), who showed that chylomicra from rat chyle accelerated the clotting of rat plasma and that pure phosphatidyl ethanolamine (P.E.) showed a similar effect. The effect of the chylomicra was attributed to their P.E. content.

The possible importance of dietary fat has also been recognized, but until recently little attention was paid to the nature of the fat in fatty foods, and the general impression existed that the total dietary fat was the most important figure for study. Thus many workers have reported the results of feeding fatty meals to human subjects and while Waldron, Beidelman and Duncan (1951), Fullerton, Davie and Anastopulos (1953), O'Brien (1956), Hall (1956) and Buzina and Keys (1956) have produced shortening of clotting times in this way, others have failed to recognize these changes either with certain techniques or after feeding certain fats (Tulloch, Overman and Wright, 1951; Manning and Walford, 1954). In our own work butter gave positive and margarine gave negative results (Maclagan and Billimoria, 1956). We feel that at least some of these discrepancies may depend on minor but important points of technique considered in the first section of this paper, and also upon the nature of the fats fed.

METHODS

Russell viper venom (*Stypven*) *clotting times.*—This is a particularly convenient technique to use since the Stypven is fat free and can be made to give very reproducible clotting times on single plasma specimens. However, a number of factors influence the results significantly, such as the initial treatment of blood, the ionic strength, the concentrations of calcium and venom, the presence of phenol in the solvent supplied by the makers, and the order of addition of the reagents. We have made a special study of the influence of these factors on the sensitivity of the system to added fat. It was established that optimum conditions include the use of platelet-poor plasma under isotonic conditions, the venom and M/30 $CaCl_2$ solution being added simultaneously as a mixture. The presence of phenol was undesirable as it produced a considerable shortening of the clotting times which was greater for fasting than for lipæmic plasma. Similar effects were produced by a delay between the addition of venom and $CaCl_2$, which therefore also reduced the effects of added fat. This difference between the delayed and instantaneous times suggests that venom interacts with some plasma component before the addition of calcium. The use of platelet-poor plasma was not so essential as, contrary to the previous suggestions in the literature, we obtained good reduction of clotting times by the addition of fat to platelet-rich plasma. The former is, however, preferable as it is more stable and the results obtained with it are more reproducible.

Recalcification methods.—Experiments with snake venom have the disadvantage of introducing a non-physiological thromboplastin so that we felt the need for other techniques and have found that the recalcification of plasma and of whole blood can be used to demonstrate the effect of an active fat. Here again it is important to use the optimum calcium concentrations and to maintain isotonic conditions.

The three techniques finally adopted were as follows:

Reagents.—

(1) *Venom-$CaCl_2$*
One ampoule of Stypven (0·5 mg.) dissolved in 5 ml. 0·1 M NaCl, 5 ml. M/30 $CaCl_2$ added.

(2) "Normal" saline (0·9% NaCl).

(3) $CaCl_2$—saline (*a*) 1 vol. M/30 $CaCl_2$.
1 vol. 0·2 M NaCl.
(*b*) 1 vol. M/15 $CaCl_2$.
1 vol. 0·1 M NaCl.

Procedure.—Blood is collected in a nylon syringe with siliconed needle into 1/9 vol. of 3·8% sodium citrate and centrifuged at 4,000 r.p.m. (2,900 *g*) for ten minutes. Plasma is stored in individual silicone tubes. Clotting is carried out in glass tubes at 37° C.

Venom	Plasma	Whole blood (citrated)
0·1 ml. plasma	0·1 ml. plasma	0·2 ml. blood
0·1 ml. saline (2)	0·1 ml. saline (2)	0·1 ml. saline (2)
0·2 ml. venom-$CaCl_2$	0·2 ml. $CaCl_2$/saline (3*a*)	0·1 ml. $CaCl_2$/saline (3*b*)

With these techniques normal fasting plasma gives the following approximate values:

Stypven time	30 to 35 seconds
Plasma recalcification	3 to 4 minutes
Whole blood recalcification ..	2 to 3 minutes

In Vitro Tests

The effects of a number of foodstuffs on blood clotting have been studied *in vitro* by those three techniques. As previously reported, only those foods containing milk fat gave strongly positive results, other fatty foods being relatively inactive. Two fatty foods, butter and margarine, were studied in some detail. It was shown with the venom technique that at optimum concentrations butter caused an 80% shortening of clotting time as compared with only 18% by margarine. Similar effects were obtained in the recalcification of plasma and of whole blood, although the percentage changes in clotting times were somewhat smaller. At very high concentrations of fat the acceleration of clotting was somewhat diminished particularly in the recalcification technique; this inhibition is provisionally attributed to mechanical interference of excess fat but is being further studied.

With the venom procedure, 10 mg. of butter per system gave a maximum shortening effect, with clotting times of 6–8 seconds. The unit of clotting activity is defined as the amount of food required to produce the same effect as that produced by 10 mg. butter, hence butter contains 100 units/gram. On this basis arbitrary units have been assigned to other foods (Maclagan and Billimoria, 1956). With less active foods, which fail to produce clotting times as low as 8 seconds, the units are calculated from a butter dilution curve so that, for example, margarine contains about 1 unit per gram.

Preparation of Active Principle from Butter

In the course of work on the isolation of the active principle from butter, during which all procedures were followed by an estimation of clotting activity as indicated above, it was found that the activity was attached to protein, and hence on centrifuging warm butter the inactive neutral fats could be easily removed. This enabled us to work with quantities of 50–100 lb. of butter at a time. The active lipoprotein was broken down with hot acetone and the activity transferred with dry chloroform on to a silicic acid column. Graded elution with methanol in chloroform yielded the most active fraction at a concentration of 8% methanol.

The phospholipid had an activity of 200 units per mg. representing a 2,000-fold concentration of the original butter. It was also active in the thrombin generation and thromboplastin generation tests. The substance is much more active than a synthetic specimen of L-dimyristoyl-phosphatidyl-ethanolamine (kindly supplied by Dr. E. Baer, University of Toronto, Canada), which gave negligible shortening of venom time with fasting human plasma. Our preparation, which is not identical with the P.E. tested by Robinson and Poole (1956), had an N : P ratio of approximately unity but contained no free amino N. Mild acid hydrolysis yielded galactose, ethanolamine and serine, and converted all the N to the amino form, suggesting an N glycoside linkage. The chemical constitution is under further investigation.

A fuller account of this work will be published elsewhere. We are much indebted to Dr. J. G. Humble, M.V.O., for advice and criticism. The work was supported by generous grants from the Endowment Funds of Westminster Hospital.

Dr. B. W. Lacey asked if colostrum fat had been tried as a source of clotting factor and if the action of the clotting factor was influenced by the level of cholesterol.

Professor N. F. Maclagan in reply: We have not tried colostrum fat. So far as we know, the plasma cholesterol does not affect clotting systems directly.

Staphylococcal Antibody in Osteomyelitis and Suppurative Arthritis

By CHARLES H. LACK

Institute of Orthopædics, Royal National Orthopædic Hospital, London

SEROLOGICAL tests for the diagnosis of staphylococcal infection are of poor repute. Nevertheless recent experience has led me to the conviction that an examination of the blood for staphylococcal antibody should be carried out more frequently for the diagnosis of unexplained pyrexias and for bone and joint disease.

Table I lists the commoner antigens of pathogenic staphylococci which have been characterized; the percentages are approximations and are based on published figures.

TABLE I.—DISTRIBUTION OF STAPHYLOCOCCAL ANTIGENS

Antigen	Produced by approx. %
Coagulase	100
Alpha-hæmolysin	80–100
Delta-hæmolysin	97
Panton-Valentine leucocidin ..	50
Hyaluronidase	95
Staphylokinase	90

If coagulase is produced by all pathogenic strains then the titration of anti-coagulase would appear to be the obvious choice, but this is impracticable at present. There appear to be at least three antigenically-distinct coagulases, and we wait on the provision of purer coagulase preparations as well as on purer fibrinogen substrate. Alpha-hæmolysin is the only staphylococcal antigen available as a standardized commercial preparation; its antibody is the one I have been measuring. Though delta-hæmolysin and hyaluronidase have almost as universal a distribution as coagulase, they are poor antigens. Interest in the Panton-Valentine leucocidin has recently been revived by Gladstone and van Heyningen (1957). I am not aware of any reports on anti-staphylokinase.

To return to the measurement of anti-alpha-hæmolysin, this is one of the simplest of serological tests and can be performed by a technician in an hour and a half. The patient's serum is inactivated by holding at 56° C. for 30 minutes. Dilutions of serum are made in 0·5 ml. volumes of saline. To each dilution of serum is added one unit of standard toxin in 0·5 ml. of saline +0·1% gelatin. The toxin is prepared from the Lyophilized Staphylococcal Alpha Hæmolysin of the Wellcome Research Laboratories. After 30 minutes standing at room temperature, 0·1 ml. of a 10% suspension of fresh rabbit cells is added to all tubes, including two controls—one serum alone and one toxin alone. All tubes are incubated for an hour and the end-point of inhibition by anti-toxin is determined by the tube showing 50% hæmolysis. As one unit of toxin has been placed in each tube, the titre of

antihæmolysin is the denominator of the dilution fraction. Most workers agree that the majority of healthy people have titres of less than 2 units.

Table II shows the distribution of antibody levels among patients at the Royal National Orthopædic Hospital; and Table III the totals of patients with raised titres expressed as

TABLE II.—ANTI-ALPHA-HÆMOLYSIN TITRES OF HOSPITAL PATIENTS

	Osteomyelitis	Secondary staph. infection	Presumed staph. infection	No staph. infection
Less than 2 units/ml. ..	33	20	—	231
2–4 units/ml.	21	11	—	13
4–8 units/ml.	10	10	1	1
8–16 units/ml.	5	2	1	—
16–32 units/ml.	5	3	2	—
Total 369	74	46	4	245

TABLE III.—PERCENTAGE OF PATIENTS WITH TITRES OF 2 UNITS OR OVER OF ANTI-ALPHA-HÆMOLYSIN

	%
No staph. infection	5·7
Staph. osteomyelitis and suppurative arthritis ..	55·4
Staph. infection elsewhere	56·5

percentages. It may be true that higher levels of antibody are encountered more frequently in patients with osteomyelitis, but in this series a patient with staphylococcal pyelonephritis had as high a titre as any patient with osteomyelitis, and the highest titre I have seen recorded (Bergquist, 1950) was that of a patient who developed staphylococcal empyema and whose titre rose from a pre-infection level of 1 unit to 440 units within a month.

The fact that about 45% of patients known to have staphylococcal infection, whether osteomyelitis or otherwise, have titres of less than 2 units would seem at first to make this test of very little value. On the other hand, we have found that a high titre, and more especially a progressively rising titre, is of the greatest help on occasions, as in the following cases.

Case I, a girl, and *Case II*, a boy, both aged 14. Each first complained of pain in the right side, the girl for eleven weeks and the boy for eight weeks. Both were diagnosed as having appendicitis, but appendicectomy did not cure the pain. In both cases the diagnosis was then changed to tuberculosis of the spine on radiological grounds. The girl was put on a course of anti-tuberculosis therapy. Both were eventually transferred to our hospital. Fig. 1 shows our findings with respect to the girl.

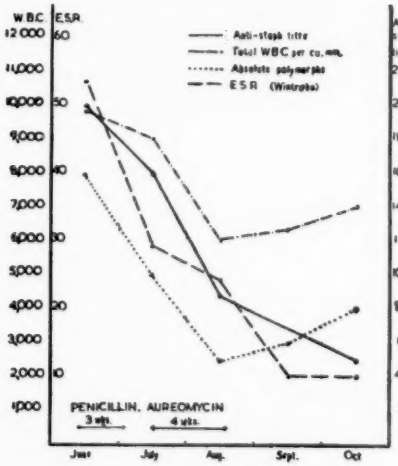

FIG. 1 (*Case I*).

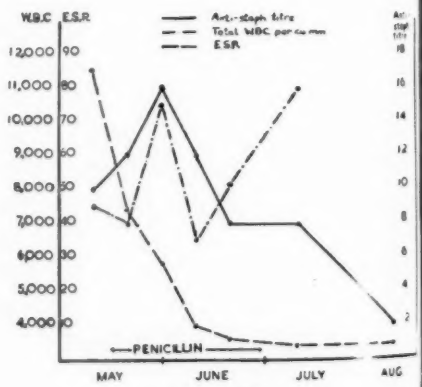

FIG. 2 (*Case II*).

On admission she was found to have 20 units of staphylococcal antibody and straight away was given penicillin. After three weeks this was changed to Aureomycin, which was continued for four weeks. By the time she was discharged her titre had fallen to 4 units.

The boy, who came to us twelve weeks after the onset of his pain and two weeks after his appendicectomy, had a titre of 10 units on admission (Fig. 2), which continued to rise for a time, while receiving penicillin, and then came down to 2 units. His total leucocyte count was even lower than the girl's, being only 7,500 per c.mm. and the absence of leucocytosis made some clinicians doubt whether this could be a staphylococcal infection.

Case III.—Woman, aged 58, developed pain radiating down the back of her right leg following a fall in December 1954. In March 1955 there was a sudden exacerbation of pain and she was admitted with a diagnosis of chronic back strain. Her antibody titre on admission was found to be 20 units, sedimentation rate 50, and leucocyte count 6,050 (Fig. 3). X-ray showed gross narrowing

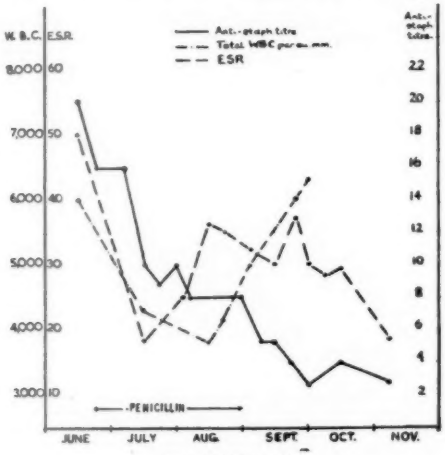

FIG. 3 (*Case III*).

of the I.V. space 4/5 and erosion of the L.V.4 anteriorly. Her antibody titre fell steadily on penicillin until, at her discharge on October 18, it was 4 units and her sedimentation rate 27 mm. in one hour (Westergren). She was then free from pain and X-ray showed that her lumbar vertebræ were fusing. A month later her antibody titre was 3 units, sedimentation rate 18 mm. and she was in excellent health. There was satisfactory consolidation of her lumbar vertebræ with no deformity.

Case IV.—A woman of 49 developed bronchitis and pleurisy at the end of October 1954. She spent fifteen days in bed and was given sulphonamide tablets. She then developed pain in the middle of her back at the level of the tip of her scapula, particularly noticeable at night. X-ray showed a destructive lesion of D.11, with loss of disc space, and the patient was admitted with a provisional diagnosis of spinal tuberculosis. On admission her only abnormal sign was tenderness over L.1 and 2, her temperature was normal and her white cell count was 17,800. Sedimentation rate 13 mm. in one hour (Westergren). Mantoux positive. Her anti-alpha-hæmolysin titre was 4–5 units. She was given penicillin and her titre fell to 3 units and her total white count to 8,000. She was discharged in good health.

This serological test has been of value in correcting the diagnosis in a variety of disorders, the most common being an early spinal lesion that has been labelled tuberculous. It has also given a clue to the cause of the fever of several patients who have been treated with cortisone for rheumatoid arthritis or lupus erythematosus and who have subsequently developed "silent" staphylococcal abscesses. In cases such as spinal disease, the results consequent on the use of this test have been highly gratifying—the patients have been cured much sooner than they would have been had they remained on their anti-tuberculous regimen. But why do only half of the patients with staphylococcal infection show this response. Is it due to lack of antigenic stimulus? By all accounts at least 80% of pathogenic strains of *Staph. pyogenes* produce alpha-hæmolysin *in vitro*. Incapacity to produce antibody is not likely to be an explanation, as the giving of toxoid to low-titre patients with staphylococcal infection has always produced a rise in antibody. The walling-off of the antigen may explain low titres in chronic cases, and we have examples of rise in antibody following operative interference, but this does not account for low antibody levels in early and progressive infections. Duration of infection cannot explain the discrepancy. We have the record of a patient whose titre rose to 8 units within three weeks of the onset of osteomyelitis. From Table IV it may be seen that the time factor does not appear to be very important.

TABLE IV.—ANTI-ALPHA-HÆMOLYSIN AND ANTI-LEUCOCIDIN TITRES OF PATIENTS WITH STAPHYLOCOCCAL OSTEOMYELITIS

Case	Duration	Anti-alpha	Anti-P.V.L.
1	3 weeks	8	80
2	1 month	10	200
3	1 month	2	12
		2–4	100
		2	40
4	6 weeks	Operation—2	Not tested
		2	100
		4	80
5	7 months	16–20	100
		10–16	80
6	7 months	8–10	16
		4–8	16
		2–4	24
7	10 years	Operation— 2	16
		2–4	24
8	37 years	2	16–20

I shall refer briefly to another antibody, anti-leucocidin (Anti-P.V.L.). The normal level in serum seems to be up to 10 units. Gladstone has been measuring the anti-leucocidin titres in the sera of some of our patients and, so far, it appears that this may be a more sensitive indicator of staphylococcal infection in some cases. Table IV sets out for comparison the two levels in a few patients. In Cases III and IV the anti-leucocidin titre was a better guide, but in Case VI the anti-alpha-hæmolysin titres were more helpful. At present it seems worth while to carry out both tests.

I would like to thank Dr. Gladstone for allowing me to quote his findings.

Dr. E. S. Duthie said that numerous measurements made by him on the antibody level against staphylococcal coagulase in the sera of normal individuals showed a wide variation. Similar results were found in 1950 by Rammelkamp, Hezebicks and Dingle in America and for this reason it was unlikely that the level of antibody against coagulase would be of value in the diagnosis of staphylococcal infections. On the other hand he had found high anti-alpha-lysin levels similar to those given by Dr. Lack in staphylococcal bone infections. Since the level of anti-alpha-lysin was relatively constant in normal cases he felt sure that this was a most valuable test and it would be interesting if at the same time anti-leucocidin values could be measured.

REFERENCE

RAMMELKAMP, C. H., HEZEBICKS, M. M., and DINGLE, J. H. (1950) *J. exp. Med.*, **91**, 295.

Dr. Herta Schwabacher said that she had found the estimation of anti-alpha-hæmolysin to be of diagnostic value only when the focus of staphylococcal infection was in muscle or bone. She asked whether Dr. Lack had ever found a significant titre of staphylococcal antibody in staphylococcal skin infections? With the co-operation of Mr. H. F. Lunn, Casualty Officer, Peace Memorial Hospital, Watford, she had examined the sera in a small series of patients with furunculosis. On no occasion was antibody detected. These patients were given a course of staphylococcal toxoid and their sera when retested failed to show any rise in titre.

Dr. Lack in his reply stated that he too had never observed staphylococcal antibody in infections of the skin, but had done so when these patients had received toxoid therapy.

Dr. K. B. Rogers asked Dr. Lack whether his work would suggest that staphylococcal antitoxin would help in the treatment of extremely ill, toxic, cases of acute osteomyelitis as in the last few years two children with staphylococcal osteomyelitis had been lost, although the staphylococci from both cases were fully sensitive to penicillin.

Dr. Lack said that he had had no experience in the use of anti-toxin for the treatment of the toxæmia of acute osteomyelitis in children.

Dr. B. W. Lacey said that the cases mentioned by Dr. Rogers would seem to be ideal for the combined use of steroid and chemotherapy.

DISCUSSION ON CHRONIC RELAPSING PANCREATITIS

Dr. Henry Doubilet (New York):

Physiological Basis of Treatment of Pancreatitis

The anatomical and physiological conclusions, resulting from experience with 500 cases, upon which the treatment of pancreatitis by sphincterotomy is based may be summarized as follows:

Neither the gall-bladder, biliary tract nor pancreas can be considered in therapy as an isolated organ subject to accidental disease. They form part of the biliary-pancreatic-duodenal system which functions physiologically as a unit for the production of digestive juices and for the digestion of food. Dysfunction or disease of any part of this system may affect the other organs or be the cause of their inflammation.

A common passageway exists in all cases of recurrent pancreatitis. This means that when the sphincter of Oddi becomes spastic, a portion of the bile may be diverted into the pancreatic duct. This common passageway can be demonstrated to be present functionally in the living patient at operation, or post-operatively, by injecting a radiopaque solution into the biliary tract after deliberately producing spasm of the sphincter of Oddi by intraduodenal instillation of N/10 HCl. A typical cholangiogram is produced with visualization of the pancreatic duct by reflux (Fig. 1). The common passageway can also be demonstrated by direct observation at operation or by reflux studies when a T-tube is present in the choledochus.

The key to the ætiology of inflammatory disease of the biliary-pancreatic duct system is the sphincter of Oddi. Increase in its tonus (or spasm) is produced primarily by frustrating emotional disturbances, exhaustion, or pain in other parts of the body (Fig. 2).

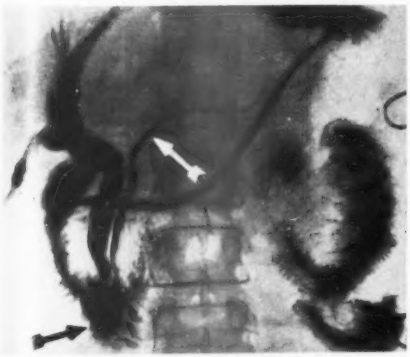

FIG. 1.—Operative cholangiogram demonstrating common passageway. While the radiopaque solution was being injected, spasm of the sphincter of Oddi was produced by the injection of N/10 hydrochloric acid through a Rehfuss tube, whose metal tip was positioned against the papilla (black arrow). The consequent reflux resulted in visualization of the whole duct of Wirsung (white arrow).

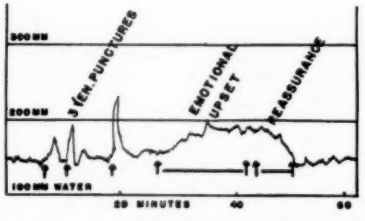

FIG. 2.—Kymographic record of the tonus of the human sphincter of Oddi showing its reaction to pain and to emotion.

The entrance, under tension, of a concentrated solution of bile salts into the pancreatic duct produces an acute inflammation varying in degree from mild œdema to fulminating hæmorrhagic necrotizing pancreatitis. It follows therefore that once pancreatitis is established a normal gall-bladder with its great ability to concentrate bile becomes a liability and should be removed. If the gall-bladder is diseased, pain due to obstruction produced by calculi in the gall-bladder, or in the common duct after their passage into the biliary

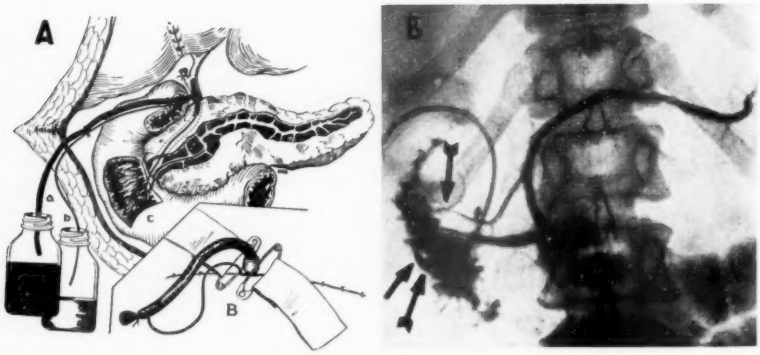

FIG. 3A and B.—Pancreatography is accomplished by inserting a plastic tube into the duct of Wirsung following sphincterotomy as illustrated in A. The tube (*b*) passes alongside the T-tube (*a*) through the cut sphincter of Oddi and up the pancreatic duct. Bile and pancreatic juice are collected separately. After four days the T-tube is tied and the polyvinyl tube inserted into it by means of a needle (insert B), allowing pancreatic juice to circulate back into the duodenum. Fig. 3B shows a typical pancreatogram; the plastic tube is shown passing down the common duct, making it circle in the duodenum (2 arrows), and passing up the duct of Wirsung. The accessory duct (one arrow) is also visualized. The radiopaque solution is contained by the ducts and does not seep into the acinar tissue.

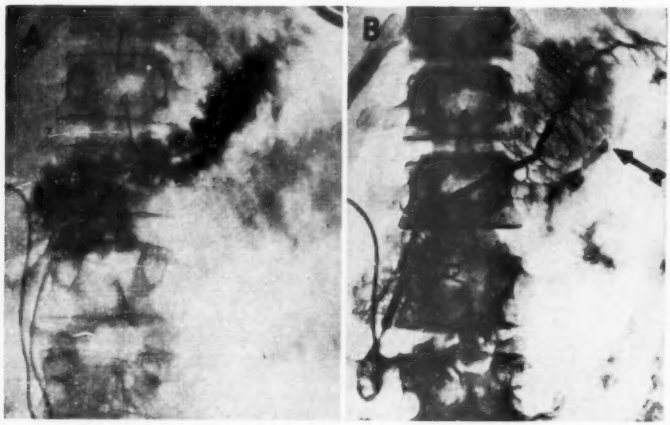

FIG. 4.—Resolution of inflammation of pancreas. An operative pancreatogram (A), demonstrated the whole pancreas due to the presence of acute inflammation and œdema. The permeability of the duct epithelium allowed the radiopaque solution to permeate the acinar tissue. Two weeks later, a pancreatographic study showed almost complete resolution of the acute process. Only a small area near the tail (arrow) was partly opaque.

tract may produce reflex spasm of the sphincter of Oddi. Depending on the anatomical relationship of the two duct systems, and on the relative variability of their pressures, bile may then enter the pancreas and produce a pancreatitis.

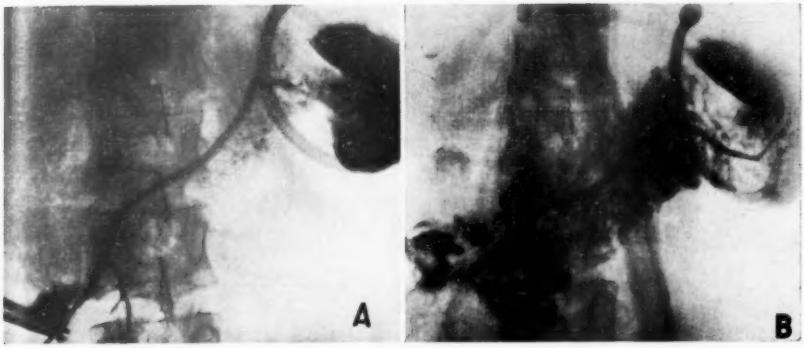

FIG. 5.—Deliberate injection of the pancreas. An operative pancreatogram (A) showed the pancreatic duct. After waiting 10 minutes for the inflammatory response to the radiopaque solution to develop, more solution was injected. Due to the resulting permeability of the duct epithelium, the whole pancreas was outlined. This radiographic technique can be used in the search for a tumour of the pancreas.

The maximum pressure of bile secretion by the liver is 300–400 ml. of water. The force of contraction of the gall-bladder is approximately 250 ml. The secretory pressure of the pancreas is also between 300 to 400 ml. However, although the liver secretes continuously, the pancreas secretes only in response to food so that there are periods when it is possible for bile to enter the pancreatic duct when the sphincter of Oddi is in spasm. Acute inflammation results in permeability of the duct epithelium so that pancreatic juice can be reabsorbed through the walls of the ducts into the tissues. This is exemplified in pancreatographic studies. A technique has been developed for intubation of the pancreatic duct (Fig. 3A). By such means not only can operative pancreatograms be made, but the subsequent course of inflammation can be followed by serial pancreatograms. Normally, in the absence of inflammation, the radiopaque solution is contained by the duct epithelium (Fig. 3B). In the presence of acute inflammation, the radiopaque solution permeates the epithelial wall and renders the whole pancreas opaque. With resolution of inflammation this opacity of the pancreatic tissue no longer occurs (Figs. 4A and B). The reverse can also be produced deliberately. The concentrated radiopaque solution tends to be irritating and, within a period of a few minutes, produces an inflammatory reaction. Injection of more radiopaque solution 10 minutes later results in the whole pancreas becoming opaque (Figs. 5A and B). High pressure within the pancreatic duct system also leads to increased permeability of the duct wall. Sphincterotomy, by lowering the pancreatic intraductal pressure, will reverse the process and help in the resolution of the acute inflammation.

The pain in pancreatitis is due to two causes: (*a*) Distension of the bile and pancreatic ducts behind a spastic sphincter. The spasm, and therefore the pain, may be intermittent or persistent. This pain is permanently abolished by sphincterotomy. (*b*) The acute chemical inflammation resulting from reflux of bile into the pancreatic duct involves the parietal peritoneum and the retroperitoneal tissues. Sphincterotomy will prevent these periodic episodes of reflux of bile into the pancreatic duct and thus abolish the pain produced by the acute inflammation.

There is no evidence that obstruction of the pancreatic duct plays a part in the origin of pancreatitis. On the contrary, the pancreatic duct is usually dilated and even sacculated in cases of long-standing pancreatitis as a result of prolonged spasm of the sphincter of Oddi (Fig. 6). The term "spasm" does not carry any connotation of obstruction. It

FIG. 6.—Dilatation of the bile and pancreatic ducts as a result of long-standing spasm of the sphincter of Oddi. This patient had a 20-year history of recurrent attacks of severe pancreatitis. The gall-bladder was normal, and the common duct was clear of stones. An operative cholangiogram revealed a dilated common duct (white arrow) and a sacculated enlarged pancreatic duct (black arrow).

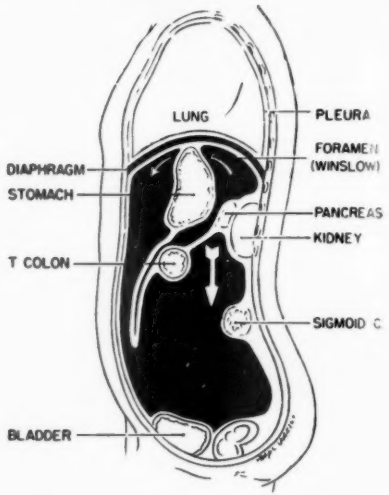

FIG. 7.—Spread of activated exudate during attack of acute pancreatitis. Diagrammatic sagittal section through the left nipple line shows (*a*) intraperitoneal spread through foramen of Winslow (curved arrow) and through the base of mesocolon (straight arrow), and (*b*) retroperitoneal spread around kidney, down to the sigmoid mesocolon, anteriorly between leaves of mesocolon, upwards to diaphragm and along aorta to the posterior mediastinum.

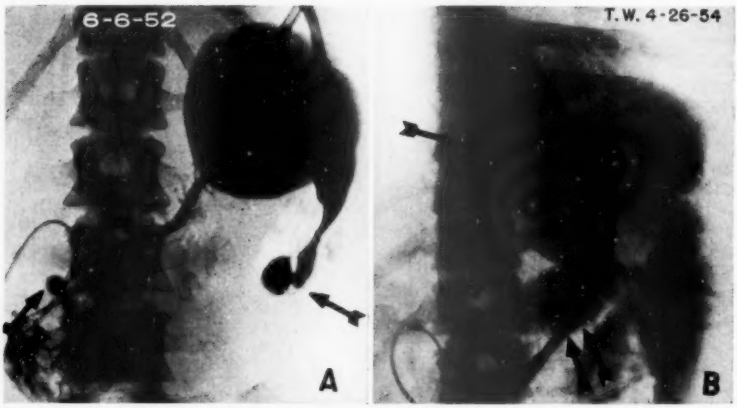

FIG. 8.—Examples of pseudocyst formation due to retroperitoneal spread of exudate and pancreatic juice. Pancreatographic studies showed a large pseudocyst (A) beneath the left diaphragm with extension down to the sigmoid mesocolon (arrow), and (B) a huge pseudocyst in the posterior mediastinum (arrow), extending to the 6th thoracic vertebra. Note (2 arrows) opacification of the pancreas due to residual inflammation. These pseudocysts resolved completely after drainage through the plastic tube inserted into the pancreatic duct through the sectioned sphincter.

means that the bile and pancreatic juice flow into the duodenum against increased resistance.

The pancreas is a retroperitoneal organ, so that rupture of any of the smaller ducts during a phase of necrosis will enable pancreatic juice to enter the retroperitoneal space. Increased intraductal pressure as a result of sphincter spasm will divert pancreatic juice into this space and result in the rapid formation of pseudocysts (Fig. 7). The pancreatic juice may dissect downwards as far as the sigmoid mesocolon on the left, upwards towards the diaphragm (Fig. 8A), and even into the posterior mediastinum along the aorta to form a pseudocyst in this thoracic space (Fig. 8B). Sphincterotomy will reduce the intraductal pressure and lead to the disappearance of these pseudocysts (Figs. 9 A–D). If a pseudocyst

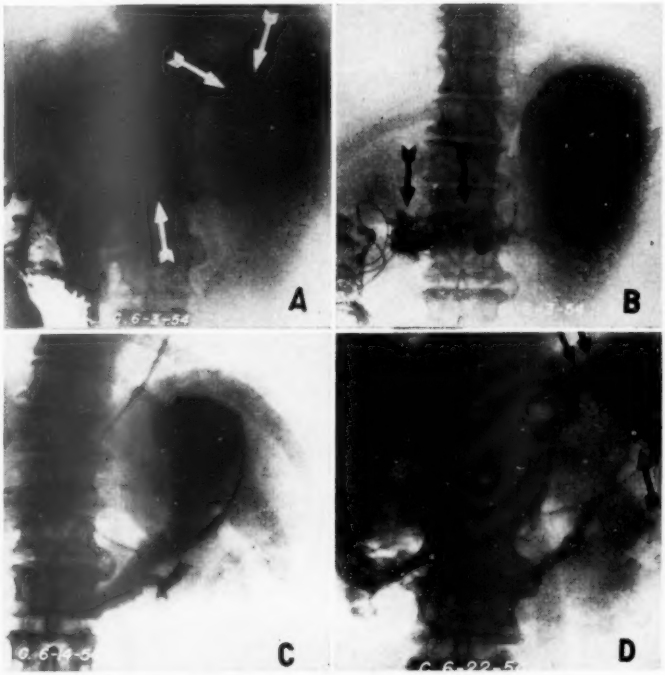

FIG. 9.—Resolution of a pseudocyst following sphincterotomy. This patient had a huge pseudocyst in the left upper quadrant. At operation, following aspiration of the cyst, a cholangiogram (A) through the cystic duct showed reflux up the pancreatic duct (arrow) and beginning filling of the pseudocyst (two arrows). Following sphincterotomy, a pancreatogram (B) was performed by injecting the duct of Wirsung. This filled the pseudocyst. Note visualization of the pancreatic tissue (2 arrows). Resolution of the pseudocyst was followed through a small plastic tube left in the pseudocyst. Note (C) that the cyst had shrunk about two-thirds in two weeks, and after three weeks (D) only a small residual space (arrow) was left. The solution passed down the pancreatic duct into the duodenum and refluxed back into the stomach (2 arrows).

is drained, a cutaneous pancreatic fistula may form by way of the retroperitoneal space, and may persist for months and years, due to spasm of the sphincter. Sphincterotomy, again, by reducing the intraductal pressure, will result in rapid closure of such a fistula. True acute cysts of the head will also disappear following sphincterotomy. Untreated, these cysts may become chronic and lose their connexion with the duct system. Cystojejunostomy is required in such cases.

The treatment of cysts and fistulas of the pancreas by sphincterotomy requires the presence of an unobstructed pancreatic duct. It is therefore mandatory that an operative pancreatogram be performed in all such cases. In the presence of partial obstruction by stone or

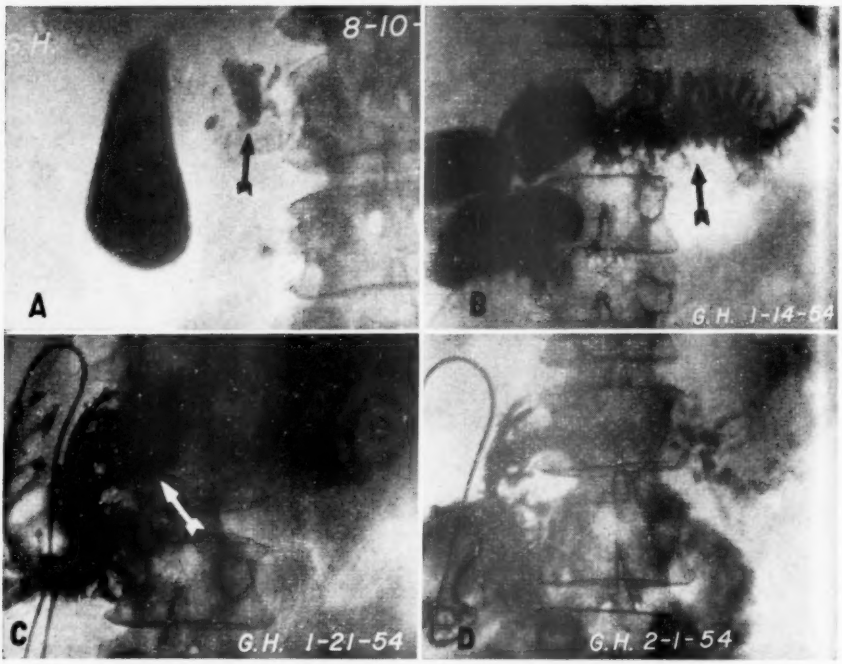

FIG. 10.—Partial obstruction of pancreatic duct by calculi. This patient had calcification (arrow) in the head of the pancreas (A). An operative pancreatogram (B) following sphincterotomy revealed enormous dilatation of the duct (arrow) distal to the partial obstruction. The head of the pancreas was incised, the stones removed, the incision closed, and the duct of Wirsung drained by the indwelling tube. Post-operative serial pancreatograms showed (C) beginning resolution of the cavity (arrow) which held the stones, and finally (D) reformation of the duct and marked reduction in its diameter.

FIG. 11.—Function of the duodenal wall following sphincterotomy. When sphincterotomy is properly performed the intact duodenal musculature prevents duodenal reflux by its pinch-cock action. A post-operative cholangiogram (A) shows the sphincter lying wide open (arrow). Following administration of morphine (B), the increased tonus of the circular muscle of the duodenal wall compresses the terminal part of the common duct (arrow) and acts as a one-way valve.

structure, either the obstruction is removed (Fig. 10 A–D) or if that is impossible a caudal pancreatico-jejunostomy is performed.

The disease process in pancreatitis is primarily that of recurrent attacks of acute inflammation, which may or may not produce areas of necrosis followed by replacement fibrosis. It follows that chronic pancreatitis is not a primary disease, but is one of the possible complications of recurrent acute attacks. If necrosis does not occur, the inflammatory œdema resolves and evidence of inflammation in the gland disappears.

The technique of sphincterotomy exploits the anatomical relationship of the sphincter of Oddi to the duodenal wall. Section of the sphincter for a distance of only 8–10 mm. does not interfere with the function of the duodenal wall as a one-way valve or pinch-cock. After a properly performed sphincterotomy, duodenal reflux does not occur (Fig. 11). The sphincter always heals in a position of retraction.

The regenerative power of the pancreas is as great as that of the liver. Our observations indicate that with reduction in intraductal pressure and cessation of recurrent acute attacks following sphincterotomy, the pancreas often regenerates. This has been demonstrated by serial secretin tests (Table I), and in several cases by histological evidence (Fig. 12).

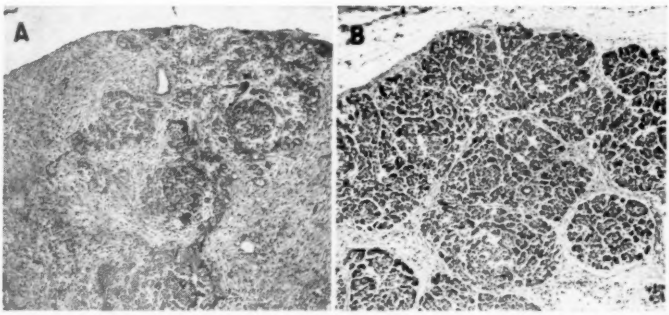

FIG. 12.—Regeneration of the pancreas following sphincterotomy. Biopsy taken at operation (A) showed infiltration, fibrosis and marked destruction of the acinar tissue. At autopsy four years later in the same patient, who died from another cause, histological section (B) shows almost complete regeneration of acinar tissue.

TABLE I.—REGENERATION OF PANCREAS AFTER SPHINCTEROTOMY (June 15, 1950) AS SHOWN BY THE SECRETIN TEST

Date	Total volume, c.c.	Total bicarbonate c.c., N/10	Total amylase, Lagerlof units
14/6/50	92	48	110
22/9/50	118	42	153
26/9/53	123	80	246
27/2/57	280	125	1,230

Once the pancreas has become injured as a result of reflux of bile into the pancreatic duct, it becomes susceptible to the noxious action of fat and alcohol. Intake of these substances will often produce a severe attack which cannot be prevented by sphincterotomy or any other operative procedure such as vagotomy, choledocho-jejunostomy, or pancreatico-jejunostomy. The mechanism of action of these substances is unknown, but it appears to be due to sensitivity of an injured pancreas to their metabolic products. However, once the pancreas regenerates, as evidenced by secretin tests, it no longer reacts to alcohol and fat imbibition. It therefore follows that sphincterotomy is but the first step in the treatment of recurrent pancreatitis. The patient must be kept on an alcohol-free and low-fat diet for a period of six to eighteen months, or until the pancreas regenerates, before cure of the disease can be considered successful.

Mr. Rodney Smith:

This disorder is, for some reason, a good deal less common in this country than in the United States, and I do not myself believe that the difference is accounted for solely by errors in diagnosis. It is a disease which can cause much disability due to incapacitating pain and not infrequently endangers life.

Rational therapy can only spring from a study of the ætiology and evidence strongly supports Dr. Doubilet's contention that reflux from the common bile duct through a common channel into the pancreatic duct is very often the cause of the recurrent acute attacks (*see* p. 630). If this reflux can be stopped, cure will result.

[Slides of biliary reflux were shown and a cine-film demonstrating the mechanism of the normal sphincteric apparatus at the lower end of the common bile duct and reflux occurring in chronic relapsing pancreatitis.]

In emphasizing the importance of biliary reflux, I am aware that there are certain apparent discrepancies which need explanation. The acute episodes occurring in relapsing pancreatitis are precisely similar to isolated instances of acute pancreatitis. Yet undoubtedly there are many causes of acute pancreatitis other than biliary reflux, and acute pancreatitis can occur in patients who have no true ampulla of Vater, the common channel necessary if reflux is to occur. Also a post-operative cholangiogram after choledochotomy for stone may show the contrast medium refluxing up the lower centimetre of the main pancreatic duct of a perfectly normal pancreas proving that reflux can occur without causing pancreatitis. An explanation is that while a normal pancreas may well be able to withstand minor reflux of bile, an attack of acute pancreatitis of any severity leaves a gland which is far from normal. One function of a normal pancreatic duct epithelium is to resist penetration by pancreatic ferments and after severe ductal damage during an attack of acute pancreatitis healing may take place with a lining incapable of resisting penetration. That some such change in permeability does in fact take place is shown by Dr. Doubilet's work on pancreatography, for contrast medium injected up the duct of an inflamed pancreas does not stay in the duct system but diffuses out and renders the whole gland opaque.

I suggest that it is the combination of two factors which causes relapsing pancreatitis; damage to the duct lining and biliary reflux, the latter ensuring that the ferments in the damaged pancreas are activated. The pancreas remains vulnerable and whenever further reflux of bile occurs a further attack of acute pancreatitis is likely to occur.

It is therefore logical to treat relapsing pancreatitis by trying to eliminate biliary reflux. The simplest method of achieving this is by the operation of sphincterotomy which, properly done, lays open the common channel so that the common bile duct and main pancreatic duct empty independently into the duodenum. In the majority of cases, therefore, where surgery is indicated for chronic relapsing pancreatitis, the first line of attack is sphincterotomy, which carries a low risk to life and offers an excellent chance of cure. It does not, however, cure every case of chronic pancreatitis and I should like to refer to several other procedures which have their place in surgical therapy.

Biliary diversion.—Reflux of bile up the pancreatic duct can be most effectively eliminated by dividing the common bile duct and reimplanting it into the duodenum or jejunum, but it is illogical to carry out this more severe procedure if the same result can be achieved by sphincterotomy. Sphincterotomy may be unsatisfactory and ineffective if œdema and induration of duodenum and pancreatic head have produced rigidity of the whole area, in this case biliary diversion may be the procedure of choice. Another infrequent indication for biliary diversion is compression and distortion of the lower common bile duct leading to partial obstruction and chronic biliary infection.

Retrograde pancreatic drainage.—This procedure is particularly indicated in those cases in which there is gross blockage of the pancreatic duct system with calculi and débris, the result of long-standing inflammation. Here, although biliary reflux may still cause intermittent exacerbations, the problem is pancreatic duct obstruction with undrained infection distally. Sphincterotomy, dilatation of the pancreatic duct, and trans-duodenal removal of pancreatic calculi may be quite inadequate if the whole duct system is packed with stones and débris. In this case, amputation of the whole of the body and tail of the pancreas may allow the duct system in the head of the gland to be cleared of all stones, and retrograde drainage established by anastomosis of the distal end of the duct to the stomach or to a jejunal Roux loop (Fig. 1).

Splanchnicectomy.—Splanchnicectomy can certainly have a useful effect upon the incidence and severity of pancreatic pain and therefore has a place in the treatment of chronic relapsing pancreatitis. It is claimed by some that splanchnicectomy also has a more direct effect and actually prevents pancreatitis by denervating and thus relaxing

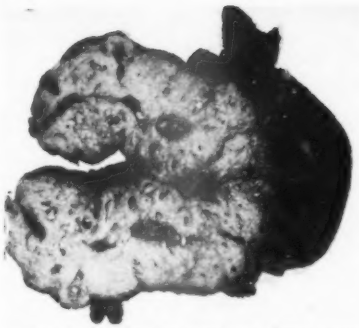

FIG. 1.—Operative specimen from a case of pancreatitis treated by resection of body and tail of pancreas and pancreato-gastrostomy.

FIG. 2.—Operative specimen from a case of pancreatitis treated by pancreato-duodenectomy. →

the sphincter of Oddi. Cine-cholangiographic studies have, however, failed to show any motor effects produced by splanchnic nerve block even though abolition of pancreatic sensation was complete. In my opinion splanchnicectomy cannot be expected to affect the frequency of exacerbations in relapsing pancreatitis, but it may be of symptomatic benefit in controlling chronic pain.

Pancreatectomy.—Distal pancreatectomy is occasionally indicated for chronic pancreatitis confined to the tail or body and tail of the gland. Such cases are rare, but may result from local trauma or changes in the blood vessels.

Pancreato-duodenectomy is an operation to be considered in those cases presenting with gross sclerosis, ductal obstruction, and calcification in the head of the gland (Fig. 2). The operation is carried out in the same way as for carcinoma of the head of the pancreas and the remaining body and tail of the gland treated by end-to-side pancreato-jejunostomy. The results of successfully performed operations of this kind are excellent, but it must be emphasized that technically the procedure is difficult or even hazardous, and Cattell and Warren (1953) have suggested that the wise surgeon will not embark upon it unless he has gained considerable familiarity with the technique by carrying out a number of resections for carcinoma. Certainly the immediate operative risk is sufficiently high to suggest that the operation should only be undertaken if it is felt that no other procedure has any chance of success.

D . W. I. Card:

To the physician these patients present themselves either as a problem in undiagnosed abdominal pain, or with diarrhœa, steatorrhœa or in a state of poor nutrition. Pain is usually the more evident symptom in the earlier stages of a process which may last some years, while, as destruction of the gland advances evidence of overt pancreatic insufficiency becomes more prominent.

The pain is due to an increased pressure in the pancreatic duct system, at any rate in some instances. In one patient we were able to reproduce her pain exactly by stimulating the

pancreas with secretin and closing the sphincter with morphine. With this procedure flow into the duodenum ceased, to reappear when amyl nitrite was given, which simultaneously relieved the pain. These observations, which were carefully controlled, were repeated and are consistent with a concept of pain as due to increased intraductal pressure. Following sphincterotomy morphine failed to stop the flow of juice produced by secretin and no pain occurred. After this operation the patient remained free from pain for two years. If pain can be reproduced in this way then sphincterotomy should relieve it. With the use, if necessary, of morphine antagonists and amyl nitrite, the procedure is safe but of limited diagnostic value.

In the differential diagnosis of pancreatic pain we have had difficulty in distinguishing carcinoma of the pancreas from a benign duodenal ulcer infiltrating the pancreas and producing the syndrome which Rivers (1947) first described. We have also observed attacks of pancreatic pain in association with a perivaterian diverticulum.

The treatment of the attack of pancreatic pain should aim at preventing pancreatic secretion by continuous aspiration of stomach contents to stop hormonal action and by full doses of atropine to block vagal action. The pain can be controlled by morphine and pethidine while nitroglycerin half-hourly helps to relax the sphincter.

Pancreatic insufficiency.—Before this state is clinically obvious, various laboratory tests may show abnormalities, in particular tests of external pancreatic secretion. Using secretin and pancreozymin stimulation of the pancreas with an 80-minute collection, the volume, bicarbonate concentration and output, and the concentration and outputs of amylase, tryspin, and lipase have been measured (Marks and Tompsett, 1957). The values for all the enzymes run roughly parallel and it seems only necessary to measure the amylase level. It can be shown that the amylase figures can be quite abnormal even though the volume and bicarbonate values are normal. A measure of the amylase output with this form of stimulation seems the most sensitive single test of external pancreatic secretion. Tests of external pancreatic secretion have been criticized by some workers in the past as providing little useful diagnostic information but these criticisms are unjustified unless pancreozymin, a specific enzyme stimulant, is used. In order to avoid the tedium of intubation, provocative serum amylase tests have been proposed whereby the level of the enzyme is measured in the blood stream after stimulation by secretin and pancreozymin. In our hands this method has not been very useful. In the latter stages of chronic pancreatitis we have found the glucose tolerance test of great value in distinguishing the steatorrhœa of pancreatic disease from that of malabsorption. In pancreatic disease we tend to find a diabetic or pre-diabetic curve whereas in the malabsorption syndrome we find a flat curve. The extent of the steatorrhœa and creatorrhœa does not allow us to distinguish between diarrhœas of pancreatic origin and those occurring with the malabsorption syndrome.

DISCUSSION ON DIAGNOSTIC FEATURES OF SOME PANCREATIC DISEASES

Dr. T. C. Hunt: So-called chronic pancreatitis includes at least two types of case, one of which is correctly described as chronic relapsing pancreatitis, and this may be sufficiently clear-cut and characteristic to enable a clinical diagnosis to be made with considerable confidence. Another is a painless type also with fairly typical features—but there are variable clinical cases between these two which are of uncertain ætiology and inconstant symptomatology.

The diagnosis of chronic relapsing pancreatitis on clinical grounds may, however, be difficult and not easy to confirm either by the laboratory or at operation. There is no laboratory test available which is able consistently to establish the diagnosis—a deficiency which should be remedied.

I have reviewed my own cases during the past eight years and also, with the kind permission of several of my colleagues at St. Mary's Hospital to whom I am very grateful, the notes of 21 other cases mostly proved at operation or post-mortem. The uncertainty of clinical diagnosis is shown by the number of doubtful cases in this series—only 59 being acceptable out of 108 suspected or presumptive diagnoses.

Chronic relapsing pancreatitis is not only difficult to diagnose *from* other conditions but is often associated *with* other conditions in many cases. In 59 cases I have found that the conditions most frequently associated with chronic relapsing pancreatitis were gall-bladder disease in 14, duodenal ulcer in 7, and neurosis in 21. This incidence of gall-bladder disease is rather lower than in some series as is that of duodenal ulcer; the considerable degree of neurosis often present is usually a result of the pancreatitis and does not precede it. In part, the superadded nervous symptoms seem to arise from the patient's determination to convince the doctor that he has severe pain and the frustration he feels when normal X-rays are regarded as proof that his symptoms are psychological. It is interesting in connexion with the occurrence of duodenal ulcer that hæmatemesis and melæna may occur in chronic relapsing pancreatitis with no evidence of chronic ulcer at any time. Such hæmorrhage occurs during an acute attack with the typical pain of pancreatitis, and though possibly due to an acute erosion, is not easy to explain.

Of these 59 cases 28 were male and 31 female. The average age of onset was 46 and symptoms had persisted for an average duration of nine years when first seen by me. In 3 cases the age of onset was under 15 and in 12 it was over 60.

The principal clinical symptom in chronic relapsing pancreatitis is pain, the other main clinical features being given in Table I.

TABLE I.—CHRONIC RELAPSING PANCREATITIS, 59 CASES

Main Clinical Features

	Cases		Cases
Pain	56	Glycosuria	5
Loss of weight	41	Calcification	4
Vomiting	32	Pancreatic calculi	3
Jaundice	10	Cysts (palpable)	2
Steatorrhœa	6		

Loss of weight is often extreme and in 22 cases was over 2 st. Vomiting is often severe but does not bring relief of pain.

Of these 59 cases the diagnostic triad of steatorrhœa, calcification and glycosuria occurred in only 5, and of these cases 3 developed without any pain at all. Palpable cysts occurred in 2 cases, in both of which pain was severe and continuous.

The pain of this disease may arise suddenly. It may be so violent that the patient collapses at work, but more often it develops over a few hours and increases gradually to a crescendo. It is usually continuous, but in a few cases comes in waves so that the distinction from intestinal colic may be difficult. Patients often describe it as excruciating or agonizing and may roll about and sweat. One doctor patient said it felt as if a piece of bowel was being stretched.

Out of 51 patients the pain was central in the epigastrium in 22, in 2 of whom it was also substernal. In 13 it was limited to the right side of the upper abdomen, in 8 to the left side, whilst in 8 it was both central and one-sided.

In about one-third of the patients—19 out of 51—the pain radiated into the back, a somewhat surprisingly low proportion, but in none did it radiate into the neck or arms which is a helpful point in excluding coronary infarction.

The pain, I have noticed, is sometimes strikingly better sitting up than lying down, in contrast to the pain of ulcer which is usually the reverse. When vomiting occurs it does not relieve the pain, and in a very few cases diarrhœa follows the pain.

In general attacks of the disease last from a few hours up to many days, the average in this series being three-and-a-half days. As a rule they are more severe and of shorter duration than the periodic attacks of duodenal ulcer. There is only rarely any direct precipitating cause but fatigue and chill sometimes seem to provoke attacks and undoubtedly in a few cases extra indulgence in alcohol. Most patients are completely free between attacks with no pain or other symptoms, but are often cautious in their eating habits especially as regards alcohol and hot fatty foods.

The diagnosis of chronic relapsing pancreatitis from duodenal ulcer may be very difficult. In the latter the sex incidence is predominantly male and attacks more often begin between the ages of 20 and 40 than between 40 and 60. Vomiting and pain and loss of weight are usually more marked in the former. Attacks of chronic pancreatitis are associated with a slight or moderate pyrexia and leucocytosis in a proportion of cases: and bed rest, alkalis and food, which produce little or no relief in chronic pancreatitis, often do so in ulcer.

Mr. Rodney Smith: I shall discuss the diagnostic problems in two major types of lesion, namely carcinoma and relapsing pancreatitis.

Carcinoma.—Professor Charles Rob and I recently analysed symptoms and signs in 190 patients with carcinoma of the pancreas or ampulla of Vater (Tables I and II).

TABLE I.—FREQUENCY OF MAIN SYMPTOMS

Symptoms	No. of patients	Comment
Pain	131	Present in 50% of ampullary carcinomas, 90% of carcinoma of the head, 100% of carcinoma of the body
Jaundice	128	Present in all ampullary carcinomas and in 94% of carcinoma of the head
Loss of weight	163	
Lassitude and anorexia	84	
Diarrhœa	61	
Itching	58	
Vomiting	43	
Tumour noticed by patient	16	
Enlarged lymph nodes	9	

TABLE II.—THE FIRST SYMPTOM

	Pain	Jaundice	Others
Head of pancreas or ampulla of Vater	59	54	14
Body or tail	49	0	8

It is particularly noteworthy that pain proved to be such a common symptom, not only in carcinoma of the body and tail but also in cases of malignant obstruction of the lower end of the common bile duct, when it was the first symptom complained of as often as was jaundice.

The "painless jaundice" still emphasized in many textbooks is thus a misleading term, at any rate if it is held to imply that painful jaundice cannot be caused by a carcinoma.

It was further observed in the series studied that fluctuation in the degree of jaundice was not uncommon, particularly in cases of ampullary carcinoma, probably caused by central sloughing of a friable tumour intermittently relieving total biliary obstruction. The observation previously recorded by others was confirmed that while a palpable dilated gall-bladder in a case of obstructive jaundice (Courvoisier gall-bladder) nearly always means malignancy, failure to feel a dilated gall-bladder means nothing and certainly cannot exclude a carcinoma. The gall-bladder may be fibrosed by previous disease; the growth obstructing the common bile duct may have extended to obstruct the junction of the cystic duct and common duct, thus preventing distension of the gall-bladder; the gall-bladder may be dilated but tucked under the liver and not palpable through a fat abdominal wall.

Of the special investigations usually carried out, mention must be made of radiography. In the hands of a radiologist with particular interest and experience a barium meal will show abnormality in some 50% of cases of carcinoma in this region. Oral or intravenous cholangiography seldom provides evidence of any value and is contra-indicated in jaundice of any depth. Percutaneous trans-hepatic cholangiography (Nurick, Whiteside and Hickey,

1953, *Brit. J. Surg.*, **41**, 27; Smith, Rodney, 1954, Progress in Clinical Surgery, London) can very often demonstrate the site and size of a carcinoma very clearly, but the risks of leakage of bile into the peritoneal cavity, calling for immediate laparotomy, are sufficiently high to suggest that this method of investigation should only rarely be employed.

The final investigation is laparotomy. Even here the diagnosis may be in doubt, for a common source of uncertainty is the enlarged irregular head of pancreas in a jaundiced patient, which could be either malignant or inflammatory. Here the state of the common bile duct will usually provide the answer. If it is grossly dilated, thin-walled, translucent and free from signs of inflammation, this means malignancy. Conversely the jaundice caused by pancreatitis is usually due partly to obstruction and partly to biliary infection and the common bile duct is moderately dilated or even not dilated at all, thick-walled, opaque, inflamed and with adherent peritoneum. In cases of real doubt, biopsy may be performed but not from the surface of the pancreas. This may well miss a deeply-placed carcinoma and carries a high risk of causing a pancreatic fistula. Biopsy from within the duodenum after anterior duodenotomy is permissible, but even this should be avoided when possible.

Chronic relapsing pancreatitis.—Dr. Hunt has dealt with many of the problems of clinical diagnosis. I would agree with him that in a fair proportion of cases a characteristic clinical picture leads to a diagnosis of pancreatitis but confirmatory evidence from laboratory investigations is lacking. It is true that during acute exacerbations, elevation of serum amylase and possibly lipase may be found but this is not invariable. Plain radiography and intravenous cholangiography may reveal pancreatic calcification or a distorted common bile duct but again X-rays are often normal. Tests of pancreatic function seldom show any abnormality until gross destruction of the gland has taken place.

In many cases of relapsing pancreatitis a clinical diagnosis has to be made, unsupported by other evidence, and it becomes necessary to carry out the final investigation—exploratory laparotomy. With the abdomen opened it is not usually difficult to decide whether the pancreas is the site of inflammation of any severity. Once the diagnosis is confirmed, it is the duty of the surgeon in carrying out a general examination of the abdominal viscera to pay particular attention to the biliary tract, and to try to assess not only the degree of pancreatitis but also the probable ætiological factors.

In a very high percentage of cases reflux of bile into the pancreatic duct from the common bile duct is important. This has been shown very clearly by cine-cholangiographic studies carried out on patients with relapsing pancreatitis.

A film "Cine-cholangiography in Chronic Relapsing Pancreatitis" was shown.

The state of the bile passages at operation should be studied, cholangiography being used in some cases, and, if sphincterotomy is carried out, catheterization of the main pancreatic duct is performed and an operative pancreatogram obtained.

To sum up then, clinical assessment should normally be followed by a cholecystogram and intravenous cholangiogram, a barium meal, estimation of serum amylase and lipase, particularly during an acute episode, and possibly tests of pancreatic function, though the value of these is very limited. If all these investigations are negative, it is logical in many cases with incapacitating symptoms to proceed to exploratory laparotomy.

Dr. Martin Bodian: My contribution on diagnostic features of some pancreatic diseases in childhood is largely based on personal pathological observations made over the period 1943 to 1956. The data have been selected from a material of about 2,500 autopsies but occasional biopsy findings have also been included.

The distribution of the material and the frequency with which individual conditions were encountered is given in Table I.

TABLE I.—PANCREATIC DISEASES 1943 TO 1956

	No. of cases
Fibrocystic disease of the pancreas	123
Congenital hypoplasia of the exocrine pancreas	3
Congenital cystosis of the pancreas	1
Pancreatitis due to various causes	7
due to congenital syphilis	10
due to cytomegalic inclusion disease	2
Diabetes mellitus	2
Hypoglycæmia	2
Annular pancreas	several
Ectopic pancreas	several

The most commonly encountered condition manifesting pancreatic pathology in our hospital experience is that of *fibrocystic disease of the pancreas* or congenital mucosis which accounted for about 5% of our autopsies.

Our basic conception of this disorder is that it is a recessively inherited congenital anomaly of mucus-secretion manifesting itself with an unduly viscous mucus which, because of its tenacity, tends to be retained in the various channels through which it normally flows freely. This abnormality would only be observed in those organs where mucus is produced and these belong almost exclusively to two major systems in the human organism, namely the respiratory system and the alimentary system which includes the gastro-intestinal tract and its adnexæ, the salivary glands, the pancreas and the liver. It will be noted from this concept that this disorder is widespread and that the involvement of the pancreas is by no means exclusive nor, for that matter, all-important. It is also our belief that the basic anomaly in this condition, the "mucosis", leads to a series of complications in different organs and that the clinical manifestations of the disease and its progression are entirely related to these complications and not to the basic lesion by itself. Thus there will be retention of secretion of mucus first of all in some of the smallest ductules of the pancreatic duct system leading to blockage of enzyme-containing secretion in the acini which are drained by these ductules. The retained secretion will lead to increasing flattening and then atrophy of the acinar epithelial cells but when the metabolism of these cells is sufficiently disturbed by the mechanical pressure exerted on them, the enzymes contained in the acinar lumen (notably the locally activated trypsin) will attack these epithelial cells and destroy them, producing a focal pancreatic necrosis. This will be followed by reactionary infiltration with inflammatory cells, later by fibroblasts and ultimately fibrous tissue will replace the area of pancreatic necrosis. More and more areas of pancreas will thus be destroyed, more and more ducts will be blocked by the abnormal secretion and there will be a progressive diminution of the enzyme-producing capacity of the pancreas: such pancreatic juice as is being produced would not be capable of passing through the blocked duct system into the duodenum.

It should be noted that the main pancreatic duct is not atretic (and we have shown this by means of serial sections) but that such blockage as may be seen ultimately is purely a late sequel to the abnormality of secretion. Ultimately the pancreas is reduced to a mere fibrous core with few residual ducts and acini showing the changes of mucosis and with reasonable numbers of islets. This core is surrounded by a cushion of lipomatous tissue.

The original idea that meconium ileus, a form of neonatal intestinal obstruction in fibrocystic disease of the pancreas, is due to atresia of the pancreatic duct and failure of the meconium to be digested owing to lack of trypsin in the gut, is completely fallacious. The abnormality of meconium is merely a reflection of the mucus anomaly in the glands of the gastro-intestinal tract and it should be remembered that meconium is almost exclusively mucous in nature.

Meconium ileus was seen in some 30% of all the fatal cases of fibrocystic disease of the pancreas or in 15% of all the cases, including survivors. Once meconium has been passed, fæcal intestinal obstruction is only rarely seen.

The clinical manifestations of the pancreatic pathology in fibrocystic disease are those of digestive disability with normal absorption of predigested foods such as glucose or amino acids. They lead in the untreated case to failure to thrive in spite of a voracious appetite and enormous wastage of undigested foods in the stools which are large, bulky and offensive.

Other pathological manifestations of this widespread disease are seen in the salivary glands, notably in the sublingual glands. There the lesion is that of pure mucus-retention without complications, hence asymptomatic.

The liver lesions are those of retention cysts in the finest bile ductules beneath the capsule with proliferation of other bile ducts in an effort to overcome the obstruction. This biliary pathology is accompanied by some atrophy of adjacent liver cells and by some increase in fibrous tissue in the affected portal areas. The lesion is focal and has been designated focal biliary fibrosis. In most instances it is asymptomatic, since there is usually ample liver tissue available which is normally functioning. Occasionally, however, and more commonly as these children grow older, more widespread cirrhotic liver lesions manifest themselves even with symptoms of liver failure and of portal hypertension.

Finally, and most important, there are the widespread lesions in the respiratory system. These again are the sequelæ to mucus-retention leading to obstructive and to inflammatory lesions in the bronchial tree and lung parenchyma with emphysema, atelectasis, bronchiolitis, bronchiolectasis, bronchopneumonia, bronchiolar abscesses, bronchitis and bronchiectasis. These complicating lesions of the respiratory tract are, to some extent, amenable to treatment with modern antibiotics. Life can now be prolonged in many cases but the struggle between antibiotics and bacteria in an effort to prevent permanent serious structural changes in the lungs with its cardiac sequelæ is by no means easy.

I have not yet mentioned the finding in recent years of an increased sodium chloride content in the sweat in these children. It is difficult to explain this observation on the basis of the concept of mucosis unless one assumes that the abnormal enzyme mechanism which is

probably responsible for the mucus abnormality is also concerned in the regulation of the salt content of the sweat.

Regarding the other conditions mentioned in Table I, I shall merely touch upon some principal data:

Congenital hypoplasia of exocrine pancreas.—Of this rare condition we have seen three examples. I have personally seen a further 4 cases from outside sources but have not included these in my survey.

This is a failure of the duct and acinar system to form fully and in some instances there are mere vestiges of acini with a poorly-formed duct system, in others there are no acini at all. The islets are well developed and they, as well as the vestiges of ducts and acini, lie in a stroma of lipomatous tissue. There is no fibrosis, no cellular infiltration and no retention cysts in the pancreas, nor is there any evidence of mucosis in any other tissue.

These children present symptoms of pancreatic deficiency and show no trypsin in their duodenal juice. They simulate in this respect fibrocystic disease but they are also liable to respiratory infections. Moreover the incidence of this disease in two siblings has been reported. The liver is usually the seat of severe fatty infiltration which may be followed by diffuse hepatic fibrosis.

Congenital cystosis of the pancreas: Of this we have seen one example not associated with cystic disease in any other organ. Conversely, none of the 4 cases of polycystic disease of the kidneys (1 with cystic disease of the liver) has shown cysts in the pancreas.

The clinical picture was that of pancreatic deficiency with absent trypsin from the duodenal juice. The child died from inanition at the age of 6 months having overcome an attack of respiratory infection. At post-mortem there were numbers of true cysts but the pancreatic ducts were patent and there was no fibrosis except in the immediate vicinity of the cysts. The pancreatic achylia was attributed to an associated absence of zymogen granules from the pancreatic acini which were otherwise normal.

Interstitial pancreatitis of various causes.—This small group of 7 cases does not manifest a uniform pathology. It includes one child, aged 3 years, with chronic interstitial pancreatitis (pancreatic fibrosis) probably secondary to polyarteritis nodosa; another child, aged 3 years, with a terminal pancreatic necrosis with widespread fat necrosis of the peritoneum associated with an acute duodenitis; one newborn mongol infant with a hepato-pancreatitis, probably a complication of neonatal virus hepatitis and a manifestation of a transplacental infection; one newborn infant with chronic interstitial pancreatitis, associated with meconium peritonitis; finally a more uniform small group of 3 infants, aged, 6/12, 6/12 and 9/12.

These 3 cases showed the clinical picture of gastro-enteritis with predominant vomiting in one and were found to be cases of isolated interstitial pancreatitis, associated with a severe enteritis in two. The duct pathology suggests an ascending infection from the duodenum. None of these cases showed at autopsy any evidence of generalized mucous gland disease (mucosis) and the pancreatic pathology was unlike that in fibrocystic disease.

There were also 10 cases of interstitial pancreatis due to *congenital syphilis*, all showing an associated severe pericellular hepatitis.

Two cases of *disseminated cytomegalic inclusion disease* showed some pancreatic involvement both of exocrine and duct tissue with areas of focal inflammatory cell infiltration and interstitial fibrosis.

Finally, I shall refer briefly to a few other conditions seen:

2 fatal cases of *diabetes mellitus* showed a striking paucity in islet tissue and there was hyaline degeneration of islets in 1.

2 cases of hypoglycæmia with fits were explored in order to identify an islet adenoma, if present. No disease was found in the pancreas of 1, but the other showed a diffuse islet hyperplasia with particular predominance of beta cells which constituted about 90% of the islet cells.

There were several instances of annular pancreas which is a ring-like extension of the head of pancreas around the descending duodenum and which is commonly associated with other malformations such as malrotation, duodenal stenosis or atresia, and mongolism.

The more severe forms produce obstructive symptoms in infancy but less severe variants may lead to symptoms of duodenal obstruction only in later childhood or adult life. The case of pancreatic necrosis associated with duodenitis had an annular pancreas and was an example of this later symptomatic manifestation. Treatment is by duodeno-jejunostomy.

There were also several instances of ectopic pancreatic islets associated with Meckel's diverticula. One particular instance was of theoretical interest in that it occurred in a case of meconium ileus with fibrocystic disease of the pancreas. The ectopic tissue showed a replica of the changes in the main pancreas illustrating that this pathology is not conditioned by obstructive disease in the main pancreatic ducts but is a manifestation of the abnormality of secretion, a dyschylia.

[*May* 28, 1957]

DISCUSSION ON SOME BLOOD DISORDERS

Hypersplenism

By M. C. G. Israëls, M.D., F.R.C.P.

(*University Department of Hæmatology, Manchester*)

The idea of a primary disease due to over-activity of the spleen was suggested about ten years ago by Doan, Dameshek and their colleagues in the U.S.A.

The essential criteria for diagnosis were: (1) An enlarged spleen. (2) Depression of one or more of the red cells, granulocytes, or platelets in the peripheral blood—anæmia, granulocytopenia or thrombocytopenia. (3) Activity in the bone-marrow of the cell series depressed in the peripheral blood; e.g. anæmia accompanied by intense erythroblastic activity in the marrow.

It followed that if these three criteria were met, the proper treatment for the patient was removal of the spleen. Then, presumably, relieved of the excessive sequestration and destruction in the spleen of the affected cells, the blood count would return to normal and the patient would be cured of his symptoms. This response made a fourth criterion.

Our attitude to primary hypersplenism has slowly changed as causes have been found for many of the cases originally labelled primary, and now a case can be made out for doubting the existence of the syndrome.

In 1950 a note of caution appeared in the work of Dameshek and Estren and a fifth point was added to the criteria, viz. that the histology of the spleen must be normal. This meant that the clinical diagnosis of primary hypersplenism was always open to histological correction.

No one will deny that a syndrome of secondary hypersplenism exists. If cells are unusually sequestrated in the spleen, they will be destroyed more rapidly. The classical example is congenital spherocytosis in which the anæmia is largely relieved by removal of what is often a grossly enlarged spleen. But the *primary* defect is the congenitally abnormal shape of the red cells, and the histology of the spleen is far from normal, showing over-filling of the pulp with red cells and resultant compression of the other splenic structures.

The classical example of primary hypersplenism was considered to be the syndrome known as acquired hæmolytic anæmia. Here there is grave anæmia, the bone-marrow shows intense normoblastic activity with pro-erythroblasts present; the spleen is much enlarged and on section the main structure remains normal, the only abnormality being some hyperplasia of reticulum cells in the sinuses.

But we have learnt from experience that splenectomy often only partially relieves the anæmia in this disease. The advent of the Coombs antiglobulin reaction has enabled us to establish the presence of hæmolytic antibodies which had been long suspected. Nowadays most of these patients are successfully controlled by cortisone treatment and splenectomy is only carried out on the few who fail to respond. It is clear that acquired hæmolytic anæmia is not a primary hypersplenism; the spleen is probably taking part in the production of abnormal antibody and its normal activity of sequestration and destruction of red cells is increased because the red cells affected by the antibody have a much shortened survival. The hypersplenism is only part of the pathological picture in this disease.

In another group, the presence of a large spleen as the sole clinical finding together with typical findings in the blood and bone-marrow have led to splenectomy; but the sections of the spleen have shown that one or other of the reticuloses is present and the prognosis is that of the primary condition (Israëls, 1953).

Splenic neutropenia is a rare syndrome. I have seen patients with chronic neutropenia but without enlarged spleens; the two patients with enlarged spleens and neutropenia but no anæmia or thrombocytopenia have turned out to have chronic infections and we have not yet removed their spleens.

From experiences such as this, it is clear that splenomegaly and primary hypersplenism may well be a non-existent combination. We do know that hypersplenism can arise during the course of another blood disease and that the effects can be temporarily alleviated by splenectomy. The cases of hypersplenism occurring in the course of chronic lymphatic leukæmia and in myelosclerosis are examples.

For all these reasons the combination of a large spleen with anæmia, granulocytopenia or thrombocytopenia means a *secondary* hypersplenism, and whether we recommend splenectomy will depend on what we think the primary disease is likely to be.

Thrombocytopenic purpura does appear to be a form of hypersplenism which fulfils the criterion that splenectomy will be effective. In a series of 65 cases of thrombocytopenic purpura who had the spleen removed, 73% showed a completely satisfactory response; i.e. the purpuric manifestations disappeared and the platelets rose to normal levels and stayed there; in 19% the platelets stabilized at a subnormal level and the patients continued to have minor purpuric symptoms; in only 5% did the operation fail completely. In thrombocytopenic purpura, there is thrombocytopenia, an active marrow containing megakaryocytes, a good response to splenectomy, and the histology of the spleen shows no abnormality of the main structure; sometimes there is reticulum-cell hyperplasia in the Malpighian bodies. But there is never a palpably enlarged spleen, indeed it is axiomatic that if the spleen is very large, the condition is not primary. At operation the spleen is usually found to be two or three times as large as normal, but this does not make it palpable in the normal person. So in the sole survivor of the primary hypersplenic syndrome, we are paradoxically denied the sign of a palpable enlarged spleen. The work on anti-platelet antibodies may place thrombocytopenic purpura in the same class of diseases as acquired hæmolytic anæmia. So far the evidence is too conflicting for acceptance (*Lancet*, 1955) and so far thrombocytopenic purpura remains an apparently primary hypersplenism.

The physician should recommend splenectomy in this group of diseases in three conditions:

(1) In thrombocytopenic purpura, after a sufficient time, usually one month, has been allowed for spontaneous remission or for cortisone to induce a remission.

(2) In congenital spherocytosis, because experience has taught us that relief can be expected in 99% of cases.

(3) In follicular lympho-reticulosis, where diagnosis is possible. The points are a grossly enlarged spleen, a patient who is remarkably well in spite of his abdominal mass and blood abnormalities, and the spleen puncture should show only lymphocytes.

In all other cases splenectomy should be avoided if possible. Sometimes splenectomy is recommended as a diagnostic measure and in the hope of temporary relief. But the prognosis should then be very guarded.

Recent Advances in the Diagnosis and Treatment of Hæmophilia

By ROSEMARY BIGGS, M.D.

(*Department of Pathology, Radcliffe Infirmary, Oxford*)

DURING the last three to four years we have seen nearly 200 patients with constitutional hæmorrhagic diatheses. The vast majority had hæmophilia and it is for that reason that most of our efforts have been concentrated on the study of this condition. Christmas-disease patients constitute about 10% of the total and patients with the fairly recently described plasma thromboplastin antecedent (P.T.A.) deficiency are very infrequent. The distribution differs in different parts of the world. In Switzerland Christmas disease is more common. In New York it appears that P.T.A. deficiency is almost as frequently encountered as hæmophilia. These distribution differences are difficult to understand.

Hæmophilia is inherited as a sex-linked recessive character, but nearly half of the patients give no history of any other affected person in the family. In these instances, either the inheritance is obscured by successive transference of the gene through generations of normal females, or the condition has arisen anew by mutation.

Hæmophilic patients have a defect in blood coagulation probably due to the deficiency in or absence of antihæmophilic globulin (A.H.G.), a substance necessary for normal coagulation. It is possible to measure this substance in the blood and the severity of bleeding is at least approximately related to its level. The classical case of hæmophilia is easily recognized. The patients suffer from repeated episodes of bleeding which include massive hæmatomata, hæmarthroses and bleeding from the nose, gastro-intestinal tract and kidneys. Many of these episodes are not clearly associated with trauma. Usually by adolescence the patient's joints are crippled as the result of multiple hæmarthroses. Laboratory tests show a long clotting time and complete absence of antihæmophilic globulin; 60–80 of our patients come into this category. The amount of disability depends partly on chance, temperament and the amount of care his mother takes.

In addition to these severely affected patients are a number who are much more mildly affected. In our series of such patients from 48 different families the proportion of mildly

affected cases is probably high because it is in these patients that difficulty in diagnosis arises. They live normal lives and hæmorrhage is nearly always related to definite trauma. Hæmarthroses are uncommon and the joints never show any permanent damage.

Analysing the results for all the mildly affected patients the A.H.G. levels have varied between about 1 and 30%. Practically all of the patients with more than 5% of A.H.G. are very mildly affected but we have seen patients whom we consider have hæmophilia with as much as 30% and 2 patients of rather doubtful diagnosis with more than 30%.

It is of interest to see what happens when these patients are subjected to operation. Since the bleeding tendency is usually disclosed only by trauma quite a high proportion of patients give a history of previous dental extraction or operation. 26 gave a history of dental extraction and without treatment all had bled for a week or more and 7 required transfusion.

12 patients gave a history of previous tonsillectomy and 2 patients told us that an affected relative had died after tonsillectomy. The A.H.G. levels and history of transfusions in these patients is shown in Table I. Patients with more than 15% A.H.G. do better than

TABLE I.—TONSILLECTOMY IN MILDLY AFFECTED HÆMOPHILIC PATIENTS

Case	Level of A.H.G.	Course of convalescence	Transfusion
1 (relative)*	6	Died	?
2	6	Bled excessively and became very anæmic	None
3	9	Excessive bleeding	Daily for 7 days
4	9	" "	Transfused
5 (relative)*	10	Died	?
6	10	Excessive bleeding	10 pints
7	15	" "	None
8	20	" "	None
9	22	" "	Transfused
10	25	" "	None
11	25	" "	Transfused
12	30	" "	None
13	39	" "	None
14	48	" "	None

*Information supplied by affected relatives seen by us.

those with less than 10%. 7 patients had had appendicectomy and this operation was surprisingly uneventful. Table II shows the remaining operations. Again patients with the most A.H.G. have done best.

TABLE II.—MISCELLANEOUS OPERATIONS ON MILDLY AFFECTED HÆMOPHILIC PATIENTS

Case	Operation	A.H.G. level	Course of illness	Transfusion
20	Laminectomy	0–4	Very excessive bleeding	Daily for 6 weeks
21	Excision of piece of lip	4	3 months in hospital	Transfused
22	Glands of neck	4	2 months in hospital	None
17	Hæmangioma	10	Excessive bleeding	Numerous
17	Hæmorrhoidectomy	10	" "	"
23	Circumcision	10	" "	?
24	Circumcision	11	" "	?
25	Circumcision	12	" "	None
26	Abscess of buttock	15	" "	Transfused
27	Gastrectomy	15	" "	2 transfusions

Two general inferences emerge from the study of these patients. One is that bleeding is likely to occur in hæmophilic patients with A.H.G. levels up to 30%. In treating severely affected hæmophilic patients whose initial level of antihæmophilic globulin is 0, no significant reduction in their bleeding tendency is likely to be achieved unless the level of antihæmophilic globulin can be raised above 15%. Surgical procedures will not be safe unless the level can be raised above 30%.

TREATMENT OF HÆMOPHILIA

A.H.G. is present in plasma and can also be separated from plasma in a more or less concentrated form. We have observed the effects of surgical treatment in hæmophilic patients both after fresh human plasma and after concentrated animal A.H.G. I shall discuss the treatment of severely affected patients.

Human Plasma

One of the difficulties in using human plasma is that the A.H.G. is very unstable and the plasma must either be used quite fresh (within hours of collection) or it must be stored with special precautions to prevent deterioration. We have found that storage at −30° C. may give adequate levels even after one to two months.

1,000 ml. of human plasma given to an adult hæmophiliac in 45–60 min. usually raises the level of A.H.G. to about 25%. Very occasionally, patients have a greater rise, some seem resistant to treatment and the rise is much less. The level achieved by plasma transfusion, in fact, seldom raises the hæmophiliac out of the hæmophilic range. This treatment does, however, bring the severely affected patient into the very mildly affected range.

For minor procedures such as dental extractions, this treatment reduces the bleeding under favourable circumstances but does not eliminate it altogether. We have found that with plasma treatment it is sometimes reasonably safe to remove as many as 12–16 teeth at one time. This policy is, however, undoubtedly hazardous and should not be undertaken without more potent antihæmophilic material available in case of emergency.

Treatment with Animal A.H.G.

The effects of a litre of plasma suggest that the dose of A.H.G. to reach a safe hæmostatic level must exceed 2 litres. Thus concentrated A.H.G. must be able to supply doses equivalent to 2–3 litres of human plasma in a reasonable volume of diluent. A mistake that has been made in the past is to assume that quite small amounts of A.H.G. are effective when to get a reasonable dose it would be necessary to dissolve the contents of 50–100 ampoules. This era is now passing and it is realized that to enter the ampoule scale in A.H.G. the material requires to be purified 2,000 to 10,000 times.

We have used concentrated animal A.H.G. initially for volunteers who needed dental extractions. 5 of such volunteers were treated and in all good solid clots formed in the sockets; in 3 healing was uneventful. One patient developed thrombocytopenia and on further investigation it was found that beef blood contains a species agglutinin for human platelets. This agglutinin is in the fraction containing A.H.G. Also one patient had an early allergic reaction. As a rule the low platelet levels are very temporary and do not affect hæmostasis. But the one exceptional case who was adversely affected ordinarily had a rather low platelet count and was taking Epanutin for epilepsy. A.H.G. made from pig blood does not have this platelet-agglutinating effect.

Both pig and beef A.H.G. are antigenic and, so far, we have never attempted to give more than one course of treatment, that is ten days of daily injections of material from one animal species. For this reason after the first volunteers the animal A.H.G. has been used only for patients who are liable to die unless they are treated with animal A.H.G.

Patients treated surgically who received animal A.H.G. included (1) a young man who had received an accidental gunshot wound of the back and arm and required the removal of a traumatic arteriovenous aneurism from the brachial artery. His case is described in detail by Fraenkel and Honey (1955). (2) A young man who had a head injury from a motor cycle accident, and (3) a boy of 15 who had an operation involving the removal of laminæ from 12 vertebræ for the treatment of a massive extradural clot.

The present position then is that plasma and blood transfusion cannot raise the A.H.G. level of a severely affected patient to the normal range. What this treatment can do is to raise the level to the top of the range for mild hæmophiliacs. For many purposes such as the control of spontaneous epistaxis or hæmaturia this may be adequate but for more serious lesions better levels are required. At present higher A.H.G. levels can only be obtained by using animal material.

The Cold Hæmagglutinin Syndrome

By J. V. Dacie, M.D., F.R.C.P.

(*Department of Pathology* (*Hæmatology*), *Postgraduate Medical School, London*)

The association of chronic hæmolytic anæmia, hæmoglobinuria, Raynaud's phenomena and cold autohæmagglutination form a syndrome which, although uncommon, is of great interest. I shall refer to it as the "Cold Hæmagglutinin Syndrome".

Cold agglutinins are formed in high concentrations in the serum of man in three main types of disease: (1) after virus pneumonia; (2) in association with hæmolytic anæmia

accompanying reticulosarcoma and allied lymphomas; and (3) in "idiopathic" acquired hæmolytic anæmia of the cold-antibody type. Patients presenting symptoms of the cold hæmagglutinin syndrome belong to this last group. In addition, cold agglutinins at abnormally high titres have been reported from time to time in a wide variety of disorders, ranging from liver disease to trypanosomiasis, but such reports mostly lack details of titres, &c., and one is not always sure whether the auto-agglutination is due to the presence of cold agglutinins or excessive rouleaux formation. The incidence of cold agglutinins at raised titres in what may be termed "miscellaneous disorders" is in any case low. Finland and his colleagues (1945), for instance, studied 809 sera from patients suffering from a variety of disorders, mainly infections, and found only nine sera containing cold agglutinins at titres exceeding 80, and even so, four of these sera came from patients with hæmolytic anæmia.

I shall discuss acquired hæmolytic anæmias of the cold-antibody type, of unknown origin, and those patients whose serum contains cold antibodies at titres in excess of 8,000 at 2–4° C., for these are the patients who present the symptoms of the cold hæmagglutinin syndrome. The first well-documented reports of this syndrome date from 1935. In that year Roth and Ernstene, and Gardner, in America, and Salén in Sweden, all described patients thought to be suffering from paroxysmal hæmoglobinuria, who in retrospect clearly were suffering from the syndrome under discussion.

The incidence of this type of hæmolytic anæmia is illustrated in Table I. The data comprise patients with acquired hæmolytic anæmia personally studied during the last ten years.

TABLE I.—A CLASSIFICATION OF 113 PATIENTS WITH ACQUIRED (AUTO-IMMUNE) HÆMOLYTIC ANÆMIA

Clinical Type	Ætiology	Serology (Type of antibody)	No. of patients
Idiopathic (Acute transient or chronic)	Unknown	Warm	67 patients
		Cold	15 patients
Secondary:			
Transient	Post-virus pneumonia	Cold	12 patients
Chronic	Reticulosarcoma, lymphosarcoma, chronic lymphatic leukæmia, other leukæmias, lymphadenoma	Warm	11 patients
		Cold	5 patients
	Disseminated lupus erythematosus	Warm	3 patients

Of the 15 patients with cold auto-antibodies, 10 were diagnosed as having the cold-hæmagglutinin syndrome, for they all suffered from well-marked Raynaud's phenomena, with or without hæmoglobinuria, in cold weather. (The other 5 patients were relatively free or completely free from these symptoms; they differed also in serological findings.)

The 10 patients with the cold hæmagglutinin syndrome make an interesting series. Some clinical data are shown in Table II. The disease clearly affects elderly subjects and is of long duration; both sexes are affected.

TABLE II.—SOME CLINICAL DATA ON PATIENTS WITH THE COLD HÆMAGGLUTININ SYNDROME

Case No.	Sex	Age	Duration of disease or cause of death
1	F	61	16 yrs. Died of anæmia
2	M	78	1 yr. Died of bronchopneumonia
3	F	67	10 yrs. +
4	F	75	4 yrs. Died of ca. pancreas
5	M	71	3 yrs. +
6	F	73	3 yrs. +
7	F	72	2½ yrs. +
8	F	60	3 yrs. +
9	M	62	"Years"
10	F	68	4 yrs. +

Data on 23 other patients in literature (15 men; 8 women).
Age range: 38–81 years. Mean age 61 years.

The patients suffer from a mild to moderately severe hæmolytic anæmia. Some hæmatological data are shown in Table III.

TABLE III.—HÆMATOLOGICAL DATA ON TWO PATIENTS WITH THE COLD HÆMAGGLUTININ SYNDROME

Red cell count (mill./c.mm.)	Hb (g./100 ml.)	M.C.V. (c.μ.) (mean)	M.C.H.C. (%) (mean)	Retics. (%)	Leucocytes (/c.mm.)	Platelets (/c.mm.)	Serum bilirubin (mg./100 ml.)
(Case 3. 8 yrs.) 2·3–5·0	6·5–14·8*	106	31·7	0·6–16	3,000–11,000	170,000–300,000	0·3–1·8
(Case 4. 3½ years. Died 1954) 1·8–4·2	6·2–14·2†	109	34	2–16	1,800–8,000	50,000–150,000	0·3–2·5

*Summer 1949. †Summer 1951.

The patients are usually significantly more anæmic in winter-time than in warm weather, but they are rarely completely free from anæmia in the summer-time (Fig. 1). If kept in bed their anæmia lessens. This is probably the result of their being kept warm; it incidentally makes assessment of the possible benefit of any other form of therapy unusually difficult (Fig. 2).

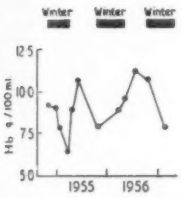

FIG. 1 (*Case 3*).—October 1954–March 1957. Effect of seasons on hæmoglobin levels.

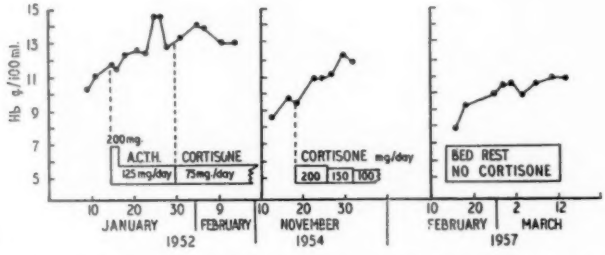

FIG. 2 (*Case 3*).—Effect of bed rest and steroids on hæmoglobin levels.

In cold weather the patients regularly show Raynaud's phenomena. Their fingers feel cold and numb and may be painful, and become bluish-purple in colour. The ear lobes and the tip of the nose may be similarly affected. These changes are quickly reversible on warming the skin, but irreversible changes may occur and gangrene of the tips of the digits is not uncommon.

The circulatory changes appear to be due to auto-hæmagglutination taking place in the cutaneous blood vessels as the direct result of cooling of the skin. As in most cases auto-hæmagglutination takes place at temperatures extending up to 29–31° C., minor degrees of cooling are all that are necessary to bring this about. The cessation of circulation may be readily seen with a skin microscope or by examining the conjunctival blood vessels with the aid of a lens, after having irrigated the eye with cold saline.

Hæmoglobinuria is a less frequently observed symptom than Raynaud's phenomena, but most patients give a history of it at some time during the course of their illness. In some, it regularly occurs every cold winter's day. Even in its absence hæmosiderin may be found in the urine deposit. Most patients, too, are visibly jaundiced in winter-time. Their spleens are usually palpable but are seldom very large.

SEROLOGICAL FINDINGS

Most characteristic is the rapid spontaneous hæmagglutination which takes place at room temperature, making spreading blood films and counting red cells by ordinary techniques difficult or impossible. However, if the blood is collected in a warmed syringe, kept at 37° C. subsequently, and then diluted with warmed diluent and placed in a warm counting chamber, counts are perfectly possible. Similarly, serum free from hæmolysis may be obtained if the patient's blood is allowed to clot undisturbed in a warm vessel at 37° C.

The serological findings in these patients are remarkable. The range of cold-agglutinin titres, and other data, are given in Table IV. Normal red cells are not agglutinated at 37° C. The direct antiglobulin (Coombs) test is positive, even if care is taken to keep the sample of blood strictly at 37° C. before the test is carried out. The indirect antiglobulin test is usually negative at 37° C. but strongly positive if the sensitization is carried out at temperatures below 30° C.

TABLE IV.—SEROLOGICAL DATA IN THE COLD HÆMAGGLUTININ SYNDROME

Cold agglutinin:		
Titre 2–4° C.		8,000–512,000
20° C.		16– 16,000
Upper thermal limit		29–32° C.
Direct antiglobulin (Coombs) test		Positive
Indirect antiglobulin (Coombs) test		Usually negative at 37° C. Positive at <30° C.
Cryoglobulins		Present in 3 out of 10 sera ("Cryocrit" 1·0–5·0%)
Serum complement	*Range* (units)	*Normal range* (units)
	10–90 (3 out of 5 subnormal)	50–150
W.R. and Kahn reactions		Uniformly negative

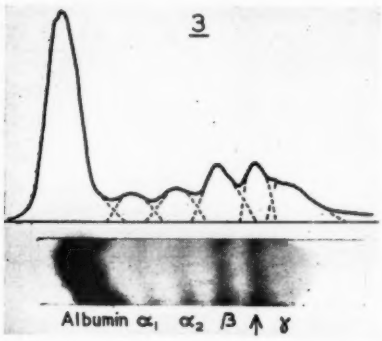

FIG. 3.—Electrophoretic pattern of the serum of Case 3 (agglutinin titre at 4° C. 16,000–64,000). The γ_1 globulin peak is shown by the arrow. From Christenson and Dacie (1957). (Reproduced by permission from the *British Journal of Hæmatology*, **3**, 156.)

Electrophoresis of the patient's sera shows the presence of an abnormal peak in the γ_1 region (Christenson and Dacie, 1957) (Fig. 3). This peak seems to be largely formed of cold-antibody protein. The evidence for this conclusion is as follows (Christenson *et al.*, 1957): (1) If the sera are absorbed with normal red cells the γ_1 peak is removed more or less parallel with the reduction in cold-antibody titre; (2) if the sera are subjected to cellulose-column electrophoresis the greatest antibody activity is found in the fraction corresponding with the γ_1 peak; (3) such peaks are found apparently invariably when the cold-agglutinin titre exceeds about 8,000 at 2–4° C. They are not found in sera containing cold agglutinins at low titres. Ultracentrifugal studies carried out by Dr. P. A. Charlwood have shown that the cold-antibody protein forming these peaks exists largely in the form of a macroglobulin ($S_{20,w}$ 16·4–18·0) (Christenson *et al.*, 1957). In some patients the γ_1 protein is cold-precipitable, i.e. it exists as a cryoglobulin.

TREATMENT

Primarily, it is a question of keeping the patient warm in winter-time, but how this should be done is beyond the scope of this paper.

Steroids do not seem to be particularly effective and it seems undesirable to start treating the patient with such potentially dangerous drugs, when the treatment, even if beneficial to some extent, will have to be continued for years. The one patient of my series treated with cortisone did not seem to derive much benefit.

Splenectomy has seldom been carried out. Baumgartner (1955) mentions one case in which no benefit resulted, and studies of the spleen uptake of radio-active chromium, carried out on one of my patients by Drs. Hughes-Jones, Lewis and Szur at the Postgraduate Medical School of London, showed an accumulation of chromium in both the liver and spleen which does not suggest that splenectomy would have been particularly effective.

Homosexuality in Clinical Practice

By DENIS PARR, M.D., D.P.M.

THE difficulty of defining homosexuality is reflected in a number of neologisms which have been devised to express variations of the same concept. Thus, homo-sociality has been used for social relationships between persons of the same sex, homo-eroticism for love relationships, and homo-genitality for contacts at genital level. In addition, terms such as latent, masked, symbolic, or unconscious homosexuality are sometimes used to describe tendencies or relationships which are neither objectively obvious nor subjectively realized. Such concepts are in the realm of theoretical inferences rather than of clinical phenomena.

In view of these disparities, it is desirable that a working definition should be stated when the subject is discussed. The studies summarized in this paper have been directed to cases where homosexual acts with others at genital level, or desires or impulses to commit such acts, are known to have occurred since puberty.

MATERIAL AND METHODS OF STUDY

The investigation was limited to male psychiatric patients. For data on *incidence*, the following groups were used:

(*a*) Mental Hospital returns for 1956, referring to sexual deviation of any kind as a recorded primary diagnosis, in a total of 24,412 patients.

(*b*) Case records of 608 male patients admitted to Belmont Neurosis Unit (detailed scrutiny).

(*c*) Case records of 721 male patients admitted to the Psychiatric Unit of St. George's Hospital at Wimbledon (detailed scrutiny).

(*d*) 500 male out-patients seen at St. George's Hospital in 1956, using only the diagnostic card index to obtain the incidence of homosexuality as a major part of the initial diagnostic formulation.

(*e*) In a review of 2,550 male patients seen in private consulting practice, the incidence of homosexuality as a major problem was established by Dr. Desmond Curran.

The method of ascertainment was, thus, different in these several groups. In all cases, equivocal statements such as "I believe this man to be a latent homosexual", without supporting evidence, were disregarded.

For *more detailed study*, a selection was made, on the sole criterion of adequacy of documentation, of 100 cases seen privately by Dr. Curran, 50 St. George's out-patients, and 35 St. George's in-patients, all of whom came within the above definition of homosexual. Visits were also made to the Social Rehabilitation Unit at Belmont Hospital where, at community meetings, requests were made for people with sex problems to come for individual review. This group approach produced 39 volunteers, of whom 15 were male homosexuals. These 15 were added to the other selected patients, making a total of 200 cases for detailed study. In all, 50 were seen with research in mind; in the remainder, records taken for clinical purposes were used.

FINDINGS

Fig. 1 shows the recorded incidence of the problem in the five groups described (*a–e*). In the St. George's and private series, the numbers who came because of a criminal charge are also indicated, by solid shading.

The 1,329 in-patient records of St. George's and Belmont were analysed for age and for associated diagnoses. There was a very striking difference in the known incidence in different age groups, which fell steadily from 12% in the under 25's to 1·6% in the over 60's. Table I compares the proportions of cases of homosexuality among 138 psychopathic personalities, 177 schizophrenics, 70 alcoholics (in the addictive sense), and 336 patients suffering from endogenous depression, or depression treated with E.C.T. The apparent differences are not significant on statistical test.

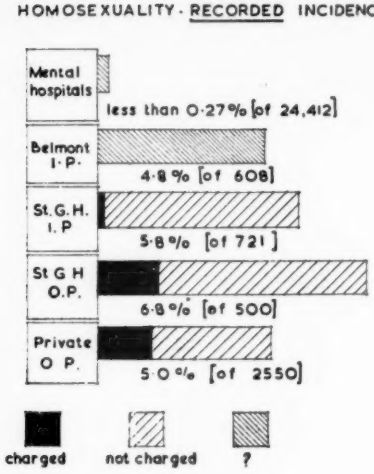

FIG. 1.

TABLE I

INCIDENCE IN DIFFERENT DIAGNOSTIC GROUPS: COMBINED HOSPITAL FIGURES

Diagnostic group	% Incidence of homosexuality
Psychopathic Personality (of 138 cases)	8·7
Schizophrenia (of 177 cases)	6·8
Alcoholism (of 70 cases)	4·3
Depression (Endogenous) (of 336 cases)	3·6
All diagnoses (of 1,329 total cases)	5·3

Estimates of the incidence of homosexuality have ranged from 2% to 100%, it being the view of many psychoanalysts that the condition is universal. For our 1,329 psychiatric male in-patients, the overall incidence was 5·3%. This is undoubtedly an underestimate. Apart from the difficulties already mentioned, there is a further special obstacle to ascertainment. It is a regrettable fact that none of us can guarantee a patient permanent and unconditional secrecy in respect of case notes. There is no knowing, for example, whether at some future date somebody, not necessarily ourselves, may be subpœnaed to reveal every detail of a case history in a court of law. For this reason, some doctors feel that it is wrong, unless clinically essential, to leave written records of criminal sexual practices in hospital files. In countries where security probes are more highly developed, the problem of documentation must be difficult and painful for the doctor.

Fig. 2 gives an indication of the age distribution and occupational groups of the 100 hospital and 100 private cases respectively. The age periods are given as decades, and as can be seen, the maximum incidence is in the group 25–35. In the mental hospital figures for 1949–1951 for male sex deviation of any kind as a primary diagnosis, the age distribution among 182 cases is similar. The classification of available criminal figures is somewhat different, but it appears that the highest incidence of detected homosexual crime is in the age group 31–40. As to occupational groups, the histograms on the right show the percentage distribution using the Registrar General's classification of occupations. (I = professional; II = semi-professional; III = skilled; IV = semi-skilled; V = unskilled.) There is a marked difference in the occupational distribution in the private, neurosis hospital and mental hospital groups. This is not in the least surprising in view of the selective economic factors operating, but the small percentage of groups (IV) and (V) who come to psychiatric notice as homosexuals or sex deviates is rather striking. The magistrate and the prison officer see a higher proportion of men from these classes.

In 40 of the 50 in-patients, homosexuality was an incidental finding only and had no part in determining admission. In the 150 out-patients, the most common reasons for referral were: criminal charge in 39 cases, anxiety over homosexual feelings in 38, various apparently non-sexual problems such as depression or excessive drinking in 39. 12 cases, all of them private, were brought by friends or relatives who asked such questions as "Why is he not married?" and 11 came with marital difficulties. Assessment of fitness for teaching was the issue in 2 cases, while one kept an appointment that he had made several months previously while in prison. One homosexual young man came several times ostensibly to seek treatment by proxy for a friend whom we never saw.

It is not worth listing all of the associated psychiatric disorders in detail in view of the complexity of multi-dimensional diagnosis. In the case of the 150 out-patients, abnormalities found consisted very predominantly in personality problems or neurotic illness rather than psychoses. 17 of the 150 were sociopathic by other criteria. 68 of the 150 were free from gross personality disorder, neurosis or psychosis during their adult lives. This may be thought a high percentage considering that all of these patients came for psychiatric attention. The

Age and occupational status of 100 neurosis hospital, 100 private and 182 mental hospital cases

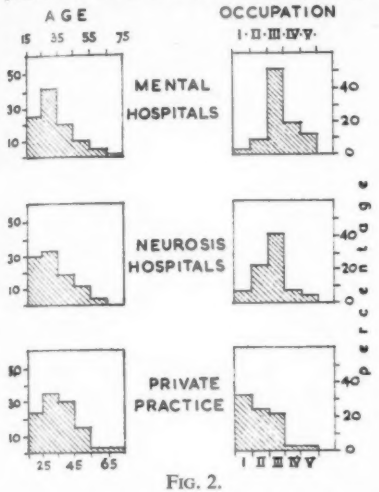

FIG. 2.

reason is that so many came because of a criminal charge or transient situational problems. I think also that many homosexuals reach a stage of wanting medical confirmation of their own belief that they are irretrievably homosexual, so that they can feel free to go on practising for the rest of their lives. When in-patients were included, out of the whole series of 200 one was defective, two dull, three demented and three certifiably insane.

All but 23 of the 200 admitted to one or more acts with others since puberty. Where information on frequency was available, it was possible to make a very conservative estimate that the practising cases committed at least seventeen criminal acts a year each. Of the practising 177, buggery was noted in 42% and fellatio in 24%. In 50 cases about whom better quality information was available because they had been seen for research purposes, the corresponding figures were 62% for buggery and 50% for fellatio. The more we see of these cases the more we incline to the view that there are few regularly practising homosexuals who do not try all variety of acts at one time or another. In the private series of 100, it was found (Curran and Parr, 1957) that those known to practise buggery differed from the remainder of the group only in having a higher level of promiscuity. This finding was confirmed in the larger series including hospital cases.

On the subject of passive or active preference, although many individuals seemed to prefer one role to the other, the majority had practised both at different times, and some were predominantly passive at one time in their lives and predominantly active at another. The exclusive passivity of one man who could masturbate only by means of a candle inserted *per rectum* was, in our experience, unique.

Mechanical details of this nature are of less clinical importance than the preferred age of the sexual partner. Pædophiliacs, meaning those with impulses towards prepubertal boys, are rather a distinct problem. Of the 200 patients studied, 29 had pædophiliac impulses at one time or another. Only 4 had at different times in their lives committed homosexual acts with adult men and with prepubertal boys. The overlap between pædophiliacs and adult-seekers, as they may be called, was therefore very small. Between those active with boys aged 14 to 16 and those active with younger or older age groups it was considerably larger. There was no evidence of any tendency for homosexuals preferring adults subsequently to commit acts with young boys—the so-called "Rake's Progress".

Significantly more of the pædophiliacs than of the remainder of the series were bisexual. The practising pædophiliacs showed a rather remarkable capacity for self-deception and self-righteousness. The special problem of the pædophiliac is, in my opinion, aggravated by the fact that he has no group affiliations in his sex life. Homosexual society differentiates and acknowledges many of its practising members with such titles as Duchesses, Queens, Cows, Bitches, Butches, and Butch-renters, but so far as I have been able to discover, there is no name for the pædophiliac.[1] He is disapproved of and rejected by the homosexual world as by the world in general, and is obliged to be a furtive lone-wolf in his sexual pursuits.

Sexual perversions other than homosexuality were noted in 30 of the 200 cases, the incidence being higher in the hospital than in the private groups. Some psychopaths admitted to experimental indulgence throughout the whole range of sexual deviation, when as normal and neurotic men were less polymorphous in these respects.

In general the series was highly promiscuous. For example, in 51 cases where relevant information was noted, the median number of homosexual partners admitted was 12 and the mean 38. Of the 200, 35 specifically admitted to acts in public lavatories, affectionately known as "cottages" in the parlance of the queer world.

It is sometimes claimed that promiscuity, as opposed to fidelity, in homosexual relationships is in itself a symptom of associated psychiatric disorder. This is an attractive thesis, particularly in relation to psychotherapy, but we have not been able to confirm it in our series. Indeed, on comparing the psychiatrically normal homosexuals with the remainder

[1] The author has since learnt from conversations during a WHO study tour that the same is true of homosexual society in Sweden.

of the series—or, if preferred, the less abnormal with the more abnormal—the reverse is found to be true. Significantly more, at the 5% level of probability, of the less abnormal sub-group admitted to 6 or more partners. Nor have we been able to confirm Henry and Gross's (1938) finding that underprivileged homosexuals are more promiscuous than the more favoured economic groups. Comparing Groups I and II with the remainder of the combined series reveals no significant difference in this respect.

In regard to civil status, 37 of the 200 cases were married. The mean age at marriage was 27·3, which is the same as the national average. Two-thirds of those who married did so before the age of 30. As many married women younger than themselves as married older women, the mean age difference being 0·3 year older than the wife, as against the national average of three years older. Some almost completely homosexual men claimed normal technical performance in intercourse. The subject of married homosexuals deserves special study, but unfortunately case material is all too hard to find.

No significant difference was detected in the psychosexual experiences in early or later life of the grammar and public school boys, who constituted respectively 20% and 35% of the whole series. It is probable that the significance of segregated or boarding school education as a contributory factor in homosexuality has been greatly exaggerated. Adult homosexuality may occur in spite of co-education at all stages of childhood and adolescence. In view of the facts that the vast majority of the population is educated at State day schools, and that many, if not most, of such schools are co-educational, it is surprising that the myth of segregated education as the principal cause of homosexuality has been so long sustained.

For reasons discussed in a previous publication, we believe the Kinsey Scale to be a most valuable classification. In these 200 patients, the Kinsey rating was often not used at the time, but the majority were classified as 100% homosexual, bisexual-predominantly homosexual, bisexual-predominantly heterosexual, or simply as bisexual. 83, that is 41·5% of the whole series, were classified as Kinsey 5 or 6 or as 100% homosexual or nearly so, and the proportions in the private and hospital series so diagnosed were practically the same.

In regard to the controversial question of early seduction and its effects, we have found no significant association within the series between a history of seduction and a tendency to pædophilia in adult life. The finding in the private series that seduction was reported more often by those on a criminal charge than by those not on a charge was not confirmed in the hospital series. In a retrospective survey (made by P.S.W. colleagues) of 100 consecutive male referrals to the St. George's Hospital Child Guidance Clinic, the number referred because of alleged seduction was 3, while seduction was an incidental finding in another 3. In none of these cases, so far as could be ascertained, was the event a major causal factor in the child's psychiatric disturbance.

The recent work of Garrone and Mutrux (1956) in Geneva reminds us that the investigation of sexual deviation on physical lines has, to date, been notably unrewarding. We have little to contribute in this connexion. Laboratory examination of semen by Dr. G. I. M. Swyer and sexing of polymorphonuclear blood cells by Dr. J. L. Stafford have been carried out in a few cases, so far with normal findings.

So far as the clinical data are concerned, our findings need to be interpreted with great caution in view of the nature and size of the sample. On the other hand, comparison of private patients with hospital patients, and of out-patients with in-patients, has revealed few important discrepancies in the main findings.

Having begun by deprecating the surfeit of speculation in the literature on homosexuality, I should like to end with some highly speculative arithmetic.

If the incidence of homosexuality in different age groups in the male population of England and Wales was the same as in the groups of in-patients we have studied, and if the average figure of fifteen criminal acts a year each applied to all these homosexuals, then the ratio of criminal acts to known indictable homosexual crime would be of the order of 2,500 to one. To take another series of assumptions, if the Kinsey findings were true of England and Wales, then within the age group 21 to 30 only, this ratio would be 30,000 to one.

Such fanciful figures may be of little more than journalistic value. Their exact validity, however, is less important than the fact that there is an almost astronomical disparity between the numbers of illicit sexual acts that occur, and those that are detected and prosecuted by the guardians of the Law. Perhaps on this point—if on no other—we can all agree.

ACKNOWLEDGMENTS

My thanks are due to Dr. Desmond Curran for his guidance throughout this investigation, to Dr. Louis Minski and Dr. Maxwell Jones for facilities for work at Belmont Hospital and Social Rehabilitation Unit, and to the Research Funds of St. George's Hospital for financial support.

Homosexuality, with Special Reference to Classification

By P. D. Scott, M.A., M.D., D.P.M.

The first impulse towards the study and classification of homosexuality as a clinical entity came from K. H. Ulrich, a legal official in Hanover in the middle of the last century. Himself sexually inverted, it is characteristic that he should have viewed the matter in two colours only; to him an individual was either an urning or a dioning and had been born that way. Subsequent investigators, accepting the plausible opinions of their patients and perhaps believing that only an inborn condition could be so resistant to treatment, persistently included in their classifications of homosexuality a "congenital" group. Many, perhaps most, psychiatrists continue to do so to-day.

In addition to his congenital group, however, Krafft Ebing (1883) recognized the outstanding clinical fact that some homosexuals have circumscribed sex perversion while others have their whole personality coloured in harmony. Schwarz, on the one hand, said that "Serious perversions are imbedded like a foreign body within a completely normal personality", while Karen Horney, on the other, maintained that character explains perversion and that sex disturbances are the effects not the causes of neurosis. This new approach had been made possible through Freudian teaching which, in essence, postulates an original and basic freedom of choice of love object and that the homosexual's choice is limited by dominance of castration fears. Ferenczi introduced two new categories, the subject-homo-erotics (more narcissistic than feminine, behaving as the subject wished his mother had behaved to him) and the object-homo-erotics (anal rather than phallic characters, wishing to enjoy sex in the same way as mother, tending to submit themselves to father figures). While these active-passive homosexual, and subject-object homo-erotic categories have real clinical significance, their usefulness is diminished by the fact, recognized by Freud and others, that the forms are commonly mixed or successive to one another.

Kinsey's work removed the concept of a third, intermediate, sex. There are hazards, however, in using for clinical purposes what were purely research categories. Placement of an individual in one of Kinsey's six grades must be highly subjective; Kinsey himself had to abandon his neat definition of homosexuality for this purpose and considered "both psychologic reactions and overt experience". Doctors tend to see mainly those in grades 5 and 6. Position on the scale does not indicate absolute frequency, force of drive, "compulsiveness", whether the homosexuality is a matter of phantasy or action. Bisexual as well as homosexual and, indeed, heterosexual persons may become recidivist sex-offenders. Conversely, an apparently totally homosexual person may be facultative in the sense of being able to respond to environmental changes, of being adaptable, of lacking a strong compulsive drive to one form of sexual behaviour. Especially where there has been long segregation in communities of one sex, or if at the time of examination the individual is living in such a community, then, even if homosexual behaviour is habitual and exclusive, there should be caution in assuming that it is irreversible. It would be reasonable to postulate two variants. One concerning choice of object (homosexual, heterosexual, &c.) and the other concerning the freedom or rigidity with which this choice is expressed (facultative, "compulsive"). In many bisexual cases there is very much less real freedom of sexual expression than at first sight appears.

Dramatic changes in mode of sexual expression are commonly observed and only serve to underline how much homosexuality is a complex adaptation as distinct from entirely an inherent tendency.

Rado describes Variational, Situational and Reparative patterns of sexual behaviour. The reparative patterns are means, largely unconscious, of circumventing early fears. He points out that these reparative patterns are highly inflexible and that the individual depends upon them for full orgastic gratification in all circumstances. He states also that such an individual cannot gain real satisfaction from standard sexual performance, evidently not accepting that some individuals are so successful in their adjustment that they are frequently able to enjoy heterosexuality provided they pay for it in the appropriate manner. His approach like that of Boss and other existentialists makes for a classification of all sexual activity rather than for a limited classification of homosexuality alone.

Equally broad and even more clinically applicable is Mangus' classification of sexual deviations—non-pathologic, subcultural and pathologic deviations. The latter he divides into seven degrees taking into account the degree to which the tendency is abnormal, the strength with which it is expressed and controlled, and the extent to which it is dangerous or embarrassing to others. It is broad classifications such as this which prevent the not

infrequent confusion of, say, homosexual play in childhood and adolescence, with reparative patterns seen in clinics, or with so-called homosexuality in ancient Greece or in isolated island communities. It is fair to state that these conditions are utterly unlike and that conclusions based on one group are by no means applicable to others.

For completeness the concept of pseudo-homosexuality, which appears in many classifications, needs comment. Some writers describe as many as twelve different forms of pseudo—or spurious—homosexuality. This throws much light on the psychopathology of homosexuality but is not really useful for classification purposes, for all homosexuality is spurious or counterfeit sex, and the personality has always to be taken into account. Since the quality of the personality seems to be of major importance in matters of prognosis and treatment the following groups (recognized as arbitrary sections from a continuum) were defined as seeming to represent the male homosexual material seen in hospital clinics, prisons and remand homes:

A. *Adolescents and mentally immature adults* sometimes go through a phase in which they are uncomfortably aware of their attraction to both sexes and do not know how to resolve their quandary. Some seem to settle in favour of heterosexuality and have no further trouble, others become homosexual or manage to become stable bachelors. In any event they are much in need of supportive psychiatric treatment and perhaps of psychoanalysis. They are not socially dangerous.

B. *Severely damaged personalities:*

(1) The very effeminate, self-advertising, female-impersonating individual who talks in an affected manner, walks with a mincing gait, wears make-up and frilly underclothes. Most of these are sexually self-sufficient but, needing to be acclaimed by others, they enjoy the chase rather than actual sexual contact, though they may become homosexual prostitutes. Most homosexuals avoid these persons unless for want of more satisfying partners. They are not socially dangerous.

If young, and they usually are, they are best placed in a hostel, but it must be one in which the warden is familiar with the problem. Many lay-people consider that such youngsters will demoralize the community. But if handled calmly and given a homely atmosphere they settle readily and harmlessly. Psychological treatment as opposed to psychologically inspired handling, does not seem to be successful.

(2) The inadequate, down-trodden, dull (whatever the I.Q.) who have never experienced a loving relationship with anyone and are almost socially isolated. They tend to snatch fleeting contacts in lavatories sometimes for payment, are not socially dangerous and are likely to be untreatable in the clinic. They are most likely to respond to very long-term supportive treatment from a probation officer or other social worker. Ideally they should be accommodated in special communities for those who cannot cope with ordinary social requirements.

(3) The deeply resentful, antisocially inclined individual usually with a long record of court appearances, starting in childhood with Truancy and Beyond Control charges. They tend to come from homes in which the mother is at the same time possessive and hostile to the boy. It is difficult to determine to what extent they really are homosexual, for they are ready to exploit anyone and anything. Socially they are dangerous to other homosexuals whom they victimize and to society through their non-sexual offences. They seem to disappear from clinics after the 20's, perhaps to prison. No treatment method has been shown to be effective.

C. *Homosexuality in relatively intact personalities* who are quite well socialized. This group includes the youths who have digested scruples and are living pleasurably, often under the patronage of older homosexuals of the same sort. Such individuals soon learn the ropes, rarely approach anyone before they are sure that it is safe. These people are happy, are able to hold useful jobs. They support one another. They are not at all socially dangerous. They do not want treatment and it should not be forced. A sympathetic attitude with explanation of the particular risks they run at time of emotional stress, is often worth while and all that is necessary. If they have been handled tactfully they will, and do, come back.

In this division also are the less happy individuals who are unlucky enough to be bound to socially more difficult love objects such as children, so that there can be no support from the minority group for them. These, of course, may be a danger to children. They benefit with psychiatric treatment and some psychotherapists are optimistic about helping if not curing them. They may also respond to probationary supervision in controlling if not in radically changing their sexual preference.

D. *Latent and well-compensated homosexuals.*—These are often men of considerable strength of character who may not appear in court or clinic until late in life. They either genuinely do not know what their real difficulty is or else have struggled in the main successfully against it. Very often they are intelligent, perhaps married with healthy children, perhaps teachers, business directors, youth workers. They are particularly at risk during times of additional stress or during the depressions of later life. They are also particularly likely to carry out one of the symbolic or "incomplete" offences, touching, fondling, exhibiting in lavatories. Unfortunately children are often involved but are always treated gently and are probably already predisposed to such approaches. They usually soon regain their poise and should then be kept under occasional observation through a supportive clinic. They may perhaps be tided over further danger periods by means of closer support, together with sexual sedatives (œstrogens). It is this group which stands to lose so much through imprisonment. Those who are so unfortunate will be very much in need of rehabilitation afterwards.

E. *Homosexuality coexisting with serious mental disability.*—This ill-defined group includes those with psychoses, organic brain damage and the extremes of personality defects. They are, of course, very dangerous socially. They are apt to injure their victims in a way which none of the others would contemplate, nor do they take only "predisposed" victims. They have to be segregated till rendered harmless by ageing or specific treatment. Actual punishment is, however, probably less useful here than in any of the categories. Section 8 of the M.D. Act 1913 or admission to a mental hospital may be indicated. This is the group which presumably should be accommodated in an East-Hubert prison-hospital.

With the help of colleagues at the Maudsley and Bethlem Royal hospitals, all the cases diagnosed as homosexual in the two hospitals during 1951 and 1952 were analysed in certain respects. There were 72, 63 males and 9 females.

A fertile field for research would seem to be the comparison of homosexuals with other selected samples, in respect of personality and family background. It has several times been stated that homosexuals are more intelligent than other sex offenders, and certainly they give the clinical impression of being in the main better integrated persons. The following assessments of social class and occupational grade with different samples of homosexuals confirms the general direction of this suggestion. The average ages of the homosexuals and exhibitionists were 34 and 31 respectively.

SOCIAL CLASS DISTRIBUTION (MALES OVER 15)
ACCORDING TO THE REGISTRAR GENERAL'S CLASSIFICATION

Social class	Greater London Conurbation 1951 Census (2,904,849) %	London exhibitionists 100 hosp. pts. %	26 prison convicts %	London homosexuals 100 hosp. pts. %	40 prison convicts %
1	4·6	0	0	2	2·5
2	16·2	4	4	16	22·5
3	55·2	68	58	60	42·5
4	10·7	19	23	19	22·5
5	13·3	9	16	3	10

Similar findings were demonstrated using the Hall and Jones Scale.

The psychoanalysts state that there is no specific homosexual ego, and clinical experience reveals no specific personality type, yet certain features occur so frequently as to suggest a linkage of common causation. The inability to reconcile dependent and assertive drives seems especially common. However able, they sometimes feel paralysed when instructed or expected to carry out a task, even though it be well within their capacity. Associated with this is their common complaint, more marked than in any other sort of patient, of procrastination.

The early belief that the child failed to develop emotional independence from his mother because of her over-gratification of his needs, has now generally been abandoned in favour of the opposite view, expressed by Fenichel—"children in general tend to identify themselves more with the parent from whom they have experienced the more impressive frustrations".

The descriptions of mother as given spontaneously by 36 homosexual patients and 36 controls (neurotic and psychotic) were classified under seven headings and compared. Approximately two-thirds of each used terms implying good, positive qualities, yet terms implying dominance and negative qualities were nearly twice as frequent in the homosexuals, implying that an ambivalent relationship is commoner in homosexuals.

Impressive frustration in the childhood of homosexuals is certainly the rule. Considering the incidence of broken homes it was found that of a group of 40 convicted homosexuals serving short sentences, one-third came from actual broken homes (one parent absent). All but 3 of the cases showed gross and acknowledged emotional disturbances in their early family life. In a series of 20 juvenile homosexual offenders, half the homes were "broken" and all but 2 showed gross emotional disturbance.

In an attempt to ascertain significant questions for the study of the backgrounds of homosexual patients, Dr. N. H. Rathod and I put a series of 197 questions to 15 homosexual patients and to 15 neurotic or recovered psychotic controls not suffering from sexual disorders. The following composite case history includes the most significant points:

> The patient is a male in his early thirties. His father is likely to be recently dead. Father was much older than mother:
>
> | | Parental age-discrepancy 5 or more years | 10 or more years | 15 or more years |
> |---|---|---|---|
> | Controls | 5 | 3 | — |
> | Homosexuals | 7 | 5 | 4 |
>
> Father is described by the patient in predominantly negative terms. He does not conceal his dislike for his father. Strict, disinterested and jealous are common terms used in describing him. Father himself was brought up strictly. Mother is alive and aged about 59. She is described as a good mother but also as determined, capable, forceful. She is not criticized freely by the patient but he indicates ambivalence to her. Very frequently he either describes his difficulty in showing affection to her, or she to him. She goes out to work and enjoys doing so. She works or has worked as a manageress, teacher, nurse or artist. She worked when the patient was a child, in many cases between the time he was 2 and 6. Mother's marriage was not "forced" by pregnancy. She wanted a boy, yet when she had one often treated him like a girl. Mother is more likely to have been the only child or youngest of her family. She had most feeling for her father, but broke off relationships with her home early. She tends to look down on men. There is no particular tendency to mental disorder on either side of the family. This patient comes toward the younger end of the family. His male siblings have more celibacy or broken marriages. Discipline at home is strict but not necessarily consistent. The patient does not feel rejected. Mother imposes discipline more frequently than father. The patient has often been fussed and

over-protected. In arguments mother gives in less frequently than father. Almost invariably the patient used to avoid fights and rough games. Apart from nail-biting, tics and masturbating, there is no marked tendency to the so-called neurotic traits or behaviour disorders. He did not especially frequently play truant, or bed-wet, or have marked fears. He was, in general, conforming and he helped his mother greatly. Tendencies to dressing-up, amateur dramatics, feminine occupations, playing exclusively with girls before puberty, were surprisingly not especially common. He got on better with adults than with young people. He did not want to be like his father. He was much aware of inferiority feelings as a child. His awareness of sexual feelings was early but the onset of puberty was not.

	First awareness of sexual feelings					Av. onset of puberty (Years)
Age in years	0–5	6–10	11–15	16–20		
Controls	—	4	7	3	Controls	14
Homosexuals	4	4	5	1	Homosexuals	14

FIG. 1.

Finally, Fig. 1 epitomizes much of the homosexual's problem. It is of a 4½-year-old boy, now an actor in his fifties, Kinsey grade 6. He is wearing a red velvet dress, his hair is dressed with macassar oil and done up in a bun; though difficult to see in the photograph he is wearing a bangle and a large ring; he carries, of all things, a whip. Even in those days it was quite exceptional to treat a boy in this way at 4½. Mother was described as "deeply religious and very, very strict". Father was twelve years older than mother and died young. Most of this boy's upbringing was left to unwilling older sisters of whom there were six. He is the only boy and youngest child. A constellation of circumstances more certain to produce sexual disorder of some sort could not have been devised; the most superficial investigation by a social worker could surely have recognized his peril. No preventive action was taken and, furthermore, despite the considerable advance in knowledge, it is scarcely any more likely that preventive action would be taken in similar circumstances to-day—half a century later. The irony of the matter is that though he did not rebel then, he has spent the rest of his life rebelling in the sexual field and otherwise, and though he was probably unhappier then than he is now, it is to those days and to that red velvet dress, that he has always wanted to get back. It is also to that age group that we should be looking for the answers to questions of causation and prevention of crime and sexual maladjustment alike.

Dr. I. C. N. Gibbens:

One of the main conclusions we can draw from this discussion is that there are many types of homosexuality and that many apparent differences of opinion may be due to people talking about different types as if they were one. My own experience has recently been with yet another type—the ordinary offender, usually thief or house-breaker, who happens to be homosexual. Recently, I examined every other lad (aged 16–21) sentenced to Borstal training in the Greater London area,

comprising a total of 200 lads. None of them was sent to Borstal for a homosexual offence or had ever been convicted of one. All of them are being seen again in Borstal a year later; since this has been carried out in the first hundred, and forms some sort of check, I shall refer mainly to them. The incidence of homosexuality was similar to estimates which have just been given. 3% were homosexual prostitutes (convicted of larceny or robbery) who talked about their inclinations freely. A further 13%—making a total of 16%—were considered to have important homosexual problems which might complicate training, although they denied any inclinations. Two were later shown to have withheld information about strong tendencies, but many of the others were suspect because they were uninterested or undecided in the direction of their interest. After following them up, it seemed that the best pointers were hostility to girls, a fear of being "bossed", or cheated by them; and an unexplained conviction that they would never marry. When seen a year later, the prostitutes had not given much trouble, and one of the others had been sent to prison for a serious offence. Again, 13% of the lads—unfortunately, not very often the same lads—had had to be dealt with for homosexual behaviour; usually of a minor kind but never an isolated event. A total of 15% therefore either showed homosexual behaviour or had declared inclinations. The figures for the second hundred were similar—5% with definite inclinations and 20% "suspects". When the suspects were contrasted with the remainder in respect of 94 objective factors in criminal and social history, the statistically significant differences were that the suspects had had neurotic symptoms and psychiatric treatment more often, and, rather curiously, that they practically never had a major physical disability. Physical defects do seem to be common in other types of sexual deviant.

The most interesting information produced by these lads, however, referred to seduction. During examination of the first hundred it became clear that many had been sexually approached by adult men, though this was often not mentioned since an experience of this sort was not considered to be related in any way to discussion about homosexual experiences at school, &c. The second hundred were asked systematically whether an adult had ever "made a pass at them": no less than 34% remembered at least one incident of this sort. Usually "a man in a cinema once put his hand in my lap": less often money had been offered in some alley-way. The interesting thing was the proportion reporting this was precisely the same whether the boy was a "suspect" or not—34%. The ordinary heterosexual boy clearly thought it of no significance and not worth mentioning in reference to his sex experiences. 8% had suffered some actual seduction; the unusual feature was that there had been a response, though some had had experience with contemporaries before and the incident only taught them that it could be financially profitable.

Little has been said about physical factors in homosexuality. I believe that these undoubtedly exist, but, again, the lack of satisfactory classification of homosexuals has prevented progress. The first one hundred were asked to agree to measurement and anthropometric photography after the manner described by Sheldon, but with the improved technique of Tanner (1951). Only 56 lads consented, and the material bearing on homosexuality is, therefore, small. As a whole, the Borstal lads were markedly mesomorphic (muscular) in somatotype. In the "suspect" group the two main characteristics were:

(1) That the extreme in each dimension—in endomorphy, mesomorphy and ectomorphy—was a definite homosexual.

(2) Pronounced endomorphy is uncommon in delinquents, and 3 of the 5 examples were suspects.

(3) The characteristic physique of the "undecided" and undifferentiated suspects was mesopenia, or lack of muscle: they looked and were rather feeble youths.

From the institutional point of view these lads fall into roughly four groups:

(1) 3% of prostitutes or others of declared inclination who are in some ways the least difficult to manage, though their response to training is problematical.

(2) 2% of older neurotic lads with strong but concealed inclinations. These are the most difficult since they are liable to emotional upheavals without notice.

These two groups are the more serious homosexuals. The remainder are composed of:

(3) 5% of rather aggressive and criminally sophisticated youths: they have strong heterosexual interest, though often with much conflict, and their activities are partly a substitute.

(4) 5% of immature undecided lads whose activity is of the common schoolboy type.

I should like to add that to an outside observer like myself the method of dealing with cases in Borstal seems to be tactful and humane, protecting the individual from undue influence, but not depriving the homosexual outright of a chance of benefiting from training.

DISCUSSION ON DISORDERS OF THE HIND-BRAIN CIRCULATION

Mr. John M. Potter (University Department of Neurosurgery, Manchester Royal Infirmary):

Arterial Blood Flow Patterns

The cerebral circulation via the vertebral arteries has received much less attention than the circulation via the carotids: because the latter are so much more easily accessible before and after death, they have received a disproportionate amount of attention.

Nearly ten years ago, we (McDonald and Potter, 1951) were attracted to the vertebral-basilar system which in the rabbit—the experimental animal that we used—is similar to but relatively more pronounced than that of man. But we were soon distracted from the cerebral circulation itself by the discovery that the blood flow in the basilar artery was laminar or streamline in type; rather than a truly turbulent (or hydraulic) flow in which the components of a fluid follow random pathways and which is wasteful of energy. That streamline flow occurs in veins has been known for many years, but the ready opportunity for observing whether or not it is present also in an artery does not arise until one is able to see two arteries joining to form another, and this is the unique feature of the usual type of vertebral-basilar junction. Moreover, in the rabbit, these arteries are sufficiently translucent to see what goes on within them.

Thomas Willis (1684), in referring to the anatomy of the brain, said that "in other parts where matters appear to the senses we do not so easily fall upon errors", and he thus indicated the general truth that knowledge comes more slowly concerning structures which are well shielded from the cursory investigator. The careful and time-consuming studies of Hutchinson and Yates (1956) have emphasized that we may indeed "fall upon errors" if we consider the cerebral circulation only in terms of the carotid arteries and their patency.

Since Willis's day, the anatomical approach has been a popular one in deducing cerebral circulatory function; but, as in other spheres, it is in itself inadequate, and this is particularly so in the study of arterial anastomoses. An anastomotic artery, it is ordinarily assumed, will have blood passing through it in one direction or the other. But sometimes blood will enter it from either end—and what happens then? We borrowed a term used by Kramer (1942), the "dead point", to describe the interface between the two such opposing columns of blood. I think now that this is an ill-chosen term, for it has a dead, anatomical inadequacy, and misses the essentially dynamic activity that is present at such a point.

[A cine-film: "Blood Streams in the Basilar Artery" was then shown by the author.]

Such evidence as I have suggests that the basic pattern of blood-flow in the rabbit is present also in man, but that in man it is probably modified by the more erratic formation of the vertebral-basilar junction. In the rabbit, the limbs of the Y-shaped junction usually lie symmetrically all in one plane, and I do not recall ever having seen (in some 60 rabbits) a basilar artery that was at all tortuous. These anatomical differences in man should not in themselves produce true turbulence of the bloodstream, but they might affect the course of the individual streams and allow perhaps spiral streams which would give in an arteriogram the appearance of filling the lumen of the basilar artery.

I have examined vertebral arteriograms of 74 patients with an eye for these points. In the first place, some of those films which were relative failures as arteriograms were of considerable interest in other ways. In nearly a quarter of all the arteriograms there was distinct evidence of streamline flow in the basilar artery, and in a third of these it was seen in the *lateral* view. Now, if it is seen in this proportion, it is likely to be the normal state of affairs, for the streams are easily upset, whereas it would be impossible, I think, to create them by injection into an already turbulent bloodstream. Furthermore, the theoretical approach suggests that the threshold for turbulent flow is unlikely to be reached in this artery except perhaps at the peak of systole in a large artery, or when there is a high pulse rate. McDonald (Hale *et al.*, 1955) has, in recent years, been concerned with the complexities that are introduced into this subject by the pulsatile nature of the blood flow, and he has kindly checked on this matter. I have supplied him with measurements taken from the arteriograms, which show a mean internal diameter for the basilar artery of 3·0 mm. with a rare maximum of 5·0 mm. and a minimum value of 1·7 mm.

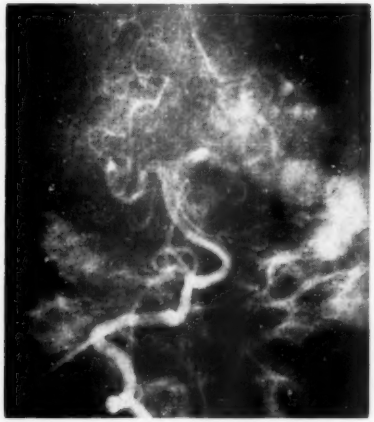

FIG. 1.—Rt. vertebral arteriogram, showing streamline flow in a large basilar artery.

Velocities of flow have to be guessed for man by analogy with animals in which they are known. A high velocity makes for instability of the streams, but it is of interest that one of the best arteriograms showing streamline flow (Fig. 1) is seen in a case of an arteriovenous malformation where the velocity of flow might be expected to be abnormally high and in which the basilar artery is rather a large one—4·2 mm. in its maximum internal diameter. Sometimes a ghostlike appearance of an artery is seen with sharp contrast medium only where it is clinging to the walls. Flow is slowest there, and the most peripheral laminæ get left behind after the more axial streams have passed on.

Finally, the contrast medium may represent only a portion of the lumen of the artery; that is, only one set of streams is shown. This was striking in one arteriogram, where an apparent difference of one millimetre in the diameter of the basilar artery was seen between that in one film which showed only some of the streams, and that in another where the lumen was fully filled with contrast medium.

Dr. E. C. Hutchinson (Newcastle, Staffs.):

When the clinical effects of occlusions of the proximal portion of the vertebral artery are considered it is necessary to define the words "proximal portion"—it refers to that part of the artery within the vertebral arterial canal and the part arising from the subclavian arteries. Stenosis or occlusions of this part of the artery play a much larger part in cerebrovascular disease than the relatively rare examples of occlusions of the intradural portion of the vertebral artery. In the 35 patients who died as a direct result of a "cerebral thrombosis" it was later shown that stenosis or occlusion of the cervical portion of the vertebral artery played a part in the final infarction of brain tissue in just over one-third of the patients. In contrast, occlusion of the hind-brain arteries within the skull was present in only 3 patients.

Analysis shows that the vertebral artery, when affected by atheroma in the neck, plays a part in the clinical picture in one of three ways. Firstly, acting alone, stenosis of the cervical portion may cause infarction of the hind-brain; secondly, combined with disease of the carotid artery it may produce a characteristic pattern of infarction of the hind-brain—characteristic in that it affects both the cerebral hemispheres and the cerebellum; thirdly, disease of the vertebral artery may be an important factor in the syndrome of carotid artery occlusion.

The 2 patients with hind-brain infarction due to stenosis of the vertebral artery have been previously described (Hutchinson, E. C., and Yates, P. O. 1957, *Lancet*, i, 2) but it should be noted in this context that the 3 patients with occlusions of individual intracranial hind-brain arteries also showed extensive disease of the vertebral artery in the neck. It may well be that further studies will define a syndrome in the hind-brain, associated with vertebral artery disease, comparable to that seen in the fore-brain with internal carotid thrombosis.

When the cervical portions of the vertebra and carotid arteries are both affected by atheroma the clinical effects are seen in one of two situations. The first occurs as a result of a fall in the systemic blood pressure from various causes. We have seen it in operative shock, Stokes-Adams attacks and carbon monoxide poisoning. Following the episode of hypotension there suddenly develop the signs of an intracranial lesion. The clinical picture is not remarkable, the patient usually being unconscious with a hemiparesis, but the pattern of infarction of the brain is distinctive since both the cerebrum and cerebellum are affected simultaneously. The infarction of the cerebellum, at least, must be attributable to disease of the vertebral artery. The second effect, and this is probably the most important role of the vertebral artery in cerebro-vascular disease, is seen in the syndrome of occlusion of the carotid artery.

One of the most puzzling features of this syndrome has been the mechanisms underlying the recurring episodes of motor and sensory disturbances so frequently seen.

In a series of 13 cases, with adequate clinical and pathological data, the clinical history followed one of two broad patterns. In 7 cases the history consisted of a single episode and this eposide was usually a hemiplegia. The mechanism of the hemiplegia as shown at post-mortem was either occlusion of the middle cerebral artery independent of the diseased carotid or extension of thrombus from the carotid to the middle cerebral artery. In each case the vertebral arteries, and often the other carotid, were free of disease. In contrast there were 6 patients who presented with what may now be called a "classical" history of internal carotid thrombosis. In each of these 6 cases not only were the carotid vessels stenosed or occluded but also the vertebral arteries in the neck were affected to a similar degree. Because of these observations we feel justified in regarding this particular presentation of carotid thrombosis as an expression of failure of the collateral circulation—an important factor in this failure being stenosis or occlusion of the vertebral artery.

Dr. P. O. Yates (Department of Pathology, University of Manchester):

Pathological Changes following Proximal Vertebral Arterial Stenosis

This paper is based on the pathological findings in 100 patients who were selected for particular post-mortem study because they had shown clinical evidence of cerebral ischæmia.

Though I am concerned with the pathological changes following proximal vertebral arterial stenosis, I do not believe that any really valid conclusions can be reached concerning the effects of disease of the vertebral or of the carotid arteries on the brain without a full knowledge of the state of all 4 vessels throughout their course. In these 100 cases, therefore, the whole length of the carotid and vertebral arteries was examined both radiologically and by dissection. This was facilitated by injecting the vessels at post mortem with a radio-opaque gelatin mass consisting of 15% silver iodide in 10% gelatin. The mixture was prepared by adding silver nitrate solution to solution of potassium iodide and gelatin in water. The cervical vertebræ were removed entire, the bone decalcified and the arteries dissected (Fig. 1).

Significant atheromatous stenosis (narrowing of the lumen by half or more, or complete occlusion) was less common in the vertebral arteries (57 vessels) than in the carotid arteries (77 vessels). In 5 cases both an internal carotid and a vertebral artery were occluded, this being the same incidence in this series as bilateral carotid occlusion.

In the vertebral arteries the sites of stenosis or occlusion were slightly more scattered than in the carotids but, like the internal carotid, the lesion was most common within 2 or 3 cm. of the origin of the artery (36 vessels). In the next part, extending from the sixth to the second cervical vertebræ, 17 vessels were affected; in the tortuous segment 8 arteries were stenosed or occluded; 4 vessels showed significant narrowing in the intracranial parts.

Thrombosis, which was found in 6 vertebral arteries (compared with 15 internal carotid arteries), was not significantly predominant at any point along the course of the vessels.

There was another type of lesion often responsible for narrowing of the lumen; this was the elevation of a plaque of atheroma by hæmorrhage into its depths (Fig. 2). Some of these lesions were recent and probably in part responsible for the terminal illness; others were older. Such lesions have been suggested as the frequent cause of coronary arterial occlusion and myocardial infarction (Paterson, 1936).

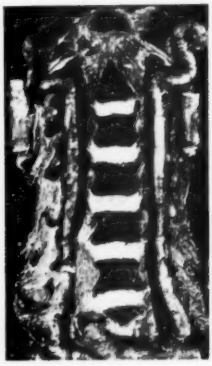

FIG. 1.

FIG. 2.

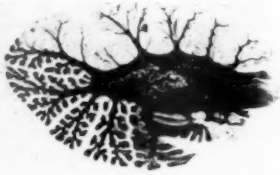

FIG. 3.

FIG. 1.—Dissected specimen showing the normal course of the proximal part of the vertebral arteries; the internal carotid arteries have been pinned to the side for display purposes.

FIG. 2.—Vertebral artery showing partial dissection of the arterial wall by a hæmatoma which had arisen in the depths of an atheromatous plaque. The lumen of the vessel is narrowed.

FIG. 3.—Complete loss of the granular cell layer in that part of the cerebellar cortex supplied by the superior cerebellar artery.

Sudden hæmatomata of this kind might indeed be responsible for the more prolonged episodes of neurological disability which characterise the clinical picture of stenosis of the carotid and vertebral arteries. They do not occur sufficiently frequently to account for minor attacks lasting perhaps only a few minutes and recurring several times in the day.

There is another phenomenon which I think is important in its effects on the cervical parts of the vertebral arteries—cervical spondylosis. In this disease the bony outgrowths that occur around the intervertebral joints may cause an anterior and lateral shift of the vessel. When the vertebral artery is otherwise normal, this change of course may be of little significance. If, however, it is already narrowed by atheroma, then movement of the neck, by enhancing the distortion, may cause complete blockage of the artery.

I will now consider the effects on the brain of stenosis of the vertebral arteries—at any rate those ischæmic effects that are indisputably obvious—cerebral infarcts. Out of the 100 cases only 35 showed actual infarction but in these 35 cases there were 74 distinct infarcts of which 16 were in the cerebellum, 4 in the brain stem and 5 in the territory of the posterior cerebral arteries. Of these 74 infarcts in the whole brain only 22 could be accounted for by occlusion or even stenosis of an appropriate local artery. This is even more striking when we consider the cerebellar infarcts since only one was of purely local origin, being an example of that relatively rare phenomenon, thrombosis of the posterior inferior cerebellar artery.

Most of the infarcts of cerebellum and brain stem resulted from failure of the hind-brain circulation either alone or, more commonly, as total cerebro-vascular failure resulting from carotico-vertebral stenosis (Hutchinson and Yates, 1957). There were only 7 cases in which the vertebral arteries alone were narrowed, the internal carotids being normal, and in only 2 of these did infarction result directly from this fact. One of these cases was the man of 47 referred to in an earlier paper (Hutchinson and Yates, 1957), who presented a final clinical picture not unlike thrombosis of the basilar artery. The remarkable thing about this case is that despite the many infarcts no local intracranial arteries were diseased and the carotids were normal. The cause of the five areas of infarction (bilateral and symmetrical in the occipital lobes, bilateral and symmetrical in the territory of the superior cerebellar artery and in the reticular tissue of the pons) was not discovered until the neck had been dissected. There was thrombosis of a large vertebral artery in its cervical portion, the other smaller artery being narrowed.

This symmetry in the pattern of infarction is, no doubt, a reflection of the unique arterial union which the vertebral arteries make to form the common basilar trunk. 8 of the cerebellar infarcts occurred as bilateral symmetrical lesions in 4 cases, either in the territory of the superior cerebellar arteries or at the junction of this territory with that of the posterior inferior cerebellar artery.

The phenomenon of infarction at the junctional zones is of some theoretical interest. These are the regions which are well supplied with anastomotic channels and are therefore

well protected from the effects of occlusion of any one local cerebral artery. However, when proximal stenosis of vertebral or carotid arteries reduces the flow of blood to both sides of the junctional zones simultaneously, then infarction will be most likely to occur in these areas. Such infarcts are characteristic of carotico-vertebral stenosis. It must be remembered that stenosis of the artery on one side of what would normally be a junctional zone causes the zone to shift in the direction of the poor blood supply. Thus the meeting of vertebral and carotid streams which normally takes place in the temporo-parietal and occipito-parietal regions may be unbalanced if there is proximal vertebral stenosis; the junctional point may then be the posterior edge of the cerebellum, the superior cerebellar arteries having become the extremities of the carotid circulation. Such derangements of the normal pattern of cerebral blood flow must be borne in mind whenever an explanation is sought for focal cerebral ischæmia and infarction.

Knowledge of the state of the proximal parts of the vertebral arteries throws considerable light on the ætiology of some forms of cerebellar degeneration. In particular the circumscribed foci of atrophy of cerebellar folia described by Lichtenstein and Levinson (1946) under the term "parenchymatous cortical cerebellar panatrophy" are clearly the result of ischæmia. Damage of this kind and even infarction of the cerebellum can occur when the local supplying artery is normal and patent, the diminution of blood supply being due to stenosis of the proximal or cervical part of the vertebral arteries.

There is another cerebellar lesion, the origin of which is in considerable doubt. Nevertheless, it seems to me that ischæmia due to proximal vertebral arterial occlusion has played at least some part in its production. The lesion is a selective degeneration of the granular layer of neurones from large areas of the cerebellar cortex. The remarkable feature of this degeneration is the complete preservation of the Purkinje cells and a layer of glial cells, forming a band between the pale granular layer and the molecular layer. I have not been able to demonstrate any marked glial or inflammatory cell reaction to this change.

The condition was present in 12 of the whole series of 100 cases; in some it was patchy and it was then most severe in the depths of the sulci at the extremity of the arterial blood supply; in others it involved almost the whole cerebellum. Occasionally the lesion was confined within the territory supplied by a single cerebellar artery. In one case this feature was strikingly obvious, the lesion being bilateral and symmetrical in the superior cerebellar arterial territory (Fig. 3).

I found that 8 of the 12 cases were diabetics and that this was about half the known diabetics in the whole series. However, several of the 8 were extremely mild diabetics and only 2 were in anything like diabetic coma before death. There were, moreover, 4 cases in which there had never been any evidence of diabetes. There was one factor that all 12 cases had in common and that was stenosis or occlusion of the vertebral arteries—indeed most had carotid and vertebral stenosis. 7 of the 12 had suffered infarction of the brain though this was not always of the cerebellum.

Selective granular degeneration has been reported before in adults. In 1943 Winkelman described 2 cases, the one an elderly diabetic the other a case of morphia poisoning with prolonged cyanosis. Bertrand and Godet-Guillain (1942) reported the lesion in 2 diabetics and 12 patients dying from carcinoma. However, in 1951 Brain *et al.* were unable to confirm this association with carcinoma and dismissed the lesion as being the result of post-mortem autolysis. The distribution and selective nature of the lesion makes this explanation unlikely.

In 1954 Hunter and Russell reported selective granular layer degeneration in a man of 37 who, 15 years previously, had shown cerebellar damage apparently the result of exposure to organic mercurial salts. This man had died of myocardial fibrosis secondary to coronary stenosis. There were also in this case severe atrophic changes of the calcarine cortex. I think that this pattern of lesions strongly suggests that failure of the hind-brain circulation might have been at any rate partly responsible for the changes; perhaps the mercurial salts acted by producing prolonged vertebral arterial vasospasm. In considering the ætiology of any mysterious degeneration of cerebellum, brain stem or occipital lobes a vascular cause cannot be excluded until the state of the proximal or extra-cranial parts of the vertebral arteries is known.

DISCUSSION: TONOMETRY

Dr. J. Gloster:

Ocular Rigidity and Tonometry

A tonometric determination of intra-ocular pressure involves an alteration in the shape of the eye. The eyeball is almost spherical and therefore its volume is the greatest possible for a given surface area, and, since fluids are incompressible, any alteration in the shape of the eye necessitates an increase in its surface area. The coats of the eye must therefore be stretched when the tonometer is applied and consequently the intra-ocular pressure is elevated artifically. It is this elevated pressure, P_t, which is measured by the tonometer but, for clinical purposes, one usually wants to know the pressure, P_o, which existed in the eye before application of the tonometer. It is in terms of P_o pressures that the tonometer must be calibrated. One method of achieving this is to connect the eye, via a cannula and a tap, to a reservoir by means of which the intra-ocular pressure can be set at known levels; having adjusted the reservoir, the tap is closed to isolate the eye, the tonometer is applied and its reading is noted. This is known as "closed stopcock" calibration and is clearly a direct way of relating P_o to readings on the tonometric scale. Despite its apparent simplicity, it was soon recognized that this procedure did not give consistent results, the tonometric reading varying from eye to eye at the same intra-ocular pressure. In contrast to the variability of "closed stopcock" readings, it was found that the so-called "open stopcock" readings were much more consistent from eye to eye. In "open stopcock" calibration, the eye is cannulated as before but remains connected to the reservoir during the application of the tonometer; with this arrangement, the intra-ocular pressure does not increase when the tonometer is applied and, in this respect, the procedure differs from the "closed stopcock" method and from the normal usage of the instrument.

Owing to the inconsistencies of the "closed stopcock" results, Friedenwald (1954) used the "open stopcock" method as the basis of tonometric calibration. However, the "open stopcock" method only enables one to relate tonometric readings to P_t values and, in order to complete the calibration, a further step is necessary by which P_t values can be converted to P_o values. For this calculation, one needs to know how great would be the increase of intra-ocular pressure for a given amount of tonometric distortion of the eye, and it has been found that this increase in pressure is the same as would occur if the eye, instead of being distorted, were distended by the injection of a volume of fluid equal to the volume displaced by the tonometer.

The relationship between a change in intra-ocular pressure and a change in intra-ocular volume depends ultimately upon the extensibilities of the various components which constitute the coats of the eye. For the rabbit eye, it has been shown that, when isolated strips of sclera and cornea are stretched, the change in tension and the extension do not conform to a simple law (Gloster, Perkins and Pommier, 1957). This is one reason why we might expect the relationship between intra-ocular pressure and intra-ocular volume to be complex, especially in view of the heterogeneous structure of the coats of the eye. The solution of this problem was attempted by Friedenwald (1937), who introduced the coefficient of ocular rigidity, K, which is given by the formula:

$$K = \frac{\log P_2 - \log P_1}{\triangle V}$$

where P_1 is the initial intra-ocular pressure and P_2 is the intra-ocular pressure after the injection of a volume of fluid, $\triangle V$ μl., into the eye. This expression was derived from the assumption that the proportional rise in pressure would vary directly with the proportional increase in volume, and Friedenwald claimed that the experimental findings of previous workers were in good agreement with the relationship which he had suggested.

Applying this expression to the calculation required for tonometric calibration, we have :

$$K = \frac{\log P_t - \log P_o}{V_c}$$

where P_t is the intra-ocular pressure with the tonometer resting on the eye (the open stopcock" pressure), P_o is the intra-ocular pressure before application of the tonometer and V_c is the volume of fluid displaced by tonometric distortion. The latter can be determined experimentally and, in order to relate P_t to P_o, it is then only necessary to assume a value for K. It is obvious that the calibration, calculated in this way, is accurate only for eyes having coefficients of rigidity equal to that adopted in the calculation also, the calibration is accurate for an individual eye only if K remains constant over the full range of pressures measurable with the tonometer.

At the Institute of Ophthalmology, Mr. Perkins and I have developed three methods for determining the coefficient of rigidity in animal eyes and in dead human eyes (Perkins and Gloster, 1957; Gloster and Perkins, 1957). Two of these methods depended upon simple distension of the eye, while the third involved distortion by a Schiotz tonometer. The

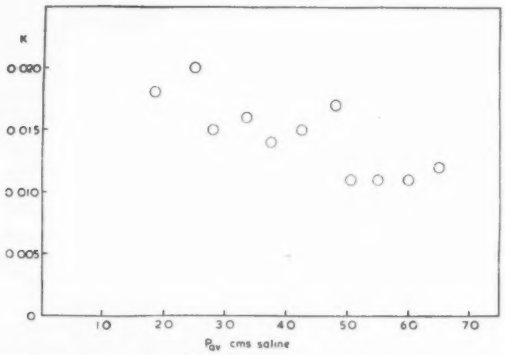

FIG. 3.—Variation of coefficient of rigidity, K, with intra-ocular pressure. Dead human eye in situ. Tonometric method.

results obtained by all three methods were in agreement. In particular, it should be emphasized that the coefficient of rigidity determined by simple distension of the eye was the same as that determined by tonometric distortion, a result which helps to clear up the doubt which has been apparent in the literature on this matter.

We found that in the rabbit eye the coefficient of ocular rigidity K was not a constant, its value increasing as the pressure at which it was measured increased (Figs. 1 and 2).

K varied in this way in both living and dead eyes, although its value was sometimes slightly greater in the latter. We also obtained some evidence which confirmed the observation by Ridley (1930) that the rigidity of the eye was increased after maintaining a high intra-ocular pressure for some time. Not only did the coefficient of rigidity vary with intra-ocular pressure in the individual eye but it also differed considerably from animal to animal, values from 0·007 to 0·031 being found at a pressure of 35 cm. saline in a series of ten rabbits. In all the rabbits the increase in K with increasing intra-ocular pressure was obvious, although this variation was more marked in some eyes than in others. In view of these findings, one would suppose that, even if consistent tonometric readings were obtained on a number of rabbit eyes by the "open stopcock" method, there would be discrepancies if the "closed stopcock" method were used and the correctness of this supposition has been demonstrated (Gloster and Perkins, 1957).

After developing the experimental techniques on the rabbit eye, Mr. Perkins and I applied them to the measurement of ocular rigidity in dead human eyes. Experiments have been done on eleven eyes (7 enucleated and 4 in situ) which were examined between eight hours and several days after death. Unfortunately, one does not know how closely results from these eyes indicate the rigidity of the living eye, although the values which we obtained for K did not differ greatly from those reported by other observers using tonometric methods on the living eye. As with the rabbit eye, there was no significant difference between the values of K determined by simple distension and those measured by tonometric distortion. We found that the coefficient of rigidity of the dead human eye varied with intra-ocular pressure but this variation was not as marked as in the rabbit eye. A more important difference from the rabbit eye was that, in all but one of the eleven human eyes, the values of K *decreased* as the intra-ocular pressure increased (Fig. 3); in the remaining eye there was a slight rise in K with increasing pressure. Mean values of K for the eleven eyes were 0·018 at an intra-ocular pressure of 25 cm. saline, and 0·013 at a pressure of 50 cm. saline. It is interesting that our finding that K decreases as the intra-ocular pressure rises in human eyes is in agreement with some observations of McBain (1957), although this author has not yet published details of his results. We found that K varied considerably from eye to eye, values from 0·012 to 0·027 being found at a pressure of 25 cm. saline, and values from 0·009 to 0·022 at 50 cm. saline.

The effect which a difference in the coefficient of ocular rigidity would have on tonometric calibration can be illustrated by the following example: Suppose two eyes, one having a coefficient of rigidity of 0·012 and the other a coefficient of 0·020, gave identical "open stopcock" readings on the scale of a Schiotz tonometer when the intra-ocular pressure with the tonometer resting on the eye (P_t) was 40 cm. saline. At this pressure, we have found that the volume of corneal indentation (V_c) produced by a Schiotz tonometer, using the 7·5 grams weight, was approximately 14 μl. Substituting these values for K, P_t and V_c in the equation given above, P_o is found to be 27·2 cm. saline for the eye in which K is 0·012, while P_o is 21·0 cm. saline for the eye in which K is 0·020. Thus, the same scale reading would be indicated by the tonometer although the initial pressures in the two eyes differed by about 6 cm. saline.

The calibration charts usually issued with the Schiotz tonometer have been calculated assuming a coefficient of rigidity of 0·0215, which was considered by Friedenwald (1954) to be the average value for the human eye. These charts are therefore perfectly accurate only for eyes having K equal to 0·0215. It has been suggested that errors due to variations in K may be overcome by taking readings with different weights on the tonometer—this, incidentally, might be considered an advantage of the "weighted" as compared with the "weightless" Schiotz tonometer. If readings with different weights indicate the same intra-ocular pressure, they may be considered reliable, since the eye examined must have the same coefficient of rigidity as that adopted for calculating the calibration. It has been claimed that tonometric readings taken with two different weights can be used to measure the coefficient of rigidity and that this allows one to make a correction for any departure from the assumed value of K; however, in our experience, even under ideal conditions this method may yield grossly inaccurate results (Gloster and Perkins, 1957).

Whilst is has been recognized that variations in ocular rigidity are partly responsible for the lack of consistency of "closed stopcock" readings, it is clear that this difficulty cannot be completely overcome by basing tonometric calibration on "open stopcock" readings and then applying a calculation which utilises an average value for the coefficient of rigidity. This is probably the best practical approach to the calibration of the Schiotz tonometer, provided that the inadequacies of the procedure and the limitations imposed thereby are not forgotten. From the purely theoretical aspect, it is evident that accurate calibration of a tonometer demands a minimal difference between P_t and P_o, and this can be achieved only by reducing the tonometric distortion of the eye, a matter which is entirely dependent upon the design and construction of the instrument.

Mr. E. S. Perkins:

Dr. Gloster has outlined some of the theoretical problems involved in tonometry and I shall discuss some of the instruments in use to-day in the light of this theoretical background.

The ideal tonometer should produce no alteration in the intra-ocular pressure and be accurate for any eye and pressure; it is obvious that we are still far removed from such an ideal and must content ourselves with an instrument which produces as little change in shape of the eye as possible. It is only in this way that errors due to variations in ocular rigidity can be avoided. In essence this means a light weight only must be applied to the eye. In addition the instrument must have a low reading error, a good mechanical design and it must cause no injury to the eye. It should be relatively easy to use so that reliable readings can be obtained by junior staff. In addition it should be easy to sterilize, as infection can undoubtedly be transmitted from eye to eye by tonometers. These points are summarized in Table I.

TABLE I.—TONOMETER—DESIDERATA

1	Small distortion of globe
2	Light weight
3	Low reading error
4	Stable mechanical design
5	Non-traumatic
6	Easy to use
7	Easy to sterilize

The two main types of tonometer in use today depend either on indentation or applanation of the cornea. Each type may be further subdivided into (*a*) instruments in which a constant force (e.g. a weight) is applied to the eye and the resulting indentation or applanation measured, and (*b*) instruments in which the force required to produce a constant indentation or a constant area of applanation is measured.

Examples of instruments of these four types will now be discussed in relation to our ideal requirements.

The Schiotz tonometer is an indentation tonometer in which a constant force is applied and the resulting indentation measured. Now we have many criticisms to make of the Schiotz tonometer, but in all fairness to its inventor it must be accepted that in a large proportion of cases it will provide a useful indication of the state of the ocular tension, and it has undoubtedly been of major importance in the development of our clinical knowledge of glaucoma.

Our first ideal requirement was a small distortion of the globe, and immediately we find the Schiotz tonometer at fault. The distortion and consequent rise in intra-ocular pressure which follows application of the Schiotz tonometer to the eye are very considerable and not fully appreciated by most people using it.

Table II shows some results obtained on cadaver eyes in which a needle connected to a

TABLE II

P_o AND P_f VALUES ON FOUR HUMAN EYES, USING A SCHIOTZ TONOMETER WITH 7·5 G. WEIGHT

Cadaver eye	P_o cm/saline	P_f cm/saline	K
I	30	39	·013
II	30	48	·019
III	30	48·5	·021
IV	30	44·5	·014

reservoir was inserted into the anterior chamber so that the intra-ocular pressure could be maintained at a given pressure. A tap on the connexion between the needle and the reservoir was then closed and a Schiotz tonometer lowered on to the eye. By comparison with an

"open stopcock" calibration made on the same eye, the pressure in the eye while the tonometer was resting on it could be calculated. It will be seen that in all four eyes a very appreciable rise in pressure took place when the tonometer was placed on the eye. The figures for the scleral rigidity of each eye were also calculated for this pressure and it can be seen that the rise in pressure is roughly proportional to the rigidity.

Now it is P_t that the tonometer measures, and the true intra-ocular pressure can only be an assumption from this value. The calibration curve used in practice is compounded from experimental data on animal and human eyes and involves a theory of scleral rigidity which certainly does not hold true for rabbit eyes, and probably does not hold true for all human eyes.

Figs. 1 and 2 show the calibration curves of a Schiotz tonometer on rabbit eyes of differing

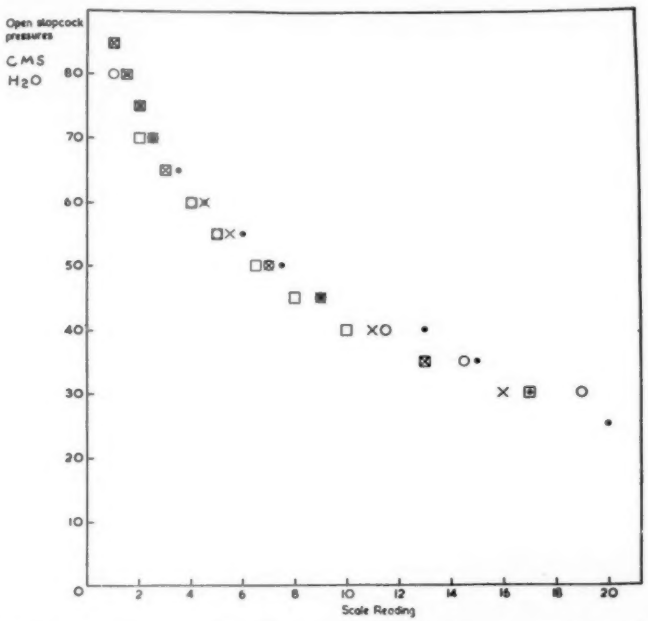

FIG. 1.—' Open stopcock" calibrations of a Schiotz tonometer on four rabbit eyes. The 4 different symbols indicate 4 different rabbits.

scleral rigidities. Fig. 1 shows the "open stopcock" calibration curves using the same tonometer on four eyes. The results are fairly consistent but in Fig. 2, which shows "closed stopcock" readings on two of the eyes, it is clear that the same scale reading on the tonometer corresponded to widely different intra-ocular pressures in the two eyes.

As with most types of tonometers, variations in corneal curvature and thickness introduce errors into the reading of a Schiotz tonometer. These have been fully investigated by Friedenwald (1954) and it is possible to correct for these errors, though it is hardly a practical proposition for clinical use.

The Schiotz tonometer is not free from the danger of trauma to the eye, and while being fairly easy to use, it not so easy to sterilize.

The Mueller electronic tonometer works on exactly the same principle as the Schiotz and is open to the same objections with regard to the degree of distortion of the globe it produces.

The principle of measuring the force required to produce a standard indentation of the cornea has not been much exploited up to now, but Maurice, at the Institute of Ophthalmology (1957) has two instruments of this type under development and trial at the moment. As the depth of indentation can be made small, the resulting distortion is much less than that of the Schiotz tonometer and, therefore, should produce a much smaller rise in pressure when applied to the eye. One of these instruments has been designed to give continuous

recording over prolonged periods, and should prove a most useful research tool. The other is designed for clinical use.

Maklakoff (1885) appears to have been the first person to appreciate the possibilities of applanation tonometry, and he solved the problem of measuring the area of applanation produced by a flat-ended weight of 5 grams by putting Bismarck brown on the cornea first

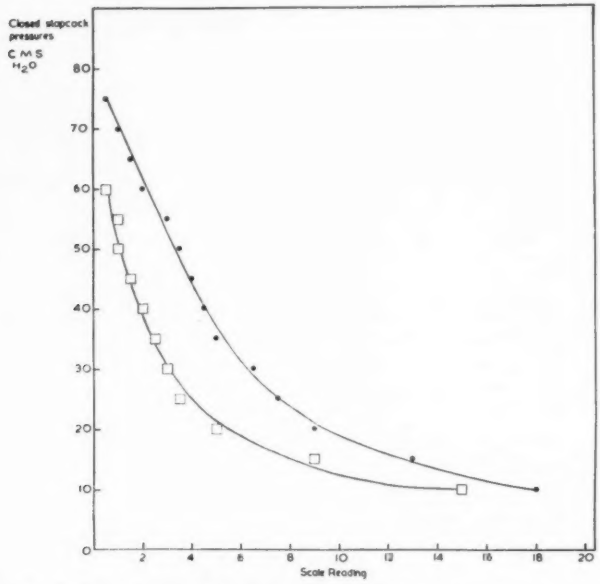

FIG. 2.—"Closed stopcock" calibrations of a Schiotz tonometer on two rabbit eyes. The 2 symbols represent the same 2 rabbits as in Fig. 1.

FIG. 3.—The applanation tonometer and brass ring.

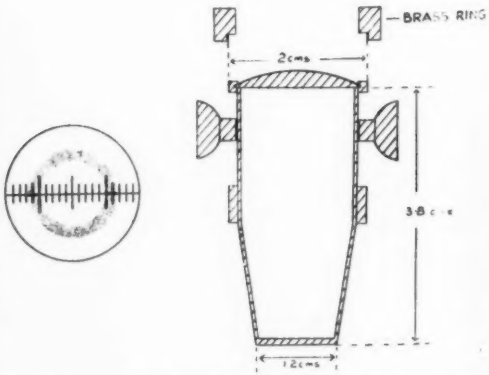

FIG. 4.—Diagram of the apparatus and a view of the scale as it appears in use. The shaded ring represents the circle of fluorescein.

and then printing the area of contact on to filter paper. This method is obviously open to serious errors and better methods are available. In 1953, I produced a simple applanation tonometer, primarily for use on laboratory animals some years ago. It consisted of a small perspex cylinder with a flat surface at one end and a viewing lens at the other (Figs. 3 and 4).

Circles or a scale were engraved on the flat end at ½ mm. intervals. A drop of 0·2% fluorescein was put on the cornea and the instrument rested on the cornea. The diameter of the applanation surface was compared with the engraved scale. The diameter can be read to within ½ mm. with this instrument and while this degree of accuracy is adequate at low intra-ocular pressures, the reading error increases badly at high pressures, as shown from the calibration curve in Fig. 5. We are working on another model in which an optical

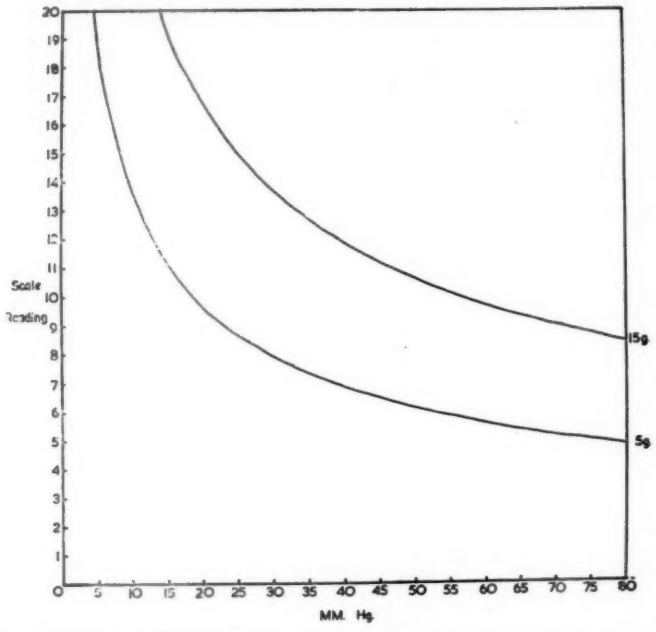

FIG. 5.—Theoretical calibration curves for the tonometer alone (5 grams) and with the extra weight (15 grams).

Figs. 3, 4 and 5 are reproduced by permission of the Editors, *Trans. ophthal. Soc. U.K.*, (1953), **73**, 261.

doubling system is used, and with this readings of the diameter of applanation can be made to 0·1 mm.

These types of tonometer have the advantage that they are light in weight and cause very little distortion of the cornea, so that errors due to scleral rigidity are minimized. The reading error can be made quite small and the instruments are mechanically simple and robust. They are, however, more difficult to use than the Schiotz type of tonometer, but can be easily sterilized and are non-traumatic.

Goldmann (1954) has recently designed an ingenious applanation tonometer used with the Haag-Streit slit-lamp which measures the force required to produce a constant area of application. By keeping the area of applanation constant the force in grams is proportional to the theoretical intra-ocular pressure from the formula:

$$P = \frac{W}{SA}$$

where P = intra-ocular pressure in mm.Hg
W = weight applied
S = specific gravity of mercury
A = area of applanation

This is the general theoretical formula for applanation tonometry. Now if this formula is correct it should be applicable to any eye. Goldmann has so far published no experimental work to justify the application of this theory, but some experiments of Dr. Gloster and myself suggest that it is not universally correct and that certain other factors are concerned.

While it would appear, therefore, that applanation tonometry offers some advantages over the usual indentation methods, more work must be done before the theoretical calibration can be accepted.

A small pressure-sensitive capsule has recently been developed which can transmit a radio signal from which the pressure of its surroundings can be determined. Perhaps in the future we shall simply implant such a transducer into the eyes of our glaucoma patients and tune in to obtain their intra-ocular pressure without touching the eye; until that time, however, we must endeavour to improve our present methods and always bear in mind the many errors and inaccuracies involved.

Dr. C. R. S. Jackson:

Standardization of X-Tonometers

We know now, and Friedenwald (1937) must be given credit for stimulating interest in this aspect of the problem, that the intra-ocular pressure is only one of a number of factors which influence the performance of an instrument of the Schiotz type. This interest is, however, of fairly recent development and I imagine that one of our duties is to restrain a tendency among our colleagues to believe too slavishly in what our tonometers tell us. I should like to persuade people to get away from the tendency to read tonometers to half-millimetres of mercury, though I admit that the present calibration charts imply a degree of accuracy of this order.

Another thing we sometimes fail to remember is the wide scatter of normal readings. Both Friedenwald (1937) and Jackson (1955), with others, have drawn attention to this previously, and Fig. 1 shows the distribution of the scale readings in a new series of 405 normal eyes, using an American standardized tonometer with a 5·5 grams load. Although the readings are distributed fairly symmetrically about the mean reading of 4·5 scale divisions (which gives a reading for the intra-ocular pressure of something just under 20 mm.Hg), the actual range of apparently normal values is considerable. I shall discuss my results purely in terms of scale divisions: I am not particularly concerned with the interpretation of my readings, but rather with the effort to obtain comparable readings from different tonometers.

The work of the American Committee on Standardization of Tonometers, the subsequent adoption of the standard for the original Schiotz tonometer by the International Committee, and the move of the Ross Foundation in following the American lead, and of the Faculty of Ophthalmologists in supporting this move, are all now well known.

All the foregoing work has been confined to the original model of Schiotz's tonometer, the one with weights. This is the most popular tonometer in the United States, but here, and in Scandinavia, there is a considerable demand for the X-tonometer, with no weights to take off and lose, and with its convex-ended plunger. Through no fault of their own, the manufacturers have not been able to make these tonometers to any uniform pattern, owing to lack of guidance from the profession, and divergent results have been obtained from instruments supposedly similar. Also, we have been faced with the difficulty of relating the readings of such X-tonometers to those obtained with the standardized weighted instruments. An attempt has therefore been made to find a way of overcoming these problems.

It was first necessary to decide what yardstick of construction we were to use and this has been done after an examination of Schiotz's original descriptions of his tonometer without weights. The basic design of the two instruments, weighted and weightless, is similar, and it has been quite easy to draw up a specification for our proposed standard X-tonometer. Table I shows the ways in which the two instruments differ in their

TABLE I.—SPECIFICATION

	Schiotz	X-tonometer
Weight of plunger assembly	5·5 g.	5·2 g.
Tonometer without handle	16·5 g.	16·2 g.
Plunger diameter	3 mm.	3 mm.
Plunger tip	Concave radius 15 mm.	Convex hemispherical radius 1·5 mm.

The zero for the X-tonometer to be set when plunger tip is 0·05 mm. below footplate.

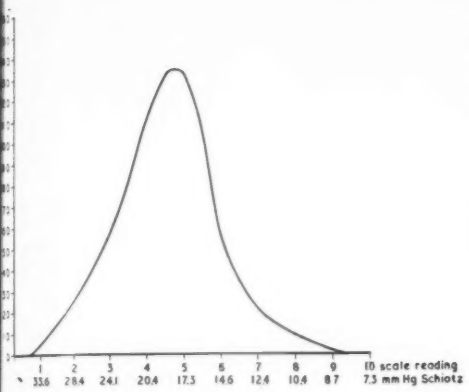

FIG. 1.

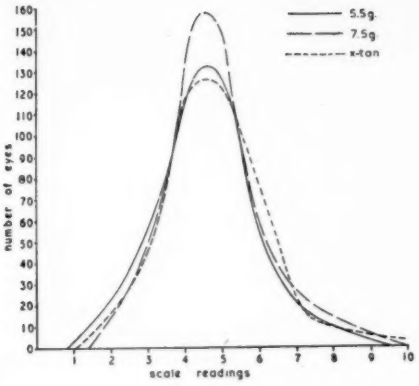

FIG. 3.

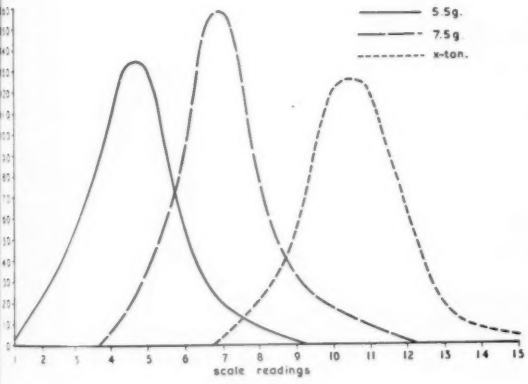

FIG. 2.

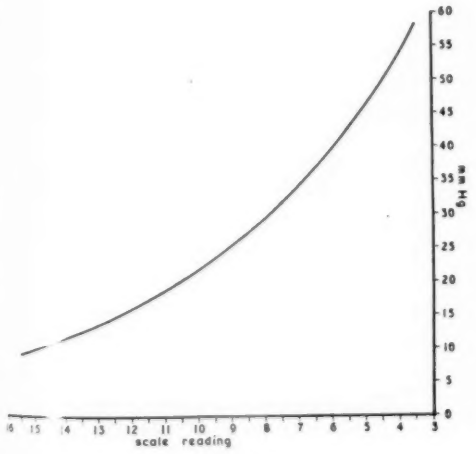

FIG. 4.

specifications. In all other respects the X-tonometer is the same as the original model. There seem to be advantages, from the manufacturing point of view, in keeping the basic design of the two instruments similar.

A useful confirmation of the reasonableness of my ideas for the X-tonometer has come from Copenhagen, where Dr. Mahneke (1957) has arrived at identical figures in his consideration of what the X-tonometer should be like. A prototype has been constructed to this specification and I hope to persuade the instrument makers to build their X-tonometers to this pattern. Even if further experience suggests that a change is necessary, no harm will have been done.

Having then obtained a prototype X-tonometer, it had to be calibrated, and I decided to do this on living eyes, as the use of cannulated excised eyes seemed to introduce a number of difficulties. The instrument used for comparison was a standardized weighted tonometer made by Meyrowitz and recently checked with regard to its compliance with the accepted specification.

Three readings were made on each eye; with the Schiotz 5·5 grams and 7·5 grams loads, and with the X-tonometer. The order in which the instruments were applied was varied

in a random way and the tonometer rested on the eye only long enough for a steady reading to be obtained. It has, I think, been shown that a brief application of a tonometer does not significantly alter the subsequent readings.

The number of eyes used was 601, of which 405 were normal and 196 pathological. The pathological eyes were mostly from our glaucoma patients, while the normal eyes were all eyes in which no suggestion of ocular disease had been raised. They were eyes which had been anæsthetized for the purpose of treating some extra-ocular condition, syringing of tear passages, incision of a cyst, and so on. It is with these normal eyes that I am now mainly concerned.

I first sought to establish that two instruments with differently shaped plungers behave in a comparable way on a series of eyes, for it has been suggested that the shape of the plunger-end governs the character of the corneal indentation. If, therefore, the X-tonometer was behaving in a manner unrelated to that of the standard tonometer, one would expect the shape of the distribution of the readings to vary as between the instruments. Fig. 2 is a graph showing the number of eyes at each reading. There is a maximum occurring at about the centre of the range in each case, while the readings are approximately evenly distributed on each side of this.

We were next looking for a way of relating these readings to one another, and, after attempting a number of mathematical treatments, it transpired that the most useful manœuvre was to correct each reading by a factor based on the differences of the means. The mean of the readings on 405 normal eyes lay at 4·5 scale divisions for the 5·5 grams load, at 7·1 scale divisions for the 7·5 grams load, and at 10·6 scale divisions for the X-tonometer. If each reading is moved toward the 5·5 grams curve by the appropriate correction factor, the superimposed curves appear as in Fig. 3.

The all-over pattern is satisfactory, but it remains to show how closely the individual corrected readings correspond.

I have applied the correction factors to each reading in this series, in both the normal and pathological eyes, and have expressed the results in a rather crude way, but one which seems to show what we want. The results are expressed in terms of the percentages of the corrected readings which lie within a given distance of the chosen standard (Table II).

TABLE II.—THE EFFECT OF CORRECTION FACTORS

	Normal %	Normal %	Path. %
	Related to 5·5 g. Schiotz		
Corrected 7·5 g.	± 0·5	83·9	82·1
	± 1·5	99·2	96·6
Corrected X-ton.	± 0	40·9	49·6
	± 1	89·3	89·5
	Related to 7·5 g. Schiotz		
		Normal %	Path. %
Corrected X-ton.	± 0·5	73	74·9
	± 1·5	95	94·5

Whether these divergences from theoretical accuracy are due to mechanical faults, to reading difficulties, or to the influence of factors other than the intra-ocular pressure I do not know, but at least this simple technique, which brings about 90% of our readings to lie within ±1 scale division of each other is sufficiently good for the present state of accuracy of our instruments.

There is something to be said for recording the results of our tonometry simply in terms of scale readings and of the weight used, but it will be difficult to get away from the practice of converting these readings into millimetres of mercury. Fig. 4 shows the currently accepted conversion chart for the Schiotz tonometer, modified to fit in with the specification outlined for the X-tonometer.

An Examination of Dentine for A and B Blood-group Antigens by the Mixed Agglutination Technique

By IVOR R. H. KRAMER, M.D.S.Lond., L.D.S.Eng.

Department of Pathology, Institute of Dental Surgery
(British Postgraduate Medical Federation)

BY a recently developed technique (Coombs and Bedford, 1955) blood-group antigens have been demonstrated in blood platelets, in adult epidermal cells (Coombs *et al.*, 1956), and in fœtal epidermal cells (Fuchs *et al.*, 1956). The presence of these substances in cells other than erythrocytes may have applications to problems in fields as varied as tissue grafting, the determination of fœtal blood group, and in forensic medicine. Therefore, it was thought to be of interest to apply the method to a calcified tissue; dentine was chosen as it has a higher ratio of cell substance to matrix than bone, and is easier to obtain free from blood.

Principle.—The method devised by Coombs and Bedford overcame the difficulty of performing direct agglutination experiments on tissue cells which do not form suitable agglutinable suspensions. The cells under investigation were exposed to sera containing the blood-group agglutinins anti-A and anti-B, and then washed free of excess serum. When re-suspended, these treated cells were mixed with washed erythrocytes of known blood group. It was found that, when the cells under test came from an individual of group A, exposure to serum containing anti-A resulted in a linking of anti-A to the cells, so that when subsequently mixed with group A erythrocytes, these erythrocytes adhered to the surfaces of the test cells. Corresponding results were obtained with cells from individuals of group B, whilst cells from group AB individuals could be "sensitized" by both anti-A and anti-B sera so that subsequently both group A and group B erythrocytes would adhere to them.

Present method.—Carious and non-carious teeth extracted under nitrous oxide anæsthesia were collected immediately after extraction, and a sample of capillary blood was obtained from each patient whilst under the anæsthetic. The blood samples were used for determining each patient's ABO blood group.

Dentine powder was prepared from each newly-extracted tooth by the following method: After preliminary washing to remove blood and debris, the tooth roots were ground on a carborundum wheel to remove the cementum. The roots were then severed from the crown, split open, and the pulp and pre-dentine removed by scraping and dental burs. The root dentine thus obtained, and freed as far as possible from pulp and cementum, was powdered in a steel mortar and passed through a 300-mesh sieve. Thus, a series of samples of powdered dentine were obtained, each sample derived from a tooth or teeth of an individual of known ABO blood group.

A small portion of each sample was then exposed for one hour at approximately 20° C. to undiluted anti-A blood grouping serum (from the Blood Group Reference Laboratory, Lister Institute) and another portion was similarly exposed to anti-B grouping serum. Following exposure to these sera, the dentine powder was centrifuged and washed three times with a large volume of Ringer's solution, and the washed powders were mixed with 2% washed erythrocyte suspensions as follows:

Dentine powder treated with			Erythrocytes
Anti-A serum		+	A
A	,,	+	O
B	,,	+	B
B	,,	+	O

The dentine powder-erythrocyte mixtures were centrifuged, the deposit was loosened by gently tapping the tube, and a portion of the sediment was withdrawn with a fine pipette, placed on a slide under a coverslip, and examined under the microscope. No evidence of erythrocyte adherence to the dentine particles was found in any preparation.

It was thought that the negative findings might be the result of inaccessibility of blood-group substances in the dentine because of the high degree of calcification. Therefore, the experiments were repeated on dentine powder decalcified by exposure for ten minutes to N/10 HCl. However, again no dentine powder-erythrocyte agglutination could be detected.

Conclusions.—Using a simple modification of the mixed agglutination technique for the demonstration of A and B blood group antigens in human epidermal cells, it has not been found possible to demonstrate these substances in human dentine.

Acknowledgments.—I am indebted to Mr. W. G. Armstrong, M.Sc., and Mrs. V. Gilchrist for preparing the dentine powder, and to Mrs. V. Markies for technical assistance.

Cervico-facial Actinomycosis with Acute Presentation.—H. P. COOK, M.B., B.S., B.D.S., F.D.S. (for B. St. J. Steadman, L.R.C.P., M.R.C.S., B.D.S.).

Male, aged 16. One week's history of difficulty in opening his mouth, followed four days later by intra-oral swelling related to $\overline{8}|$, and marked external swelling at the angle of the mandible.

He was treated with four-hourly hot mouth washes and intramuscular penicillin, but failed to respond and was admitted. Temperature rose to 103·5° F. and intra-oral incision was carried out. Pus grew normal mouth flora. Temperature was normal for twelve hours, then rose to 103° F.

External incision and drainage carried out. Pus—smear: Gram-positive branching filaments. Culture: *Actinomyces israeli.*

Therapy.—Penicillin crystalline 4,000,000 units i.m. b.d. for thirty-two days. Streptomycin ½ gram b.d. i.m. for five days, from the seventh and the twenty-second days.

All signs and symptoms disappeared on this therapy. No relapse after six months.

Probable portal of entry of organism: erupting wisdom tooth crypt.

Fracture of Mandible.—JOHN CAMBROOK, M.R.C.S., L.R.C.P., F.D.S.

A. W., aged 35. He received a blow on his right mandible from the skull of an opponent during a game of football.

He was seen four days later when X-rays showed a vertical fracture through the socket of a horizontally impacted $\overline{8}|$.

There was a very slight vertical deformity of the posterior fragment. Penicillin therapy was started, $\underline{8}|$ extracted and splints cemented on the following day.

After twenty-four hours the fracture was reduced and the splints immobilized. Penicillin was discontinued after seventeen days.

The interest of the case, which was shown five weeks after the injury, was the method of causation and the extremely good state of the mouth due to the hygiene practised by the patient; also the manner in which he had been able to take food, maintaining both his weight and sufficient energy to carry on with his training.

Erosive Lichen Planus of the Mouth.—JOHN CAMBROOK, M.R.C.S., L.R.C.P., F.D.S.

C. H., aged 68. He had an operation for leucoplakia of the anal region—June 1956. During convalescence he noticed slight skin rash on his left arm and right leg.

Four months later he complained of soreness of the inside of his cheeks. His dentures were adjusted but without relief. Treatment with local penicillin and Bradosol produced no improvement. He was consequently referred to me when he had a large area of superficial ulceration inside the cheeks extending on to the gums. The appearance was similar to aspirin burns and there were no lines or striations of lichen planus. Bacteriology showed no significant organisms or fungi.

The lesions on the limbs were confirmed as lichen planus by Dr. Lipman Cohen.

Shortly afterwards the usual characteristics of lichen planus were seen in the mouth and on the lips. It was felt that initially the mouth had been overtreated, so that only a local application of 10% silver nitrate to the raw areas was made twice weekly, and the condition had markedly improved.

Chondrosarcoma of the Maxilla and Septum.—GEORGE T. HANKEY, O.B.E., T.D., F.D.S., M.R.C.S.

B. T., female, married, aged 54.

1.2.56: First noticed a painless infra-nasal swelling, which made her nose look crooked. A month later she removed two upper incisors because they had become very loose: later still |3 was extracted by a dental surgeon for acute infection. For a while the swelling decreased, then got steadily larger. Referred by her doctor to St. Bartholomew's Hospital on 26.5.56.

On examination.—The upper lip was pushed out and the floor of the nose and left ala nasæ were raised by a swelling which was expanding the whole pre-maxillary alveolus. The swelling was tense and the mucous membrane over it slightly reddened. 21|123 had been recently extracted, but there was still a sinus of the |2 socket up which a probe could be passed 2 to 3 cm. upwards and backwards with the sensation of contacting soft tissue: no bone felt. X-rays (Fig. 1) suggested a large dental cyst in the mid-line occupying a position between the hard palate and the floor of the nose.

Operation (15.6.56) (four and a half months after swelling was first noticed).—Buccal approach: reflection of an infra-nasal mucosal flap exposed a firm encapsulated tumour: consistency soft and friable, calcified in places, colour pinkish grey. Removed by blunt dissection, leaving a space 4 × 4 × 3 cm. between the roof of the hard palate and the remainder of the nasal septum. Part of the epithelial lining of the floor of the nose unavoidably removed with the growth. Buccal approach closed with sutures and the cavity packed via the nose with B.I.P. on gauze. Uneventful convalescence.

Histopathology.—Posterior nasal specimen: Greyish tissue with well-circumscribed capsule. Mottled grey, fawn and brown appearance on cut surface. Well-differentiated cartilaginous masses in some areas and, in others, necrosis of cartilage, the latter occupying most of the section (Fig. 2). Some evidence of ossification of cartilage in one or two areas. Many areas of myxomatous degeneration.

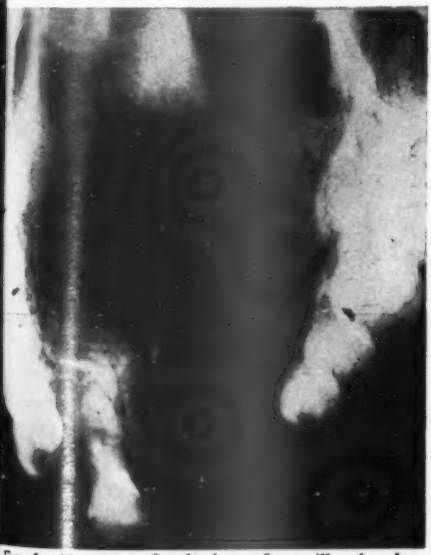

FIG. 1.—X-ray—occlusal view of maxilla showing outline of tumour, with centre structureless and rarefied as in cyst.

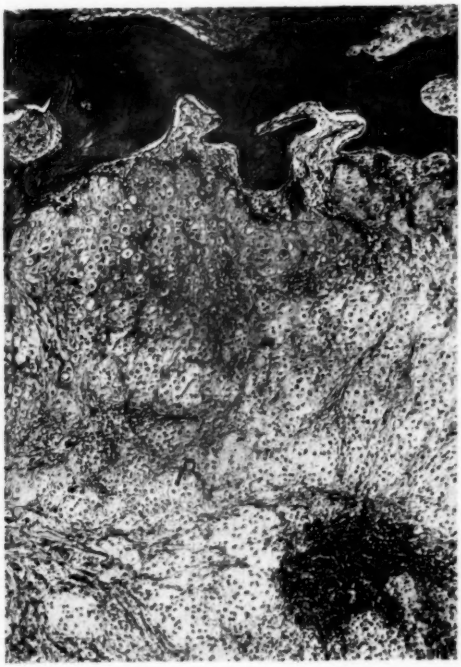

FIG. 2.—A fairly well-differentiated cartilaginous area, → but some irregularity of cells and hæmorrhage present. Stained H. and E. × 39.

Anterior oral specimen: Sections show a rather different picture. The cartilaginous material is somewhat irregular in its arrangement, but still well differentiated, the nodules being separated by a rather loose cellular fibrous tissue in which the new formation of cartilage can be seen. There are areas of ossification and calcification and frequent hæmorrhages and necroses. While the appearances are generally those of a well-differentiated chondroma, the irregularity and the rather young connective tissue component suggest that there may be a low-grade malignancy in the tumour.

Comment.—Miles (1950) summarizes the literature and behaviour of six previously reported cases and adds two more himself. Their degree of malignancy varies; they are not sensitive to radium or deep X-rays; radical surgery would seem to have the best prognosis.

To date the patient is well, with no sign of recurrence.

Acknowledgments are due to Dr. R. J. R. Cureton for the histopathology and photomicrographs and to Mr. R. F. McNab Jones for the after-care of the nose.

Primary Squamous-cell Carcinoma of Mandible arising from Epithelial Lining of Dental Cyst.—GEORGE T. HANKEY, O.B.E., T.D., F.D.S., L.R.C.P., M.R.C.S., and J. A. PEDLER, M.D.S., F.D.S., L.R.C.P., M.R.C.S.

History and treatment (*G. T. H.*).—Man, aged 75, retired carpenter.

History of one month's painless enlargement of left side of mandible. 14.1.57: First attended dental department of The London Hospital with a tense reddened swelling below the left border of mandible. First impression was a cellulitis resulting from many septic teeth. Radiographs (Fig. 1) showed cystic area extending from $\overline{3}$ to $\overline{8}$ region. A few days later the swelling was more tense and external incision resulted in evacuation of a pus-like material. *Bacteriological culture* showed saprophytic growth only; no pyogenic organisms. The swelling did not subside and a slight discharge continued. No intra-oral sinus or communication with cyst. Pre-operative dental extractions were begun.

FIG. 1.—Radiograph of left body of mandible—occlusal view.

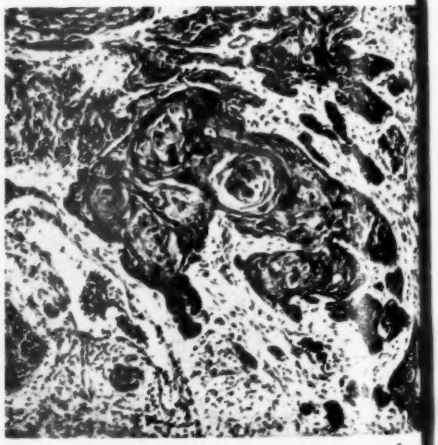

FIG. 2.—Keratinizing squamous cell carcinoma from tissue adjacent to mandible. × 8.

22.2.57: *Operation under general anæsthesia.* External approach by incision beneath lower border of mandible. After evacuation of about 1 oz. of thin, cheesy material the swelling was found to consist of soft, pink, friable tumour-like tissue with no encapsulation. The lesional tissue was invading the soft tissues of the neck and was emerging from an erosion in the lower border of the mandible. The lesional tissue was removed as widely as possible and the cavity in the mandible was cleared. There was no opening into the mouth.

Histopathology (*J. A. P.*).—Material from three sites was received for examination.

(1) From lesion external but adjacent to mandible; four irregular rubbery grey-brown fragments. Microscopically this consisted of a mass of keratinizing squamous cell carcinoma (Fig. 2).

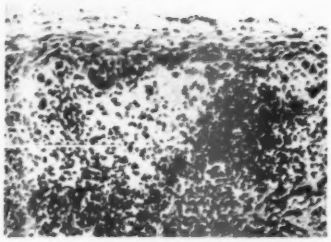

FIG. 3.—Typical dental cyst lining from cavity of mandible. A, squamous epithelium. B, fibrous wall with chronic inflammatory infiltration. × 73.

(2) From tissue lining the cystic cavity within the bone of the mandible; two rubbery grey-brown sheets (the larger 1·8 × 0·8 × up to 0·2 cm. thick). Microscopically the appearance varied from place to place but extensive areas were consistent with a typical dental cyst, i.e. a fibrous cyst wall with heavy infiltration of chronic inflammatory cells and a lining of stratified squamous epithelium (Fig. 3). Some parts of this material showed evidence of malignant change.

(3) From orifice of sinus in cervical skin; fragment of skin 1·5 × 1·1 × up to 0·5 cm. thick with a ragged through and through aperture. Microscopically this consisted of a keratinizing squamous-cell carcinoma comparable with the material originating just adjacent to the mandible.

Conclusion.—The presence of extensive dental cyst-lining with some areas of early malignant change, associated with a frank squamous carcinoma eroding the mandibular cortex and invading the tissues of the neck to become attached to skin, is regarded as good evidence that this is a case of primary carcinoma arising in a dental cyst lining.

8.3.57: *Post-operatively* a course of X-ray therapy was instituted.

[*April* 29, 1957]

Acute Monocytic Leukæmia.—H. P. COOK, M.B., B.S., B.D.S., F.D.S. R.C.S.

Acute monocytic leukæmia is one of the uncommon types of leukæmia. There are only 13 cases recorded at the Westminster Hospital in the last ten years. This case terminated fatally after a very rapid course, the total duration of symptoms being only three and a half weeks.

Patients with this disease often present as a dental problem. Fitzgerald (1943) reported a case in which the swollen gums were initially treated as Vincent's infection. The gingivæ are, in fact, very constantly affected. In a review of 133 cases of monocytic leukæmia, Osgood (1937) found that in the 88 cases in which the gums were mentioned, 80% showed swelling and ulceration.

Case history.—Female, aged 48. Her gums had become swollen and painful during the previous two weeks. Over the same period, she had suffered intermittent headaches, felt tired and weak, and became breathless on exertion. After a week of these symptoms, she saw her doctor and dentist in consultation. They prescribed intramuscular penicillin and oral vitamin B, which were given for eight days without benefit.

FIG. 1.—Marked gingival enlargement.

Examination.—The patient looked ill, her features were pale and muddy and she had an air of great lassitude. Temperature 99° F.

The gingivæ showed marked generalized swelling, most obvious anteriorly in relation to some bridge work (Fig. 1). The enlarged tissue was purplish in colour and partially covered the tooth crowns on buccal and lingual aspects. No spontaneous hæmorrhage or ulceration was seen at this stage.

She was not clinically anæmic. There were enlarged, soft, discrete, mobile lymph nodes bilaterally palpable in the axillary, inguinal, cervical and supra-clavicular groups. The spleen was palpable (two fingers) and the liver edge just felt.

Investigations.—Hess test negative.

Chest X-ray normal.

Full blood count: Hb 85%; R.B.C. 3,900,000/c.mm.; W.B.C. 90,000/c.mm. (polymorphonuclear neutros 5%, eosinophils 1%, lymphocytes 4%, monocytes 86%, monoblasts 2%, myelocytes 1%).

Sternal marrow: Total nucleated count—400,000/c.mm. A sheet of abnormal monocyte-like cells in all stages of development, with reasonable numbers of myelocytes and nucleated red cells.

She was put on Prednisone 10 mg. t.d.s. but went down-hill rapidly, the gums showing ulceration on the fifth day of admission. Achromycin V 250 mg. q.d.s. was given to alleviate this.

She became progressively anæmic, the white count rising to 160,000/c.mm., 95% monocytes. On the ninth day of admission, she became unconscious with pin-point pupils. Multiple petechial hæmorrhages were present and the bleeding time was 180 minutes. She later collapsed and died.

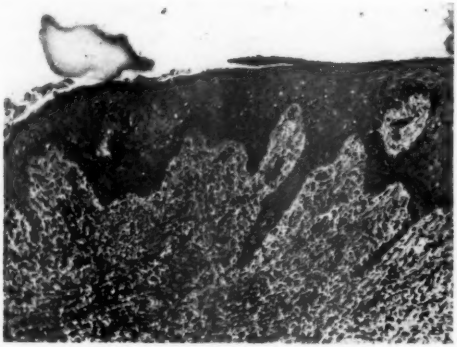

FIG. 2.—Photomicrograph. Gum showing dense infiltration of submucosa by leukæmic monocytes. H. and E. × 125.

Autopsy findings.—(1) Profuse hæmorrhages into most of the organs including a massive cerebral hæmorrhage. (2) Enlargement of all elements of the reticulo-endothelial system, including liver, spleen, tonsils and lymph nodes. (3) Infiltration of many organs with leukæmic cells.

A piece of gum tissue showed microscopically dense infiltration of the submucosa with leukæmic monocytes (Fig. 2).

Acknowledgments.—I am grateful to Mr. R. Sutton Taylor and Dr. K. A. Newton for permission to report this case. To Dr. A. D. Morgan for the photomicrograph, to Dr. J. G. Humble for the blood reports and Dr. P. Hansell for the photographs.

DISCUSSION ON ARTIFICIAL INSEMINATION

Dr. Margaret Hadley Jackson pointed out that, whereas in animal husbandry artificial insemination was primarily used to conserve and make full use of a valuable sire, in the human field its main use was to overcome barrenness. For this purpose there were two forms of insemination: (1) Donor insemination (A.I.D.=donor) where a fertile donor was needed and (2) husband insemination (A.I.H.=husband) when the husband's semen was used. The two forms have distinct and different clinical uses and their moral and legal implications are also different. For the former, which inevitably is the more controversial, there is a small but steady demand and its four main uses are:

(1) Where the husband is irremediably sterile according to present knowledge or totally impotent (i.e. unable to copulate or to produce an ejaculate).

(2) Where there have been one or more Rhesus tragedies in a family, then a Rhesus-negative donor is indicated.

(3) Where the husband is a carrier of some severe hereditary disability.

(4) Finally, and somewhat theoretically, A.I.D. can be considered as a means of improving the stock by using donors with outstanding mental and physical attributes.

From a total of some 2,500 infertile couples seen during the past twenty-five years only about 200 had needed and asked for A.I.D. but not all had proved suitable. The selection of cases was a difficult and responsible task as also was the building up of a panel of donors. One of the most awkward problems from the doctor's point of view was choosing the correct day in the wife's cycle for doing the insemination. Dr. Jackson summarized the results in 174 couples where A.I.D. had been carried out either with or without the husband's semen being added (*see* Table I). In 85% of the successful inseminations this was done between

TABLE I

	A.I.D.	A.I.D. and H.	Totals
No. of cases	136	38	174
Gave up too soon or went abroad	25	7	32
Failed to conceive after fair trial	39	14	53
Trying now	15	4	19
Have conceived	57	13	70
PREGNANCIES			
Pregnant now	6	—	6
Live birth	56	13	69
Still birth	4	—	4
Miscarriage	10	4	14
Pregnant more than once	17 had 2 pregnancies 1 had 4 „	2 had 2 pregnancies 1 had 3 „	

cycle days ten and fourteen inclusive, the outside extremes being eight and twenty-two. In the majority of cases the day of conception was within 36 hours before or after the change over from low to higher temperature levels on the basal temperature chart. In 3 cases conception occurred more than a week before the "rise"; none occurred more than 48 hours after. In 38 cases the husband was grossly subfertile but not azoospermic and A.I.H was attempted mostly alone at first and then boosted by fertile donor semen or in a few cases boosted from the beginning. Taking this small group first it will be seen that 7 (or one-fifth) of them abandoned the unequal struggle before A.I. had been given a fair trial; 14 (two-fifths) failed to conceive in spite of repeated attempts and another 13 (two-fifths) conceived on one or more occasions (17 pregnancies in 13 women with 13 live births and 4 miscarriages). In the larger A.I.D. group the 136 husbands were azoospermic or homozygous Rhesus-positive with a sensitised Rhesus-negative wife; 25 (less than one-fifth) gave up too soon for various reasons, 39 (rather less than one-third) failed and 57 (well over one-third) have conceived once or more (76 pregnancies in 57 women; with 56 live births, 4 still-births and 10 miscarriages, 6 being pregnant now). Twenty-one couples have asked for A.I.D. to be repeated; 19 have had two pregnancies, 1 has had three and 1 four. It is important to arrange for the same donor if there has been a previous live birth, but it is not invariably possible. The results on the whole are extremely encouraging, the children are well up to the average mentally and physically and, with one exception, the marriages have been consolidated and improved.

Turning to A.I.H., Dr. Jackson pointed out that the indications for this are quite different and include certain forms of impotence, vaginismus, deformity of the sex organs and aberrations of ejaculation; there is also a small group of cases where the semen is oligozoospermic and the sperms are lacking in motility and viability but the volume is adequate (2 ml. or over). The husband can, with practice, learn to divide the ejaculate into two fractions and the first fraction, which usually contains more than 80% of the motile sperm, can then be used for cervical insemination. This can be done either by the doctor using a syringe or by the wife using a plastic cervical cap of one sort or another. This method of collection increases the chances of success with A.I.H. quite considerably. Dr. Jackson went on to discuss the degree of concentration obtained by fractionation—these observations being based on the examination, by Mrs. C. Harvey at Exeter University, of 93 fractionated ejaculates from 21 men. The degree of concentration obtained is shown in Table II; from this it will be seen that 90% of the first fractions show marked superiority over the whole ejaculate, particularly with regard to the number of motile sperm.

TABLE II.—FREQUENCY OF VARIOUS DEGREES OF CONCENTRATION OF SPERM IN 1ST FRACTION

		Ratio of sperm in 1 ml. of 1st fraction of ejaculate (or whole of this fraction if less than 1 ml.) to sperm in 1 ml. of complete ejaculate				
	Number of ejaculates	0·8 1st Fr. inferior	0·8—1·2 No sig. difference	1·21—1·99 Fair concentration	2·0 and over Good concentration	Highest value
All sperm ..	93	8 (8·6%)	16 (17·2%)	48 (51·6%)	21 (22·6%)	3·9
Motile sperm ..	87	3 (3·5%)	4 (4·6%)	41 (47·1%)	39 (44·8%)	4·6

In cases where A.I.H. is being given a trial it is certainly worth asking the husband to collect his semen in two parts if the volume of his complete ejaculate is usually over 2 ml.

It must, however, be recognised that where the total sperm count of the whole ejaculate is only one or two million, or where the motility is very low, putting all the sperm available into 1 ml. of fluid does not greatly increase the chances of success.

There is some indication that, given a reasonably skilful donor, it should be possible to find the optimum volume for the first fraction or, putting it another way, what proportion of the whole ejaculate can most profitably be contained in the first fraction. This may be considerably less than half the total volume and in some men may be as small as 0·25 ml. while in others the first 0·25 or 0·5 ml. of fluid may be composed entirely of prostatic fluid and therefore devoid of sperm and it is not until about 1 ml. goes into the first fraction that a satisfactory concentration is obtained.

JACKSON, M. H. (1955) *Proc. 5th int. Conf. Planned Parenthood,* p. 245. Internat. Planned Parenthood Fed., London.

—— (1957) *Eugen. Rev.*, **48**, 4.

Mr. Reynold Boyd:

Indications for and Techniques of Artificial Insemination in Man

Although artificial insemination (A.I.) is so successful and widespread in veterinary practice it has been little used in man. Most of the current textbooks make little or no mention of it in their sections on sterility. In the treatment of human infertility there are, however, many clear indications for employing artificial insemination, which in suitable and selected cases, yields a high rate of success.

Indications for Artificial Insemination (A.I.H.=husband)

Impotence is an obvious indication. A masturbation specimen can be produced, with few exceptions, even when the failure is due to age. The subsequent pregnancy usually provides a cure in the younger group, in whom the cause is always psychological.

Absent ejaculation which may be classified according to type and cause as follows:

(*a*) Delayed ejaculation in apparently virile or potent young men and

(*b*) Retrograde ejaculation which may be idiopathic or follow endoscopic resection of the prostate.

(*c*) In tabetics where impotence is often an early sign.

(*d*) Following dorsal sympathectomy.

(*e*) In partial or complete paraplegia following accidents to the spine or operation for herniated intervertebral disc.

(*f*) Following denervation of the seminal vesicles in abdomino-perineal resections.

Oligospermia, where the volume is persistently low—in the neighbourhood of 0·25 c.c.—probably due to absent, atrophied or fibrosed seminal vesicles and consequently unresponsive to testosterone therapy.

Oligozoospermia and asthenospermia, making the best possible use of a poor specimen. In this group the failure rate is high but the occasional success justifies the continued use of A.I. In any event, it gives better results than relying solely on stimulatory therapy of dubious value.

Mechanical failure, as evidenced by a negative Huhner test in cases of hypospadias, retroversion, ectropion, fluor vaginæ, etc.

When intercourse is impossible on account of burning vaginal pain in disseminated sclerosis or on account of deformity as in Peyronie's disease, etc.

Indications for Donor Insemination (A.I.D.=donor)

When the husband is sterile or suffers from a grave hereditary disease or from Rhesus incompatibility, donor insemination is indicated if the wife desperately desires a child of her own and the husband prefers to bring up this child rather than any other.

Prerequisites for Donors (1) Between 30 and 40 years old. (2) Fertile with a minimum of morphological defects in the semen. (3) No hereditary disease. (4) Good physical condition. (5) Superior mentality. (6) Matching the husband racially, physically and in aptitudes. (7) Having the same Rhesus factor as the recipient.

Techniques

Self insemination for cases of hypospadias, impotence, dyspareunia and, more particularly, of delayed ejaculation, in which the specimen is collected usually at an inconvenient hour, in a polythene glans bag, moistened with fructose-saline solution. The specimen is drawn up into a nylon syringe and introduced into the vaginal vault by means of an attached piece of polythene tubing. Or the specimen may be injected into a pre-fixed plastic cervical cap through an attached tube. (Fig. 1).

Fig. 1.—The Milex cap. The cap is pre-fixed and the semen is introduced from a nylon syringe through the dependent tube in which there is a bead to prevent leakage.

Standard procedure. The results of A.I. are greatly improved by attention to details such as (*a*) Using plastic containers. (*b*) Mopping out the vaginal vault. (*c*) Aspirating the cervical mucus. (*d*) Leaving the patient in the Trendelenburg position for half an hour.

With regard to aspiration of cervical mucus there are pros and cons. It must be done gently or bleeding will occur making successful insemination less likely. It has been argued that the cervical mucus is protective, filtering abnormal forms and infection—but I do not believe that abnormal forms have fertilizing powers nor that ascending infection is ever caused by removal of the mucus *per se*.

The cervical canal is cleared by aspiration and with the help of weak bicarbonate solution or Alevaire and then filled with semen, any excess being put into the vaginal vault. The patient is left in the head-low position for 20–30 minutes with legs crossed except in some obese subjects in whom this produces fluor vaginæ. Indeed at times it is best to leave the speculum in situ so as to be certain that the os is bathed in semen.

Intra-uterine insemination is unwise as it frequently causes severe uterine cramps and there is a real possibility of introducing infection with a resultant salpingitis.

Intra-cervical insemination is the method of choice when using the *split specimen technique.* The first, smaller fraction of a masturbation specimen usually contains a much higher density of sperms of a much higher percentage motility than the second, larger fraction; indeed some 80% of the total number of spermatozoa will be found in the first half of the ejaculate. Sometimes the density is five times as great. But when, through anxiety or at the initial attempt, this first portion is kept too small it may be made up almost entirely of prostatic secretions in which very few spermatozoa will be found.

When using a small volume specimen or a split specimen, the cervical canal should be filled to "bulging" but not allowed to overflow or the contents will be siphoned out.

The results of the split specimen method are very encouraging and show that it is a major advance in the handling of the subfertile male. This technique has now replaced centrifuging which concentrates debris as well as sperms and markedly reduces the viability of an already deficient specimen.

In some 10% of cases of oligozoospermia and asthenospermia, however, there is no significant difference between the two fractions and in these cases cap insemination is the method of choice.

Cap insemination (*C.A.I.*) allows the whole ejaculate (or up to 4 c.c.) to be kept in contact with the external os for 6 or more hours. It is eminently suitable for some cases of oligozoospermia and asthenospermia, for pin-hole os, etc. It is amazing how often a pin-hole os can be dilated and still remain the same! Fluor vaginæ is also an indication; this condition has long been discounted as a cause of infertility but the longer fertile semen is in contact with the external os at the right date the greater the certainty of a pregnancy.

Asthenospermia is usually associated with great increase in volume—from 6 to 10 c.c. In many cases the first part of a split specimen shows no advantage in numbers but if the specimen is produced in two approximately equal portions the first will be found to contain most of the active spermatozoa; and it is this half that is used for C.A.I.

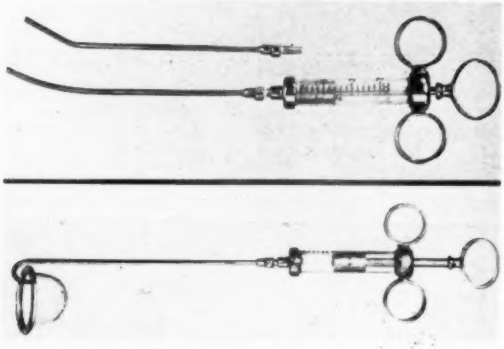

FIG. 2.—Above: syringe and cannula for intra-cervical insemination.
Below: Plastic cap and crooked cannula for C.A.I.

The Milex cap with its attached tube for easy filling can be used but the crooked cannula technique is preferable (Fig. 2).

The procedure is as follows: The vagina and cervix are exposed and cleansed by dry mopping. No lubricant is used. The speculum is removed. A plastic cap of 28 to 30 mm. size is inserted into the vagina and pushed on to the cervix before reinserting the bivalve speculum through which it is, unfortunately, too large to be introduced. The cap is now held firmly in place with the help of bullet extracting forceps, while the crooked cannula is brought down between the cervix and the rim. The semen is then introduced and will be seen to rise and cover the external os. The cap is left in place for six hours or longer. A strong thread can be attached to the rim to facilitate removal but on the first occasion it is wise for the patient to return to the clinic so that leakage can be excluded.

For all these methods it is best for the semen to be not more than 1 hour old but I have had a success at 5 hours in a patient who brought the specimen from Worcester to London and much longer time-lapses are recorded.

Special techniques are required for cases of absent ejaculation.

(i) *Retrograde ejaculation* due to neuromuscular imbalance is easier to deal with than when it follows endoscopic resection of a prostatic bar. After a salt-free diet for forty-eight hours and restricted fluids for twenty-four hours the patient empties his bladder and then attempts to produce a specimen, part of which can easily be collected for insemination from the prostatic urethra by means of a Guyon posterior urethral metal cannula.

(ii) *For retrograde ejaculation* due to altered mechanics following endoscopic resections a different technique is required. The bladder cannot be emptied completely nor is there an integral prostatic urethra. In these cases the urine must be

(*a*) dilute. (*b*) strongly alkaline—pH 7·4.

An alkaline mixture and free bland fluids are given for twenty-four hours. The bladder is "emptied" normally. It is useless to expect a patient to be able to "produce" a specimen immediately after catheterization so a certain amount of dilute residual urine must be accepted. A plastic catheter is passed into the bladder and urine is withdrawn. The latest fraction will be the least diluted semen and on examination density will be found adequate for artificial insemination and progressive motility unimpaired.

In many of these cases spermatozoa will be found in spite of recurrent attacks of bilateral epididymitis. The depressant effect of sulphonamides on spermatogenesis should be remembered and precautionary antiseptic or bacteriostatic therapy is best interrupted for several weeks prior to attempting A.I.

(iii) *Absent ejaculation* often occurs after dorsal sympathectomy for hypertension.

Semen can only be expressed by vaso-vesicular massage, the resultant specimen being all too frequently only minimal in quantity and quality. Even if a satisfactory volume is obtained a great proportion of the sperms will be found to be aged and immotile. The same difficulties arise in some cases of complete impotence where the only ejaculations are in the form of unpredictable night-losses and also in cases of psychological absent ejaculation subject to the same losses.

Vaso-vesicular massage to yield results must be meticulously performed and should be distinguished from the V.D. clinic procedure of taking a prostatic bead. It must be remembered that the vesicles are freely mobile and carry the vasal ampullæ with them. The stripping should be done with a broad movement of the index finger which suddenly descends on the vesicle "unawares" and sweeps inwards and down to the centre line. Finally the prostatic and posterior urethra are emptied by pressure between finger and thumb.

Electrical stimulation of ejaculation should be possible in all these cases. It is most successfully applied to rams and the technique is easily applicable to man. A sine type wave is used, the leads being attached to small electrodes placed on either side of a ring or thimble worn at the end of the right index finger, which is introduced per rectum and placed as nearly as possible over the vasal ampullæ. Care must be taken to avoid trauma to the anal mucosa and if there is difficulty a speculum should be used. After insertion the ring can be easily recovered and slipped on by pulling on the leads. The current must be kept on for up to twenty minutes at times and several attempts may be needed to educate the musculature involved.

(iv) When absent ejaculation follows perineo-abdominal excision of the rectum (which has sometimes to be performed in quite young men) massage is impossible. Here one must

resort to the forming of a vaginal spermatocele (seminal "hydrocele") from which spermatozoa can be withdrawn at times suitable for A.I. (Fig. 3).

(v) Attempts have been made in paraplegics to produce an erection and ejaculation by means of an intrathecal injection of prostigmine. In my hands this has not been popular enough to repeat as patients complain of the painful erections and of the subsequent headache. If spermatozoa can be found in the vesicular bead indicating that the inevitable repeated attacks of epididymitis have not yet blocked the tubules or vas then vaso-vaginal

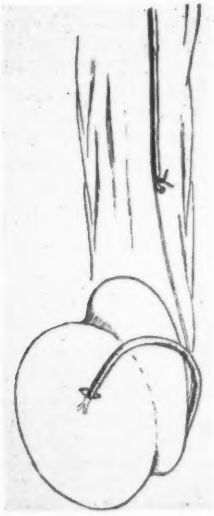

FIG. 3.—Vaso-vaginal implantation.

implantation is indicated. It can be performed without anæsthesia and healing is uncomplicated. It should be added that pregnancies have followed insemination of progressively motile sperms recovered from spermatoceles in spite of the current maturation theories.

The timing of ovulation.—Many of the methods of accurately timing ovulation have a post hoc connotation and are beyond the laboratory facilities of the busy specialist. For all practical purposes temperature recordings are sufficient, the assessment being confirmed by the appearance of the cervical mucus, by spinnbarkeit, and by a positive palm leaf (Arborization) mucus test. In my own cases, 83% of success has followed insemination on the morning of the temperature drop or before the biphasic rise, 5% from A.I. two days before the rise, 10% on the top of the rise and 2% the day after the rise.

These figures are not really strictly comparable and are only meant to indicate that conception can and does arise from insemination well on either side of what is the most favoured date.

The Principles and Practice of Bone Conduction Audiometry: A Review of the Present Position

By J. D. HOOD[1]

WHEREAS the technique of air conduction audiometry is well established, the basic principles of bone conduction audiometry are still far from being generally understood. In consequence, the tests are still too often inefficiently performed, and hence fail to provide the vital diagnostic information which is their purpose.

As will be shown, this disappointing state of affairs is quite unnecessary, and requires for its correction no more than a rational standardization of our technical equipment and test procedures, whereby proper use is made of the considerable body of acoustic and physiological knowledge now at our disposal.

An essential requirement with all bone conduction tests is the exclusion of the untested ear by means of an efficient masking sound, so that all threshold readings can be validly related to the tested ear. In order to understand how this requirement arises, we need to know, firstly, certain facts concerning the transmission of air and bone conducted sounds across the head; and, secondly, the physical characteristics of a sound which confer upon it maximum efficiency for the masking of pure tones of specified frequency.

The facts relating to sound transmission across the head are conveniently studied in subjects with normal hearing in one ear and complete deafness of the other.

The results obtained are shown in Fig. 1. The calibrated columns are taken to represent the available hearing capacity of each ear; the solid column at the left represents total deafness of

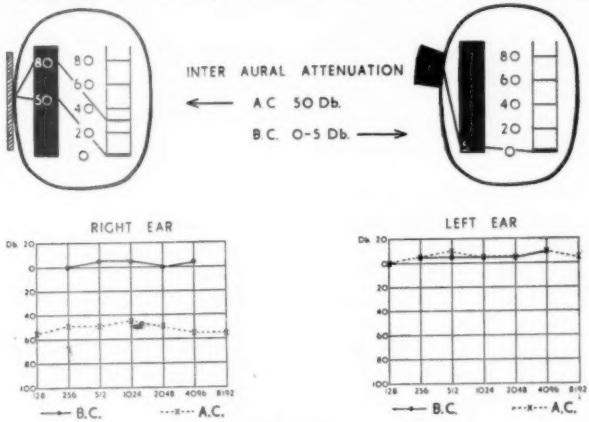

FIG. 1.

the right ear. If an air-conducted sound of 50 db. is applied to the right, or deaf ear, it will be heard in the left ear at threshold intensity. Similarly, a sound of 80 db. applied to the right ear will be heard in the left ear at a level some 30 db. above threshold. The reason for this is that sound from an air conduction receiver is transmitted across the skull with an inter-aural attenuation of the order of 50 db. By contrast, the inter-aural attenuation for sound from a bone conduction receiver applied to the right mastoid is negligible, and the sound will be heard at the left ear with a loss of only a few decibels.

In the lower half of Fig. 1 are shown the pure tone audiograms of the right and left ears for air and bone conduction carried out without masking. They indicate normal hearing for the left ear, and a severe conductive deafness for the right ear. In agreement with this, the classical tuning fork tests applied to the right ear lead us into that well-known pitfall of

[1]From the Otological Research Unit, Medical Research Council, National Hospital, Queen Square, London, W.C.1.

clinical practice, the false negative Rinne. In fact, for the reasons given, the threshold readings, both for air and bone conduction, obtained for the right ear and shown in the audiograms, are false readings derived from the left or untested ear. In the case of air conduction, owing to the comparatively high inter-aural attenuation of 50 db., such false readings are only obtained when the stimulus intensity exceeds this level. Clearly enough, true readings would result with any degree of deafness of the right ear below this level.

Hence the rule that when the difference in the air-conduction thresholds of the two ears exceeds 50 db. the readings for the worse ear cannot be relied upon, unless the better ear is excluded by masking.

In the case of bone conduction, however, the situation is much more difficult. Here the inter-aural attenuation is negligible, and hence, if the bone-conduction threshold of the right ear be raised by any amount above 5 db., a receiver on the right mastoid will give false normal readings derived from the opposite untested ear. Hence the rule that *all* bone conduction tests require the exclusion by an air-conducted masking sound of the untested ear. A variety of masking noises has been devised to serve this purpose. A few, like those

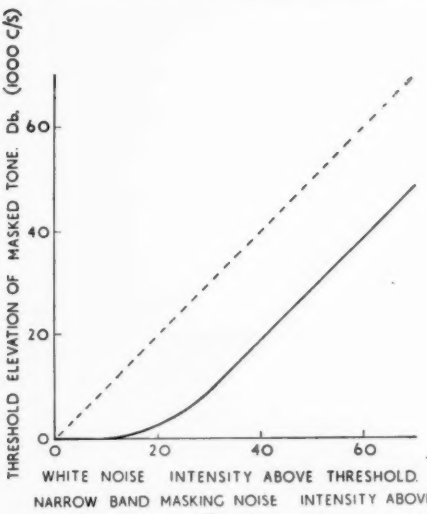

FIG. 2.

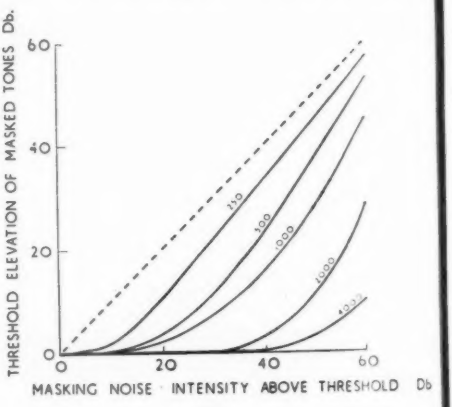

FIG. 3.

described by Zwislocki (1951), or Denes and Naunton (1952), are efficient, but of the majority it can only be said that they raise the threshold of the masked ear in some vague unspecified manner.

In order to understand what makes a masking sound efficient, it is helpful to consider first the masking of pure tones by white noise, that is to say, noise having a flat frequency

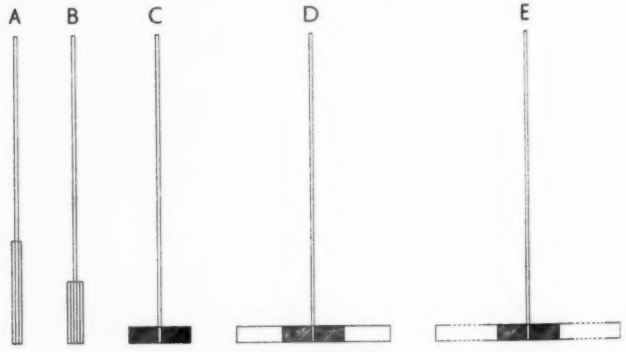

FIG. 4.

spectrum covering the whole audible frequency range with equal sound energy per cycle. In Fig. 2 is shown the elevation of the threshold of a pure tone of 1,000 cycles in the presence of white noise. The noise intensity is expressed in decibels above normal threshold, and it will be seen that below the 20 db. level it produces negligible masking of the pure tone. Above this level there is an incremental equivalence in decibels of masking and of masking

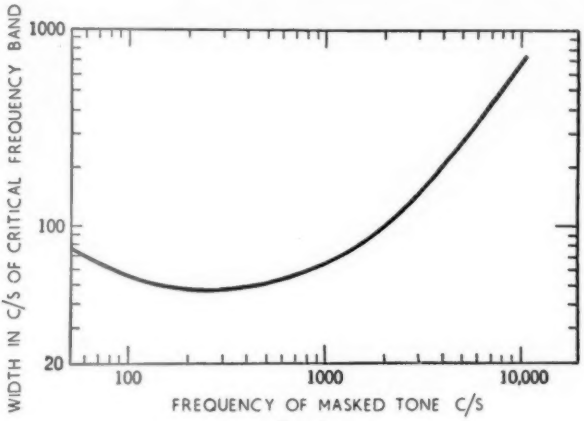

FIG. 5.

noise intensity. At any masking level, therefore, the loudness of the white noise will be much in excess of the pure tone, since its intensity will at all times be some 20 db. higher.

This brings us to the first important requirement of a masking noise, namely, high masking efficiency which Denes and Naunton have defined as "good masking ability, but minimal loudness". Clearly, white noise does not conform to this ideal. Nevertheless, it is superior to some of the masking noises incorporated in many commercial audiometers. A typical example is shown in Fig. 3. The masking noise is modified mains hum, its intensity level in decibels above normal threshold is shown on the horizontal scale, and on the vertical scale the resulting threshold elevation of various pure tones. It will be seen that for frequencies above 1,000 cycles masking is grossly inefficient. At 2,000 cycles no masking at all is produced below an intensity level of some 50 db. at which point it is already becoming unpleasantly loud to the subject.

Having considered these examples of inefficient masking sounds, we will consider next how we set about our task of designing what we really require, that is to say, sounds which have the maximum possible efficiency for the masking of the limited range of specified pure tones, which are conventionally used for bone-conduction audiometry. Here, as usual, we turn for guidance to some of Fletcher's (1940) early work upon frequency discrimination, loudness and masking, which led him to define the existence of certain so-called critical frequency bands. Their significance lies in the fact, firstly, that in any masking noise only those frequencies within a certain critical band centred around the pure tone contribute to its masking, and secondly, when the tone is just audible against the background of noise, the total acoustic power of the components within the band is the same as that of the pure tone. The principles are illustrated schematically in Fig. 4. This shows noise bands of varying widths centred about a single pure tone which is just audible in their presence. The acoustic energy, both in the bands and in the pure tones, is represented by the enclosed area of each. Band A is only three cycles wide, and since its total energy is the same as that of the pure tone, the energy per cycle of the noise is only one-third that of the pure tone. Band B is five cycles wide. Once again, its total energy is the same as that of the pure tone, which thus has five times as much energy as each cycle of the band. The width of Band C is that of the critical band, and yet again the total energy in the band is equal to that of the pure tone.

In bands D and C the noise spectrum extends beyond the critical band, so that the total energy of the bands is much increased. Since, however, it is only the energy in the critical band which contributes to the masking, these noise bands possess no greater masking power, and the energy level of the just masked pure tone remains the same. In other words, those components outside the critical band, while they may have the effect of making the noise

very much louder, contribute nothing to its effective masking power. This provides us with the theoretical basis for the concept of high masking efficiency; clearly our first objective must be to remove as much as possible of these unnecessary components.

Are we likely to gain anything from the use of band widths which are only a fraction of the critical band, as for example in Band B? Apart from the fact that to do so would present very difficult technical problems of sound filtering, we should gain nothing in efficiency and, in addition, would be faced with the added difficulty of the tonal similarity of the pure tone and the masking noise which might result in some confusion to the patient. If, however, the band width of the masking noise is extended to correspond roughly to that of the critical band, as in Band C, then we find that though masking sound and pure tone are identical in pitch, they are still readily distinguishable, and hence are not confused by the subject tested.

The critical band widths for the various frequencies are shown in Fig. 5. As will be seen, they are of the order of only a hundred cycles wide. It would be technically impossible to produce noise bands to these specifications, nor, as will be shown, is this necessary.

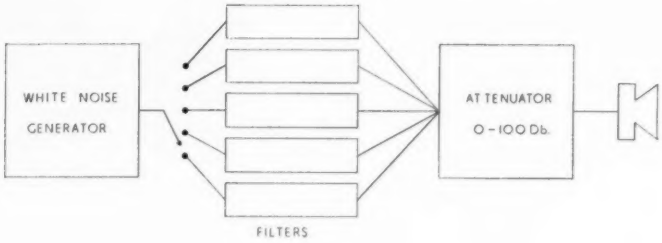

FIG. 6.

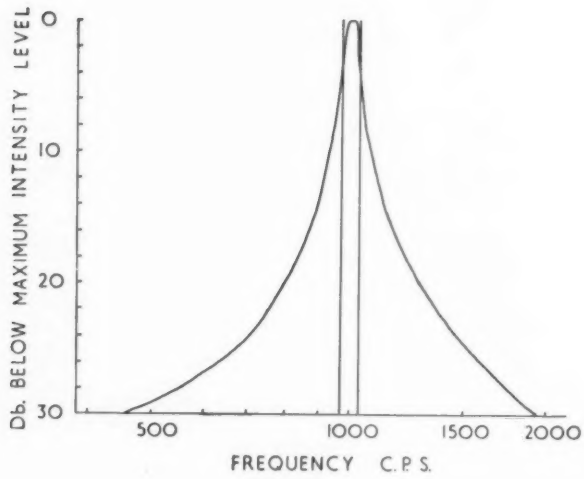

FIG. 7.

In Fig. 6 is shown schematically the equipment we have used for obtaining narrow bands of noise, having the masking efficiency required. A white noise generator is followed in turn by a number of filters of high selectivity centred around each of the pure tones normally used in bone conduction audiometry, followed in turn by an attenuator calibrated in steps of 10 db. Each of the filters can be selected by means of a switch, and passes only a very narrow band of frequencies.

The selectivity curve for the band centred at 1,000 c/s, which is typical of the other curves, is shown in Fig. 7. At the centre, the two vertical lines give the measure of the width

of the critical band. The curves extend somewhat beyond the critical band at the base; nevertheless, the maximum energy in the band is centred within the two parallel lines.

The dotted line in Fig. 2 illustrates the high masking efficiency obtained with this band.

In contrast to the masking effect of white noise, there is 100% masking efficiency. The curve begins at zero, and there is an exact one-to-one relationship between noise level and masked threshold. Thus, if the noise is raised 20 db., the pure tone threshold is raised by an identical amount, and so on. All the noise bands are similar in this respect, and we regard it as one of their most important features. Thus, if it is desired to raise the threshold of a pure tone by, say 40 db., it becomes a simple matter of raising the intensity level of the noise band by exactly the same amount. The practical importance of this is best illustrated by considering the simple application of these noise bands to the technique of bone conduction tests.

Fig. 8 is a schematic illustration of the rationale of the procedure employed at the Otological Research Unit, and referred to for convenience as the "shadowing" technique. Let there be a pure nerve deafness of 40 db. of the subject's right ear to be tested, and no loss of hearing of the left ear. As before, the columns on each side are taken to represent the available hearing, and are calibrated in decibels. The solid portion of the left column represents the nerve deafness of the right ear. A bone conducted sound at normal threshold intensity applied to the right mastoid is heard in the subject's left ear. This provides us with the first point on the graph shown below, in which the masking intensity at the left ear is plotted on the horizontal scale and the bone-conduction threshold responses on the vertical scale.

Now, as shown in Fig. 8, the masking noise at a level of 10 db. applied to the left ear

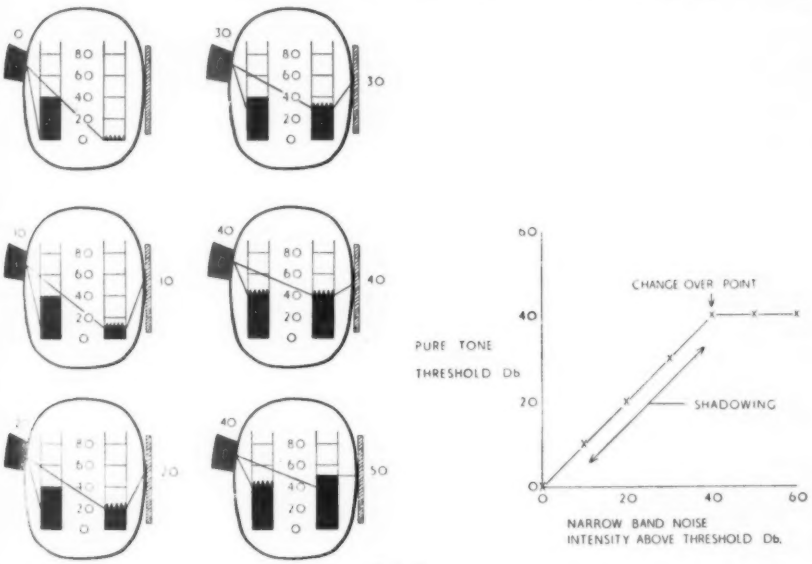

FIG. 8.

raises its threshold for the bone conducted test tone by 10 db. In the same way, increases in masking noise intensity of 20 or 30 db. will bring about increases of identical magnitude in the threshold values for the test tone. Reference to the graph shows, up to this point, this step by step correlation, the "shadowing" effect between the intensities of masking noise and test tone thresholds. When, however, the masking noise reaches the 40 db. level it will be seen that the bone conducted test tone will be heard at threshold by the right as well as the left ear. A further intensity increase of the masking noise to 50 or 60 db. will further raise the threshold of the left ear alone, leaving the test tone to be heard by the right ear alone without further elevation above its true threshold value, 40 db. The true threshold for the right ear will thus be shown at a point on the graph, referred to as the "change-over" point, at which the slope of the curve changes from 45 degrees and becomes horizontal. In the case being considered, the change-over point occurs at 40 db. If, extending the

argument, the deafness of the tested ear had been 50, 60 or 80 db. identical values of masking noise intensity would have been required to reach the "change-over" points. In all cases, true threshold readings would be obtained.

The essential steps of the test procedure are thus:

(1) The demonstration of the "shadowing" effect. This establishes that both masking noise and test tone are confined to the untested ear.

(2) The identification of the "change-over" point. This establishes the true threshold of the tested ear.

The case analysed in Fig. 8 is one of comparative simplicity in that the unilateral deafness was of the "nerve" type. In unilateral deafness of the conductive type, however, we are confronted with a situation of considerably greater difficulty. This arises, as will be shown, from the fact that the inter-aural attenuation of an air-conducted masking sound does not exceed some 50 db.

The situation is illustrated in Fig. 9.

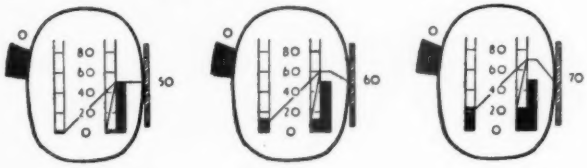

FIG. 9.

Here, the subject has normal hearing of the right, or tested, ear, and a pure conductive deafness of 50 db. of the left ear. This is indicated by the solid area adjoining the calibrated column which represents the inner ear hearing capacity of the left ear.

In ascertaining the bone-conduction threshold of the right ear we must, as usual, apply an air-conducted masking noise to the left ear. Here a serious difficulty arises, since before this noise can become effective its intensity must reach 50 db., the amount of the conductive deafness. At this intensity it will just overcome the inter-aural attenuation for air-conducted sound, and begin to exert a masking effect upon the right ear as well as the left. If the intensity of the masking noise be further increased in steps of 10 db., a "shadowing" effect will occur, and the bone-conduction thresholds, derived equally from the two ears, will rise *pari passu*. In this instance, however, the "shadowing" effect will continue indefinitely, and no "change-over" point will be reached.

The underlying difficulty is clearly to be found in the fact that the inter-aural attenuation of the air-conducted masking noise has a limit of some 50 db. What is needed, therefore, is some means of extending this limit, and providing a zone of masking noise intensities which will be above the air-conducted threshold of, and at the same time confined to, the left ear. Within this zone, the "shadowing" procedure could be applied, and the absence of a "shadowing" effect would then prove that bone-conduction threshold readings were derived from the right ear, and could be accepted as valid.

The manner in which such an increase of the inter-aural attenuation can be accomplished stems from a brief report on the use of insert receivers which appeared in the Report of the Electro-Acoustics Committee "Hearing Aids and Audiometer", 1947. In this it was

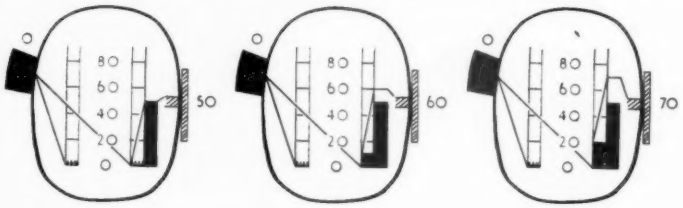

FIG. 10.

suggested that the acoustic linkage between the two ears which occurs when any air conduction receiver is used arises from the vibrations imparted to the skull at the air-bone interface bounding the receiver. Both Littler *et al.* (1952) and Zwislocki (1953) have carried out further studies, and it has been shown that the vital factor affecting the attenuation is

the area of the receiver in contact with the head. Thus, the smaller the area the greater the attenuation, and in the limiting case when an insert receiver is used, thus presenting the smallest possible surface to the skull, the inter-aural attenuation increases to a figure as high as 90 db.

As Littler *et al.* (1952) so ably pointed out, the practical importance of this finding is considerable, making possible as it does the accurate determination of bone-conduction thresholds in the presence of conductive deafness well beyond the limit of 50 db. This is illustrated in Fig. 10. Masking noises of intensities up to 90 db. are applied to the left ear by means of a rubber-tipped-insert receiver without fear of cross conduction to the right ear.

Thus, at any intensity between 50 db., the air-conduction threshold of the left ear, and 90 db., the masking noise will be effective in the left ear alone. If we now apply the "shadowing" procedure, and make step by step changes of masking intensity within this range, they will be found to leave unaltered the bone-conduction threshold readings. In other words, the "shadowing" effect is absent, and the threshold reading, 0 db., can be accepted as valid for the right ear.

When the deafness is bilateral, and of the mixed conductive and nerve type, bone-conduction tests may be greatly complicated, and indeed it is only within certain limits that accurate results are then obtainable.

An audiometrician needs to know what these limits are, and it is fortunately possible to define them with reasonable accuracy. The situation is analysed in the cases shown in Fig. 11 (A, B and C). In 11A the subject has a nerve deafness of 60 db. of the right ear and conductive deafness of 30 db. of the left ear. In order to establish the bone-conduction threshold of the right ear, the usual masking noise must be applied to the left, and owing to

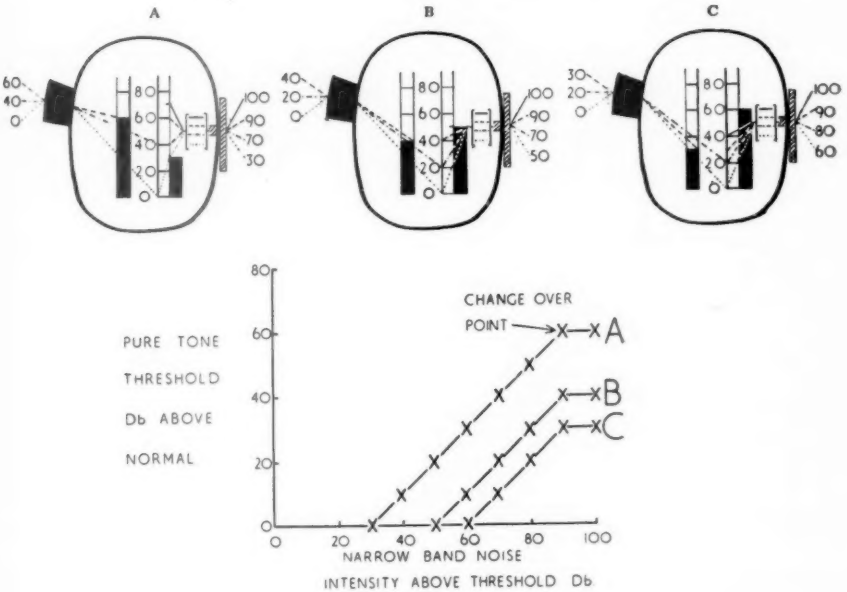

FIG. 11.

the conductive deafness its minimum effective intensity will be 30 db. Above this point shadowing will occur, as shown in the graph (A). That is to say, both masking noise and test tone will be confined to the left or untested ear. When the masking intensity reaches the 90 db. level, its true masking effect upon the left ear will be restricted to 60 db. by the conductive deafness and the test tone will now be heard at threshold in the right ear as well as in the left. This is the critical change-over point, and beyond it a further increase of masking intensity to 100 db., the maximum practicable level, will raise the threshold of the left ear by a further 10 db. while leaving unaffected at 60 db. that of the right ear. This, therefore, will be its true threshold.

Two factors determine the results thus obtained. Firstly, 100 db. is accepted as the

maximum intensity of masking noise which it is practicable to use for clinical tests. With this the critical change-over point occurs at a level 10 db. lower, 90 db., and to this is convenient to refer as the maximum critical masking intensity. Secondly, the threshold of the tested ear can be determined only if it lies at or below the level of masking induced by the maximum critical masking intensity in the untested ear.

Now, in the case 11A this level is reduced by 30 db., the amount of the conductive deafness and hence, 60 db. is the maximum measurable elevation of the bone-conduction threshold of the right ear. From this we may derive the limiting formula:

Maximum measurable bone-conduction threshold=90−conductive deafness (db.) of opposite ear.

The application of the test procedure to the three cases A, B and C, represented in Fig. 11, is shown in the graph.

In all three the amount of the nerve deafness of the tested ear is the maximum measurable according to the limiting formula. Thus:

Case A 60 db. (90–30)
Case B 40 db. (90–50)
Case C 30 db. (90–60)

In each case the true threshold is given by the change-over point which occurs at the maximum critical intensity, 90 db. of masking noise.

Although for simplicity of explanation the cases shown in Fig. 11 have been selected to exhibit conductive deafness alone of the untested ear and nerve deafness alone of the tested ear, accurate bone-conduction tests are still possible within the limits of the formula when the deafness, of either one or both ears, is of the mixed type. This is illustrated in Fig. 12. In the right ear there is a conductive deafness of 40 db. with a nerve deafness of 60 db. The air-conduction audiogram thus shows a loss of 100 db. In the left ear there is a conductive

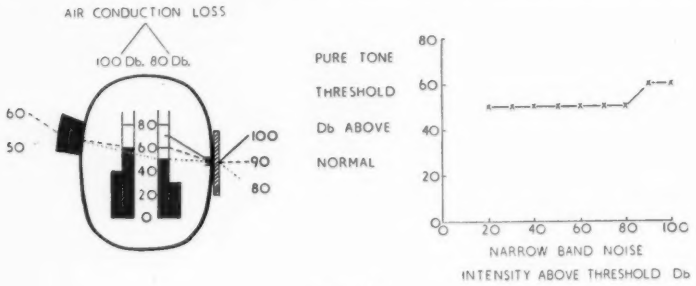

FIG. 12.

deafness of 30 db. with a nerve deafness of 50 db. The air-conduction audiogram thus shows a loss of 80 db. With no masking noise applied to the left ear the bone-conduction threshold reading is 50 db. derived, in fact, from the left ear, though this cannot be specified at this stage of the test.

This reading remains constant with increase of masking noise intensity up to 80 db. With the masking intensity increased to 90 db., however, and still confined at this level to the left ear, the threshold reading is increased to 60 db. and remains unchanged when the masking intensity is further increased to 100 db. As shown in the graph, "shadowing" occurs between the 80 and 90 db. levels of masking noise intensity with the "change-over" point at 90 db. It follows that up to the 80 db. level of masking noise intensity, the threshold reading, 50 db., must be derived from the left ear. Further, that at and above the 90 db. level, the threshold reading, 60 db., is derived from the right ear. Subtraction of these bone-conduction losses from the air-conduction losses gives the amounts of the conductive deafness, thus:

Right ear 100–60=40 db.
Left ear 80–50=30 db.

In each case, the amount of the nerve deafness is the maximum which can be measured according to this formula. Thus for the right ear:

60 db. (amount of nerve deafness)=90–30 (amount of conductive deafness of left ear).

For the left ear:

50 db. (amount of nerve deafness)=90–40 (amount of conductive deafness of right ear).

As will be seen from the foregoing analyses, the use of the maximum efficiency masking

technique described in this communication brings within the resolving power of air and bone-conduction audiometry all but the few exceptional cases which lie beyond the bounds of the limiting formula.

In all cases, however, careful attention should be given to the fundamental features of the test procedure which is outlined as follows:

(1) Establish the air-conduction audiogram of both ears in the normal way with masking, if necessary, of the untested ear, i.e. when the difference in the hearing loss between the two ears exceed 50 db.

(2) Find the bone-conduction threshold with the bone-conductor applied to the mastoid of the tested ear without masking of the untested ear.

(3) Apply the masking noise of the appropriate band to the untested ear by means of an insert receiver and find a bone-conduction threshold reading.

(4) Apply the "shadowing" procedure thus: Increase the level of the masking noise by 10 db. above threshold and re-test the bone-conduction threshold. If the bone-conduction threshold is raised by 10 db. increase the masking intensity by another 10 db. and repeat. Continue this procedure until the point is reached at which the bone conduction remains constant with further additional incremental steps of 10 db. of the masking noise. This is the "change-over" point, and gives the true bone-conduction threshold of the tested ear.

Suggestions for the improvement of standard equipment tend to encounter two kinds of objections. Firstly, that they involve excessive technical difficulties. Secondly, that the solution they offer is far from complete, and hence further development should be awaited. Neither of these objections appears to be applicable in the present situation. No serious difficulties attend the generation or application of the masking sounds described, and as for further developments, these cannot be expected since in many respects the efficiency obtained is 100%, at which level an ample reserve is provided for the attainment of practically all the clinical results which are required. It is, therefore, to be hoped that the methods described will find useful application in improving the design of standard audiometric equipment.

Recent Work on the Biochemistry of the Labyrinthine Fluids

By L. CITRON[1] and D. EXLEY[2]

THE search for new knowledge of the endolymph has received a strong impetus from the evidence, spectacular but still unexplained, of its circulatory derangement in certain important diseases of the mammalian inner ear, among them Ménière's disease and the Scheibe type of hereditary cochleosaccular degeneration. In the course of earlier work much has been made of the abundant morphological data at our disposal, but their value is clearly limited when we come to apply them to the problems of the origin, flow and absorption of a fluid of unknown function and composition. Thus, Shambaugh's (1908) observation of the cellular structure of the stria vascularis led him to attribute thereto the secretion of the endolymph. But his arguments could not be regarded as conclusive, and much the same must be said of the studies of Secretan (1944) and others who have interpreted certain histological appearances in the saccus endolymphaticus as evidence both for and against its absorptive function. Nor have experimental methods been entirely neglected, and Guild's (1927) use of the Prussian blue granule technique led him to conclude that a flow of endolymph took place from the scala media by way of the saccule to the saccus endolymphaticus, whence it was absorbed into the radicles of the surrounding venous sinuses. However, the technical difficulties of these experiments were great and, so far as we know, they have never been repeated.

This conflict of evidence has long made apparent the need for new and more penetrating methods of investigation, and the present contribution is concerned with the application to the problems of the endolymph of modern methods of micro-chemical analysis. The history of the subject is very short. In 1940, Aldred, Hallpike and Ledoux described a method for

[1] From the Otological Research Unit, Medical Research Council, National Hospital, Queen Square, London, W.C.1.
[2] From the Cell Metabolism Unit, Medical Research Council, Department of Biochemistry University of Oxford, South Parks Road, Oxford.

the collection from the scala media of the cat of small samples of endolymph, which they used for the first estimations of its osmotic pressure. Ledoux (1941, 1943, 1950) later used this method in his studies of the chemical and physical properties of the labyrinthine fluids. It is, however, to Smith, Lowry and Wu, of Washington (1954) that we owe the first detailed account of any measurements carried out by means of modern micro-chemical techniques of the electrolyte contents of the mammalian labyrinthine fluids, and the primary purpose of the present investigation has been to repeat and extend their observations. One of us (L. C.) carried out the collection of the labyrinthine fluid samples; the other (D. E.) was responsible for their microchemical analysis.

Methods

A. Collection of Fluid Samples

The essential step in the collection of the samples has been the insertion of fine glass pipettes into the endolymph system of the cat and guinea-pig. These pipettes were made of boro-silicate glass, and were especially drawn in the laboratory. It was found necessary that the pipette tips should have an outside diameter within the range 50 to 100 microns. Penetration was difficult with larger tips, whilst smaller tips did not permit the passage of the perilymph samples. Endolymph samples were easier to obtain from the cat by passing the pipettes through the round window membrane. After removal of this membrane, a finer pipette was then introduced into the endolymph-filled scala media, through the basilar membrane (Fig. 1).

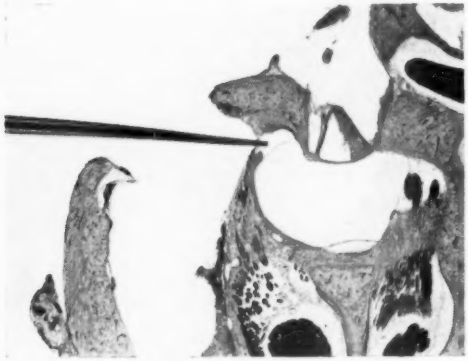

Fig. 1.—Collection of endolymph from cochlea of cat.

In the guinea-pig, specimens of the perilymph were obtained by passing the pipette either through the round window membrane, or else through the thin ligament around the stapes foot-plate. The stapes was then removed, and endolymph collected from the utricle in the manner of Smith *et al.* (1954) (Fig. 2).

The operation was conducted under Urethane anæsthesia. The head of the animal was firmly immobilized by means of a clamp attached directly to the skull. The pipettes were carried upon a micro-manipulator working under 10 x magnification of a Leitz dissecting microscope. Contamination of the specimens with blood was a serious difficulty, and constant suction was necessary throughout the operations to avoid it. All specimens were drawn up by suction into the collecting pipettes, which were then heat-sealed at both ends and immersed in Terpineol. This oil has a refractive index very similar to that of glass, and examination of the immersed pipette under a high powered microscope readily revealed the presence of red blood cells in the specimen. All specimens containing more than a few red cells were discarded. The sealed pipettes found to contain satisfactory specimens were then packed in vacuum flasks, filled with CO_2 snow, and despatched to the Department of Bio-chemistry at Oxford.

B. Microchemical Analysis.

The maximum amount of endolymph obtained was 0·5μl., generally about 0·2μl. This is about 1/1000th of the amount usually taken for a blood count. On a microscope slide 0·2 cl. forms a drop which will approximately cover a typewritten full stop. For various reasons these very small samples cannot be pooled, and new methods have been required for their analysis.

By comparison with those required for the usual micro-methods of analysis the volumes

of our fluid samples are less by one-thousandfold, calling for the estimation of millimicrograms instead of micrograms. Estimations have been carried out of the inorganic ions, sodium, potassium, calcium, magnesium and chloride. Protein and non-protein nitrogen estimations have also been made. In addition, the finding by Jensen and Vilstrup 1954 of an apparently high concentration of hyaluronic acid in the endolymph of certain dogfish has led us to carry out estimations of its concentration in the labyrinthine fluids of the guinea-pig.

For work on the inorganic ions flame photometry was used. With this method an aqueous solution of the sample is atomised in a flame in which the elements all emit their characteristic spectra. This light is then passed via an optical system which can be arranged to select the spectrum of the desired element only. This selected light band then falls on a photosensitive cathode of a photoelectric cell, which converts it to current which can be read on a meter. The Beckman flame photometer is the most sensitive instrument available commercially, and can be used with either an oxy-hydrogen or an oxy-acetylene flame, which with aqueous solutions give temperatures of about 2,500° C. The current is amplified by means of a photo-multiplier, the instrument having an overall amplication of about 300,000. Readings are taken on a potentiometric scale, and are produced by operating a potentiometer to balance out the current produced by the element with the aid of a null point meter.

The time taken to obtain a reading, using this instrument, is about 30 sec. and in this time 1 ml. of solution is atomized. Thus, to obtain a reading, it is necessary to dilute a

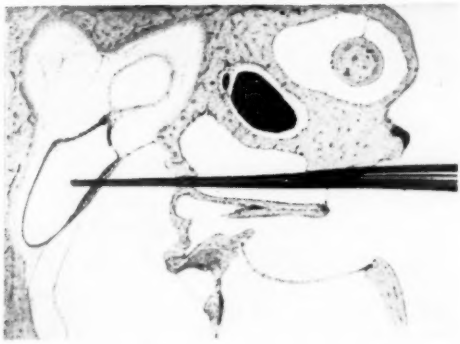

FIG. 2.—Collection of endolymph from utricle of guinea-pig.

0·2μl. sample 5,000 times. This very sensitive instrument was, however, not sensitive enough to measure most elements in our own samples at the required millimicrogram level, particularly such weakly emissive elements as magnesium.

Efforts were, therefore, made to increase the emission of inorganic ions, and it was found that the hotter the flame used, the greater the sensitivity. Using one of the hottest flames possible produced by burning 90% acetone in 5% HCl in an oxy-hydrogen flame (here the temperature was about 3,500° C.) it was found possible to increase the emission of calcium and magnesium about 50 times. In this flame our samples, 0·2–0·5μl. diluted to 0·1 ml., were atomized in 3·5 sec. The flame photometer was modified so as to increase its sensitivity and speed of operation. Thus, the photo-multiplier was operated with very high dynode voltages to increase the current. The circuit was also changed so that this current charged a condenser, its discharge current through selected known resistors being then read directly on a sensitive galvanometer or on a recorder. Instantaneous readings could, therefore, be taken and less material was required. The instrument had an overall amplification of about 50 million with semi-automatic operation. Graphs were constructed using standard amounts of elements against times of discharge to known arbitrary levels fixed on the recorder. From these graphs unknowns were readily calculable. Improved in this way the equipment proved to be about 1,000 times more sensitive than the original Beckman instrument and it was possible to detect a ten-billionth (1×10^{-12}) gram of sodium.

Investigation of the hyaluronic acid content of the labyrinthine fluids was carried out using the technique of absorption spectro-photometry. The approach was an indirect one, and the concentration was established not of the acid itself, but of one of its derivatives, hexosamine. For this a new colorimetric procedure was developed. The hexosamine was separated from other sugars by shaking with a few grains of an ion exchange resin. It was then de-aminated to produce a compound which reacts with pyrrole to give a yellow colour. The absorption of this yellow colour was measured by absorption spectrophotometry with

the use of special ultra-micro-capillary cells. These cells hold only 0·1 ml. of liquid and possess a 5 cm. light path, and are possibly the most sensitive absorption cells yet used.

Results

The results of previous analyses of the cerebrospinal and labyrinthine fluids of the cat and guinea-pig are shown in Table I. Our own results are shown in Tables II, III. The findings are noteworthy in two respects.

Table I

Analysis of Cerebrospinal and Labyrinthine Fluids of the Cat and Guinea-pig: Results of Previous Investigations

Animal	Properties and constituents	Cerebro-spinal fluid	Perilymph	Endolymph	Reference
Cat	Osmotic pressure (g.NaCl/100g.H_2O)	1·017	1·046	1·058	Aldred *et al.* (1940)
	Index of refraction $\left(n_D^{22°C}\right)$	1·33435	1·33495	1·33455	Ledoux (1941)

Sodium (mEq./l.)	140 (4)	150 (12)	148 (12)	26 (8)
Potassium (mEq.l.)	4·5 (4)	4·0 (12)	5·0 (12)	142·0 (9)
Chloride (mEq./l.)	—	122 (9)	120 (9)	110 (3)
Protein (mg./100 g.)	—	20 (6)	75 (6)	25 (6)
Non-protein nitrogen (mg./100 g.)	—	21 (6)	20 (6)	21·5 (6)

B. Cat

Constituent	Serum	Cerebro-spinal fluid	Perilymph	Cochlear endolymph
Sodium (mEq./l.)	155 (12)	162 (12)	164 (12)	66 (12)*
Potassium (mEq./l.)	6·7 (12)	5·9 (12)	6·0 (12)	117·0 (12)*
Chloride (mEq./l.)	—	150 (4)	150 (4)	—
Protein (mg./100 g.)	—	25 (5)	142 (5)	—
Non-protein nitrogen (mg./100 g.)	—	20 (5)	21 (5)	—

*In many of these samples the Na+ and K+ concentrations suggested contamination with perilymph. Three samples, however, showed the high values for K given in the table. The bracketed figure appended to each entry represents the total number of observations upon which it is based.

Table III

Analysis of Cerebrospinal and Labyrinthine Fluids of the Guinea-pig: Present Investigations

Constituent	Cerebro-spinal Fluid	Perilymph	Endolymph
Calcium (mEq./l.)	3·0 ± 0·2	3·0 ± 0·2	3·0 ± 0·2
Magnesium (mEq./l.)	2·0 ± 0·2	2·0 ± 0·2	0·9 ± 0·2
Hexosamine (mg./100 ml.)		5–8	5–8

(1) Utricular endolymph has a high potassium concentration and a low sodium concentration compared with perilymph or cerebrospinal fluid.

(2) The protein level in perilymph is higher than that of the other fluids. In other respects, however, the composition of the perilymph approximates closely to that of the C.S.F.

These results provide strong evidence of a wide difference between endolymph and perilymph. They indicate, too, that perilymph is mainly derived from cerebrospinal fluid.

As shown in Table III, we have found that the calcium content of endolymph in the guinea-pig was similar to that of cerebrospinal fluid and perilymph, having a value of

3·0 mEq./l. A magnesium content of 2·0 ± 0·2 mEq./l. was found for perilymph and cerebrospinal fluid, but 0·9 ± 0·2 eq./l. only in utricular endolymph. This is only half the value found in the other fluids. This result once again adds emphasis to the fact that utricular endolymph, at least of the guinea-pig, is very different from the perilymph.

In 1953, Jensen and Vilstrup isolated hyaluronic acid from the labyrinths of *Acanthias vulgaris*. By pooling the contents of 300 of their labyrinths, the largest known, these workers obtained very large quantities of endolymph. This was found to be viscous, possessing a relative viscosity of 24·24, with a hyaluronic acid content of 73 mg./100 ml. Accordingly, they attributed the high viscosity to the presence of this large amount of hyaluronic acid in its polymeric form. It was thought that if such high viscosity was also found for the endolymph of the higher vertebrates it would be an important factor in the rapid damping of the fluid movements in the semi-circular canals. Further, the dilatation of the endolymphatic sacs observed in patients suffering from Ménière's disease might well be an osmotic consequence of the depolymerization of hyaluronic acid. Our own examination of the perilymph and utricular endolymph of the guinea-pig have revealed a hexosamine content of 5–8 mg./100 ml. If all this had existed as hyaluronic acid the concentration of the acid in both fluids would only be 10–15 mg./100 ml. which is considerably less than the 73 mg./100 ml. found by Vilstrup using elasmobranchi. It does not seem likely that the viscosity of the mammalian endolymph is much higher than that of perilymph, or C.S.F., whilst its small hyaluronic acid content is not likely to provide any explanation of the endolymphatic distension found in Ménière's disease. In addition, the samples of perilymph and endolymph examined, as judged by their behaviour in a capillary tube, exhibited no significant degree of viscosity.

To summarize the results for Na^+, K^+, Ca^{++}, Mg^{++}: these confirm the very special nature of the endolymph. Whilst the high K^+ low Na^+ content is characteristic of intracellular fluid, the Mg^{++} content is not, being, in fact, slightly lower than that of extracellular fluid.

Otologists will naturally wish to know how the remarkable chemical characteristics of the endolymph will help in the understanding of the mechanism of Ménière's disease. With regard to its metabolic function, the significance of its unusual electrolyte pattern is far from clear. Moreover, it is difficult to reconcile the high potassium content of endolymph with the positive DC potential of the scala media demonstrated by Békésy (1952). Here the electrical polarity is the reverse of that found for muscle and nerve, in which a negative potential is associated with the side of the membrane having a high K concentration. It is, however, possible that this positive potential provides the basis of the electric triggering of the response to sound of the hair cells of Corti's organ.

Regarding the formation of endolymph, the stria vascularis may well play the part already attributed to it of secretory action. The maintenance, however, of constant ionic levels on either side of Reissner's membrane probably involves a biochemical mechanism known as "active transport". Here an accumulation of K^+ and extrusion of Na^+ takes place against concentration gradients. This may maintain a high K^+ level, without any difference in osmotic pressure on the two sides of Reissner's membrane.

This osmotic pressure is intimately coupled with water balance. The breakdown of this mechanism would probably tend to disturb this water balance with resulting distension of the endolymph system. It is hoped that further analytical work will bring us nearer to a fuller understanding of these mechanisms, and so to the rational treatment of Ménière's disease.

Acknowledgments

Our thanks are due to the Editor of the *British Medical Bulletin* (Citron *et al.*, 1956) for kind permission to reproduce Figs. 1 and 2, and Tables I and II.

Section of Otology with Section of Laryngology

JOINT SUMMER MEETING HELD AT THE UNIVERSITY OF BRISTOL

OTOLOGICAL SESSION

Chairman—PHILIP J. JORY, D.S.O., F.R.C.S. (President of the Section of Otology)

June 27, 1957]

A DISCUSSION was held on **Plastic Surgery of the Middle Ear.** The following opening papers were read: **Myringoplasty,** by Mr. STUART MAWSON; **Plastic Middle Ear Operations with Particular Attention to the Cavum Minor Technique,** by Dr. NILS G. RICHTNER (Stockholm); **Some Problems of Tympanoplasty,** by Mr. P. H. BEALES.

Mr. F. MCGUCKIN, Mr. R. L. FLETT, Mr. GAVIN LIVINGSTONE, Mr. I. B. THORBURN, Mr. I. SIMSON HALL, Mr. E. G. COLLINS, Mr. W. S. MCKENZIE, Mr. J. F. O. MITCHELL, Mr. E. H. RAINER and Mr. S. W. ALLINSON took part in the subsequent discussion.

LARYNGOLOGICAL SESSION

Chairman—J. ANGELL JAMES, M.D., M.R.C.P., F.R.C.S. (President of the Section of Laryngology)

[*June* 28, 1957]

A PAPER on **The Histochemistry of the Nasal Respiratory Mucosa** was read by Dr. MILES TAYLOR and was discussed by Dr. A. YOUNG, Professor F. C. ORMEROD and Mr. A. MACKENZIE ROSS.

Professor J. M. YOFFEY, read a paper entitled **The Passage of Fluid and Other Substances through the Nasal Mucosa,** which was illustrated by a film; it was discussed by Mr. R. G. MACBETH.

A Discussion on **Management of Post-cricoid Carcinoma** was opened by Professor F. C. ORMEROD, Mr. RONALD W. RAVEN and Dr. M. LEDERMAN. Dr. R. C. TUDWAY, Dr. SYDNEY CURWEN, Mr. H. D. FAIRMAN, Mr. I. SIMSON HALL, Mr. R. G. MACBETH, Mr. A. J. MOFFETT, Mr. R. D. OWEN, Mr. KENNETH G. MALCOMSON, Mr. GEORGE SEDD, Mr. R. S. LEWIS and Mr. J. A. SEYMOUR-JONES took part in the subsequent discussion.

[*June* 29, 1957]

A CLINICAL MEETING, arranged by the South Western Laryngological Association, was held at the Bristol General Hospital. A film on **Submucous Resection and Rhinoplasty** was shown by Dr. BEN WITHERS (Houston, Texas).

These meetings will be reported in the *Journal of Laryngology.*

BOOK REVIEWS

The Essentials of Modern Surgery. Edited by R. M. Handfield-Jones, M.C., M.S., F.R.C.S., and Sir Arthur E. Porritt, K.C.M.G., C.B.E., M.A., M.Ch., F.R.C.S. 5th edition. (Pp. xv+1276; illustrated. 75s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

The greatest compliment which can be paid to a textbook is that it should be bought by successive generations of students and that further editions should be demanded from time to time. It is eighteen years since your reviewer was first sent a copy of this book and this is the fifth edition; an eloquent tribute to the excellence of the work.

This textbook is the result of multiple authorship and the editors have not put their contributors in strait jackets, but rather left them to go their several ways. The result is surprisingly homogeneous, but it has the advantage of presenting the work in a variety of styles which tends rather to hold the interest. The actual arrangement also has some unusual features. For example, the appendix still has a whole chapter to itself and this is quite right since diseases of this organ form such a large part of surgical practice. This particular chapter, written by Julian Taylor, still remains one of the most outstanding in the book. There is an excellent account of venereal disease, which is a subject rather neglected in modern textbooks. On the whole there is a nice balance held between the various sections of the book.

Criticism, which is only about details, arises chiefly because of over-simplification in some parts which is due to a laudable desire to keep the text as brief as possible. For example, it is not generally held that Dercum's disease is a manifestation of hypothyroidism. Seminoma is not separated from teratoma in the prognosis of tumours of the testicle; there is no mention of the stripping operation for varicose veins; subacute thyroiditis is not usually accompanied by a raised polymorphonuclear cell count; surely thiouracil is not still on trial and finally the description of the treatment of Hirschsprung's disease by removing the affected colon is rather ambiguous.

However, such points as the above are only minor criticisms of what is an excellent text to be put in the undergraduate's hands for learning his surgery. He would be well advised to keep it on his shelves for reference after qualifying. The printing is excellent and the paper of such good quality that the book is a little heavy for the binding in which it is produced. The illustrations are well chosen, numerous and of high quality. The whole format of the book is most attractive and Messrs. Livingstone have designed a cover which is in keeping with a number of their more recent publications.

A Text-Book of Psychiatry for Students and Practitioners. By Sir David Henderson, M.D.Edin., F.R.F.P.S.Glas., F.R.C.P.Ed. and Lond., and the late R. D. Gillespie with the assistance of Ivor R. C. Batchelor, M.B., F.R.C.P.Ed., D.P.M. 8th edit. (Pp. xii +746. 35s.) London, New York, Toronto: Oxford University Press. 1956.

Those who, like your reviewer, first read Henderson and Gillespie at a time when there was no comparable English work to challenge it, can only receive this the eighth edition with affection and pleasure. With this edition Sir David Henderson has a new collaborator in Dr. Ivor R. C. Batchelor who, in addition to other contributions, has rewritten the chapter on epilepsy which is now helpful and up to date. The sections on ætiology and on physical treatment have also been revised and rearranged.

Paranoid schizophrenia and paraphrenia have been discarded, and "paranoid state" has come to replace them, mainly on the grounds that paranoid states develop later, are not usually associated with deterioration, and—less acceptably—"have a strong affective component—which may be responsive to treatment". While the authors believe this simplification long overdue, it is doubtful whether everyone will regard it as helpful. Both paranoid schizophrenia and paraphrenia are well known and easily recognized entities and psychiatrists will probably continue to use these names in referring to them. It is useful to stress that paranoid symptoms can colour *any* psychosis including schizophrenia but the abolition of two diseases is perhaps a little drastic as a method of doing so.

By leaving much of a well-written book unaltered over a considerable period of time, the psychoses can be seen in their historical setting, and the psychoanalytic view of psychopathology is still set out in detail. While this at the best has an old-world look, and at the worst seems frankly bizarre, it is still desirable for the cultivated psychiatrist to know what McCurdy thought in 1925, not least perhaps because undergraduate medical students sometimes come to their hospital work fairly well informed on such matters.

If one criticism may be ventured, it is that the legal section should be revised—drastically. Here old-world phraseology cannot be excused on any grounds. Thus (page 683) there are

no longer any paupers or lunatics at large in this country. This is not so much due to redistribution of income as to the fact that Parliament abolished them in section 20 of the Mental Treatment Act of 1930. It should be noted too (page 683) that the Reception Order on Petition applies to non-private as well as private patients since the National Health Service Act of 1946.

These are small criticisms in a large work which can be cordially recommended as upholding the great tradition of its predecessors.

Psychosynthesis. A "Project for a Scientific Psychology". By John Pardey Crawford, M.D.Lond., M.R.C.P.Lond., D.P.M.Lond. (Pp. 104; 2 illustrations. 21s.) London: Ash & Co. Ltd. 1956.

This is a most interesting little book intended, it seems, to place related physical and psychological phenomena into relation with one another to form a "Gestalt" or integrated whole. In considerable measure Dr. Crawford has succeeded, and where he has failed it is because of the limitations of our knowledge and the inherent difficulty of the subject matter. The author's knowledge of the literature is extensive and the references are here available though not readily, for although they are listed at the end of the book, there is no index.

The survey is wide and must inevitably be greatly condensed in 92 pages, so that it is not an easy book to read. Providing the reader knows his individual trees—and there are many of them, then this book will show him the wood. Perhaps it would be fair to say that the book will be a joy to senior registrars especially in psychiatry, but will present difficulties to senior consultants both in psychiatry and neurology. Nevertheless, there are few who will fail to profit in some measure by reading it, and the book deserves to be successful. Some expansion in a future edition would make it easier for his readers to share the fruitful holistic standpoint of the author.

Anatomie Chirurgicale des Hernies de l'Aine. By Henri Fruchaud. (Pp. 488; illustrated.) Paris: G. Doin & Cie. 1956.

Le Traitement Chirurgical des Hernies de l'Aine chez l'Adulte. By Henri Fruchaud. (Pp. 386; illustrated.) Paris: G. Doin & Cie. 1956.

Henri Fruchaud was displaced from his surgical chair at the School of Medicine of Angers by Hitler's invasion of France. He served as surgeon to the Free French forces in the Mediterranean theatre of war, and at its close was appointed surgeon to the hospital of Saint-Louis at Aleppo. These two books deal with herniæ of the groin, a group that includes oblique and direct inguinal hernia, femoral hernia, and pre-vascular hernia (Nareth's hernia.)

Both volumes are encyclopædic in their completeness, and unique among books dealing with hernia in the number and technical excellence of their illustrations. These illustrations are so numerous and so beautiful that any reader, even though his knowledge of French gets no farther than "la plume de ma tante" stage, can follow them and learn from them. The volume on surgical anatomy starts with a chapter on the history of inguinal anatomy, introducing drawings by the ancient anatomists from Leonardo da Vinci to Astley Cooper, and concludes with one on the comparative anatomy of the groin in the anthropoids and in quadrupeds. The greater part is taken up with a detailed description of every structure in the inguinal region, illustrated by figures that in their accuracy of detail and their beauty of craftsmanship could hardly be excelled. The many variations in these structures, in the arrangement of the external oblique aponeurosis and the inguinal ligament, in the origins of the lower fibres of the internal oblique and transversalis, in the composition and insertion of the conjoined tendon, and the great variability in the strength and attachment of the transversalis fascia, are described and illustrated.

The second volume is equally well-produced. Dr. Fruchaud describes the well-known standard operations for the repair of hernia, and their modifications. Considerable space is devoted to the operation of repair performed at Aleppo, one that deals with the inguinal canal with a combination of French delicacy and Oriental ruthlessness. One can imagine the Professor, as he washes up for a hernia operation at Aleppo, saying to his Syrian House Surgeon:

> "Ah love! Could thou and I with fate conspire
> To grasp this sorry scheme of things entire:
> Would we not shatter it to bits,—and then
> Remould it nearer to the heart's desire."

Then he puts on his gloves and proceeds to do exactly that, to the astonishment and alarm of the English reader.

These two volumes are admirably produced, and they will remain standard works of reference on the surgery, and still more on the anatomy, of the inguinal region.

Section of Pædiatrics

President—D. V. HUBBLE, M.D., F.R.C.P.

[*February* 22, 1957]

MEETING AT QUEEN CHARLOTTE'S MATERNITY HOSPITAL, LONDON

DEMONSTRATIONS

I.—**Radiological Exhibit** by E. ROHAN WILLIAMS, F.R.C.P., F.F.R., and Miss A. E. MADDEN, M.S.R., on **Radiology in Respiratory Distress in the Newborn Infant.**

Approximately 80 neonatal chest radiographs were shown illustrating the following conditions:

(1) Anectasis (primary atelectasis).
(2) Hyaline membranes with secondary atelectasis (both with recovery and proven at post mortem).
(3) Migrating atelectasis.
(4) Liquor and meconium aspiration pneumonia.
(5) Intrapulmonary hæmorrhage.
(6) Staphylococcal pneumonia and abscess formation.

II.—**Human Milk Bureau:** Sister RIGGALL discussed details of the work carried out.

III.—**Pathological:** To show the normal bacterial flora of the umbilical cord and how it is affected by various applications, by R. M. CALMAN, M.B., Ch.B., and the clinical staff.

IV.—**Social Service:** Socially and physically unacceptable babies born in and out of wedlock were discussed by Miss NOBLE, A.M.I.A. (Head Almoner), and Miss GROOMBRIDGE, A.M.I.A.

V.—**Breast Feeding:** Investigation to show the value of special ante-natal and post-natal supervision. By Sister FAREBROTHER.

VI.—**Morbid Anatomy:** Causes of neonatal death with special reference to the respiratory system; development of neonatal lung; atelectasis and hyaline membrane formation in the neonatal lung and in the experimental animal; and demonstration of naked eye and histological specimens of various pathological conditions affecting the neonatal lung. By A. E. CLAIREAUX, F.R.C.P.

CLINICAL DEMONSTRATION

Cases 1–6 are cases with jaundice as a feature. In none were Rhesus antibodies concerned. Two were given exchange transfusions because the hyperbilirubinæmia seemed to be approaching a level likely to produce kernicterus.

I. Galactosæmia with Hyperbilirubinæmia Treated by Exchange Transfusion.—Dr. A. P. NORMAN.

Patricia K. (A.19411), female.

Born 21.6.55, a spontaneous vertex delivery at 39 weeks. Weighing 5 lb. 12¾ oz. she made good general progress until the age of 6 days when she became lethargic and refused all feeds. Jaundice, first noticed on the third day, had become marked (serum bilirubin 19 mg.%), the liver was enlarged one fingerbreadth and firm. At 8 days her condition remained poor with frequent vomiting. Galactose was demonstrated in the urine and feeds were changed to Galactomin. (Galactomin (1955) contained a proportion of lactose and is not the same preparation now marketed under this name.)

The baby's condition did not improve, the jaundice increased and an exchange transfusion of 450 c.cm. blood was given. Liver function tests showed thymol turbidity 1 unit, alkaline phosphatase 10 units, pseudocholinesterase 30 units (normally over 70 units).

Following transfusion the jaundice decreased. The baby's further progress was complicated by oral thrush at 11 days, a urinary infection at 25 days and several further febrile upsets for which no clear reason could be found.

At 62 days a galactose tolerance test (2·6 grams given) gave an abnormal result. Plasma electrophoresis (Dr. C. Forsyth) showed agammaglobulinæmia and following this two injections of gammaglobulin were given at weekly intervals. As progress was slow a special feed of groats, sugar and egg was tried. This was followed by vomiting and pyrexia and at 69 days feeds were changed to glucose and Hartman's solution. Chest X-ray showed a right mid-zone opacity.

Real progress began on the same solution with the addition of groats and sugar from the 87th day and the diet was gradually enlarged with liver and vegetables in the routine way. The baby was discharged at 102 days, clinically well, with a slightly enlarged liver, weight 8 lb.

At 4½ months, weight 10 lb. 11½ oz., she was doing really well. Further progress is reported as satisfactory, but she is thought to be somewhat slow in development at 20 months.

Family history.—The mother has had three previous pregnancies: The first child (1949) is now alive and well; the second (1950) weighing 5 lb. 9 oz. died with jaundice at 4 weeks and the third (1952) weighing 5 lb. 8 oz. died with jaundice at 6 weeks. *Sections of the liver* of one of these (Dr. M. Bodian): There is diffuse fine portal fibrosis with proliferation of portal bile ducts and dilatation of intralobular bile ducts, many containing bile. The ducts are lined by cuboidal epithelium, a change which has been noted in cases of "metabolic hepatitis," including galactosæmia.

II. Galactosæmia.—Dr. A. WHITE FRANKLIN and Dr. ISOBEL SMITH.

Baby L. (A.24111), female, was born 13.12.56, at term, weight 8 lb. 1 oz., length 20½ in. Pregnancy and delivery were normal, and condition after birth satisfactory. Feeding was difficult, thought to be due to the mother's very small nipples and large breasts.

The baby lost 8 oz. in four days and gained on the fifth day. Thereafter breast feeds were taken reluctantly, the baby was feeble and uninterested and weight dropped steeply to 7 lb. on the seventh day. The liver was slightly enlarged. On the eleventh day weight was stationary, tube feeding was started, slight jaundice developed and examination showed a large firm liver. On the twelfth day the condition remained poor, jaundice was more marked, liver firm and extended to umbilicus. Urine: Benedict's reaction positive, "Tes-tape" glucose test negative, methylamine test for lactose negative. Chromatography demonstrated a considerable amount of galactose. Blood: Group A, Rh positive, Coombs negative; total bile pigments 7·9 mg.% (direct 4·5 mg.).

Family history.—Mother weighs 20 stones, and comes of a very obese family. (Antenatal W.R. negative.) Father alive and well, as are the two previous children, born 1953 (weight 9 lb. 1 oz.) and 1955 (weight 7 lb. 6 oz.) both having been successfully breast fed.

Progress.—Improvement in feeding followed Galactomin, weight curve rose and at 4 weeks she weighed 8 lb. 2 oz. The liver was smaller. There has been no ophthalmic abnormality. A breast abscess developed which responded to oral Terramycin and drainage (*Staph. aureus*). At 7 weeks weight 8 lb. 12 oz. The liver was just palpable, and progress was normal on Galactomin feeding. One week later she started to cough, and oral thrush was noted. Despite treatment her condition deteriorated and she was admitted to St. Bartholomew's Hospital, aged 8 weeks, with thrush in the mouth and on the buttocks, conjunctivitis and acute respiratory infection; weight 8 lb. 15 oz. Urine contained no reducing substance but some excess of amino acids. Plasma electrophoresis

showed almost absent gamma globulin. Galactomin feeding was continued and there was some improvement, despite vomiting of large tough curds. However, a change to lactose-free synthetic "milk" mixture was followed by a gain of 1 lb. in one week with no further vomiting.

Family study.—Galactose tolerance curves of both parents are normal.

III. **Galactosæmia.**—Dr. A. WHITE FRANKLIN.

Susan D. (19.1.57), female, was born at full-term by spontaneous vertex delivery; weight 6 lb. 2 oz. She was breast fed but owing to the mother's sore nipples was fed expressed breast milk after two days. Weight dropped to 5 lb. 11 oz. on the third day and began to rise, reaching 5 lb. 12 oz. on the fifth day. During the next two days the baby began to refuse feeds and to lose weight again.

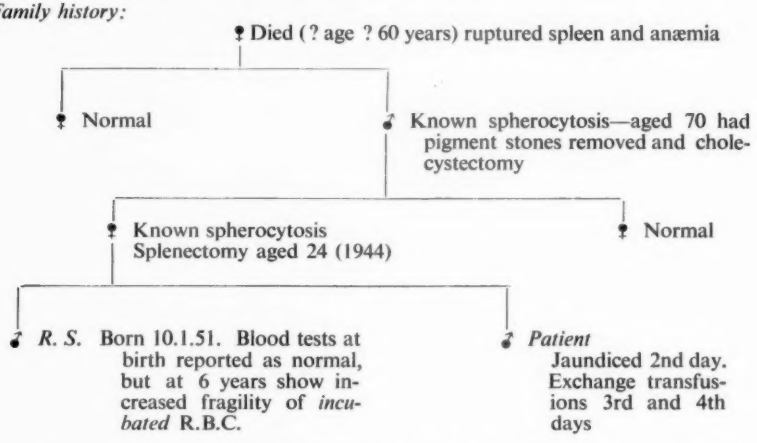
At 8 days she became jaundiced and lethargic, vomiting feeds; she commenced oral Terramycin as a case of possible infection. After improving on the 9th day, she deteriorated with more marked jaundice, vomiting food and a trace of blood. She was transferred at 10 days to St. Bartholomew's Hospital where she appeared jaundiced, ill, with a liver enlarged to the umbilicus and firm. Weight 5 lb. 4 oz. Blood: Hb 146%. Coombs negative, thymol turbidity 4·5 units, serum alkaline phosphatase 48 K-A units, serum bilirubin 5·9 mg.% (direct positive), pseudocholinesterase 37 units, W.R. negative. Urine contains galactose 5 g.% and excess of amino acids both in amount and number.

On the 13th day she commenced Galactomin with a weight gain two days later, reduction in size and firmness of liver, disappearance of galactose and excess amino acids from the urine. At three weeks there were improved liver function tests, thymol turbidity 1 unit, serum alkaline phosphatase 17 K-A units, serum bilirubin 0·4 mg.%: but the pseudocholinesterase level remained abnormal at 46 units.

On the 26th day she collapsed acutely ill, with refusal of all feeds, diarrhœa and vomiting, weight 5 lb. 14 oz. It was then appreciated that as well as lactose in small amounts in Galactomin, she had for seven days been taking one ascorbic acid tablet daily containing 65 mg. of lactose. A transfusion of 90 c.c. of fresh blood was given by drip hoping to introduce by this means the missing transferase; a course of tetracycline was started and one injection given of gammaglobulin, which had been noted as present but decreased in the baby's serum. She then began the special lactose-free diet with extra calcium as gluconate (0·45 gram in each feed) and Abidec 0·6 c.c. daily, to provide routine vitamins and any special vitamin B needed because of the absence of lactose and galactose from the diet. Weight gain and general progress have been excellent on this new regimen. Weight at 5 weeks 6 lb. 12 oz.

Family study.—Mother has a normal galactose tolerance curve. Father has a galactose index of 299 (normal range 0–160).

Discussion (Cases 1, 2 and 3):



The three cases of galactosæmia come respectively from Weymouth, London and Welwyn Garden City. The first was expected owing to the death of 2 out of 3 siblings from liver disease at 4 and 6 weeks of age. In all progress was normal until the sixth day, from which time loss of appetite and loss of weight were followed by enlargement of the liver and jaundice. Pseudocholinesterase levels in 2 and 3 were low and the first 2 cases where there was a tendency to rather frequent infection have hypogammaglobulinæmia which may be physiological. All responded to diminished lactose feeding, although case 1 was very slow to gain. In Cases 2 and 3 the progress on modern Galactomin was not maintained and there was much vomiting of large tough curds. Both are now on a special lactose-free mixture made of egg, cereal, arachis oil fortified with calcium gluconate and extra vitamin B.

IV. **Congenital Familial Spherocytosis with Neonatal Hyperbilirubinaemia Treated by Exchange Transfusion.**—Dr. I. SMITH and Dr. A. WHITE FRANKLIN.

Philip S. (A.22384), male. Born 18.10.56, weighing 7 lb. 1 oz., by spontaneous vertex delivery, after 38 weeks normal pregnancy. Mother is Rhesus negative, without antibodies. Condition at birth was normal, without jaundice, anæmia or splenomegaly. Blood Group A, Rhesus positive, Coombs negative. Jaundice, first noted on second day, increased and became severe by the fourth day. Total pigment was 16·8 mg.% at 36 hours and rose at 60 hours to 26·4 mg. (direct only 1·0 mg.). At this time Hb 115% (fœtal Hb 66%); red cell fragility markedly increased, commenced at 0·52% and complete at 0·4%.

saline; spherocytosis marked. The increasing hyperbilirubinæmia led to exchange transfusion at 65 hours. (550 c.c. given and 560 c.c. removed.) Although at the end total pigment had fallen to 13·7 mg., eighteen hours later it had risen to 23·8 mg. (direct 1·3 mg.). A second exchange transfusion was given (570 c.c. given, and 555 c.c. removed). Thereafter jaundice gradually faded and he was discharged home on the 13th day, weighing 7 lb. 3 oz., Hb 103%. The spleen was palpably enlarged.

Family history:

NOTE.—All affected members of this family have been noticeably fair: auburn-haired. All unaffected members dark-haired.

Progress.—Since discharge progress has been excellent and at 4 months he weighs 15 lb. Spleen tip palpable.

Case shows *anticipation* in a family affected by congenital spherocytosis with a risk of kernicterus in what is assumed to be the fourth generation. Following the exchange transfusions the red cell fragilities returned to normal. On the 112th day increased fragility was clearly established again (Dr. H. F. Brewer).

V.—Congenital Extra-hepatic Biliary Obstruction, Bile Peritonitis, Choledocho-duodenostomy.—Dr. A. WHITE FRANKLIN and Mr. R. S. CORBETT.

Carol G. (S.B.H. 353078), female, born 22.8.56, weighing 6 lb. 12 oz. Pregnancy and delivery normal.

Meconium was passed on the third day and normal curdy stools were reported thereafter. She had a poor appetite, vomited occasionally and failed to gain weight. On the 24th day she was transferred to hospital for observation. The stools were noticed to be formed and white (Fouchet's test negative). There was no jaundice, no enlargement of liver or spleen. As there was no progress and jaundice appeared on the 34th day she was transferred to St. Bartholomew's Hospital, aged 35 days. The abdomen was somewhat distended, shifting dullness was noted, liver and spleen were still not enlarged.

Bilirubin 2·5 mg% direct negative: pseudocholinesterase 60 units (Dr. H. Lehmann). During the next ten days the abdomen increased in girth. Paracentesis produced 150 c.c. of heavily bile-stained fluid. Six days later, aged 7 weeks, the baby collapsed, respirations were laboured, pulse 170. After restorative measures Mr. R. S. Corbett explored the abdomen removing much bile-stained ascitic fluid and fibrin clots. The liver appeared normal and not enlarged. A large bile-containing cavity was found under the right lobe. What was assumed to be a cyst of the bile duct was anastomosed to the duodenum.

The baby made excellent post-operative progress and after two days passed brownish stools. Stools are at times white but Fouchet's test is positive. Clinical progress has been slow but sure. Liver function tests before operation were normal, except for pseudocholinesterase, which has risen to normal since (107 units at 3½ months).

Liver biopsy section (Dr. A. G. Stansfield) showed evidence of obstruction, with gross distension of sinusoids, and no disorganization of liver architecture. Bile pigment is present in many of the Kupffer cells and there are bile thrombi in the dilated canaliculi. Glisson's capsule is thickened with some organizing exudate on the serous surface.

VI. **Intra-hepatic Calcification, Staphylococcal Liver Abscess, following ? Occult Umbilical Sepsis.**—Dr. A. WHITE FRANKLIN.

Peter F., born 22.1.54 at 41 weeks, by spontaneous vertex delivery, weighing 9 lb. 10 oz. He was breast fed for five days and then weaned to bottle. At six days temperature rose to 101° F. Thrush was present and some signs suggestive of pneumonia. He improved with Aureomycin and was discharged from Queen Charlotte's Hospital, aged 25 days, well and completely normal on physical examination. After five days he became jaundiced and was admitted to St. Bartholomew's Hospital with rapidly increasing abdominal distension due to gross liver enlargement and splenomegaly. X-ray showed intrahepatic calcification, lungs were normal.

He ran a course of intermittent febrile attacks controlled to a limited extent by oral Terramycin, and failed to make real progress until aged 3 months. A diagnosis of portal pylephlebitis, probably secondary to occult umbilical sepsis, was made but no action taken and he went home aged 5 months weighing 13 lb. He became ill again at 10 months and eventually developed a sinus from the umbilicus from which bile and pus containing *Staph. pyogenes* were discharged. At 13 months a laparotomy (Mr. J. P. Hosford) revealed a thick-walled track from the umbilicus to an abscess cavity containing bile-stained pus between the lobes of the liver. He slowly recovered after drainage and has since made excellent progress. The calcification has been shown to be intrahepatic by tomography and remains visible at 3 years of age.

The Place of the Pædiatrician in the Maternity Hospital

By ALFRED WHITE FRANKLIN, M.B., F.R.C.P.

FIFTEEN years ago when this Section visited Cell Barnes Hospital, St. Albans, I read a paper on the place of the pædiatrician in the Emergency Medical Service. Among his functions was the supervision of newborn babies in Sector hospitals and evacuated maternity homes. Since those days the National Health Service has disseminated widely through the country physicians informed about the newborn. This same period has seen the recognition by almost all concerned of the logic of allowing, or even encouraging, these pædiatricians to take part in the care of the newborn. Because evolution is always a painful process, there have been problems and difficulties not yet all overcome. Similar problems have in the past surrounded the evolution of obstetrics out of midwifery, which in England has, so far, taken over 300 years.

It was the Chamberlen family and especially Dr. Peter, the elder, by his invention of the fenestrated forceps at the turn of the sixteenth to seventeenth centuries, who really brought the man-midwife seriously into obstetrics by way of the abnormal case. The Chamberlens were on the side of the midwives or at least of good midwives and on several occasions during the seventeeth century attempted to incorporate and make a society of midwives against successful official professional opposition.

In the course of time the man-midwife or midman has displaced the midwife to an assistant position. The midwife had always had responsiblity for the care of the newborn. Did the man-midwife displace her in this? If he did, it was subluxation rather than dislocation. Many obstetricians became knowledgeable about newborn babies and included sections on their care in health and disease in books and pamphlets. Pædiatrics owes much to these pioneers. Sir James Y. Simpson pleaded one hundred years ago for autopsies in all cases of neonatal deaths—a plea only now beginning to be answered.

This recent dawn of pædiatrics has drawn in the pædiatrician, first for the abnormal or sick baby. Here he was displacing both midman and midwife, a displacement not always easy and never complete. Now the pædiatrician is invited to concern himself with the whole problem of the newborn, normal and abnormal; but, it must be stressed that everything depends on the condition of the baby when the obstetrician hands it over.

One result of the change, making progress possible, has been to clear the doctor's mind of all concepts of disease and treatment, based on studies of the mature human. The child is not the human in little, nor the baby the little child. The neonate in its anatomy, its physiology, its pathology is a peculiar person. The metabolism of bilirubin in the newborn provides one clear example, as does the anatomy of the developing lung in prematures and many of the special histological changes.

I have purposely taken the title "the place of the pædiatrician", rather than "the place of pædiatrics", because pædiatrics has been practised in association with midwifery from the

earliest times. Someone has been at hand to tie the cord, to resuscitate the infant, to help decide whether to expose the abnormal infant on the nearest mountain top and—I suspect—to dogmatize about feeding. What is new is the idea that a specialist in diseases of children might be the best person to advise on the management of the newborn and on the treatment of disorder and disease during the mother's puerperium. Queen Charlotte's Hospital was founded in 1739. In 1929, after 190 years, Dr. Eric Pritchard was appointed its first pædiatrician, followed from 1936–50 by Professor Alan Moncrieff. These men and their successors took charge of pædiatrics but they did not take charge of all babies from the moment of birth. The obstetrician and the obstetric staff must dominate any obstetric hospital or department. Their duty is to help the greatest possible number of women to produce normal babies with the smallest possible risk and to launch them back into family life, well, happy, able to enjoy the feeding of and the caring for their babies, in a word—satisfied. The duty of the pædiatric staff as of all the other ancillary staff is to help the obstetrician to discharge this whole duty.

At present at Queen Charlotte's Hospital the functions of the pædiatric staff are:

(1) To advise in consultation with Matron and the nursing staff on the routine care and management of the babies, no change being made without the obstetricians' approval.

(2) To help in resuscitation in the labour ward in conjunction with the obstetrician and the resident anæsthetist.

(3) To take charge of all sick babies, including those suffering from birth trauma, respiratory disorders or infection.

(4) To advise about the management of all cases of congenital abnormality either physical or mental or both.

(5) To admit to the special nursery under direct care all premature babies of birth-weight 3½ lb. or less, or over if presenting a difficulty.

(6) To examine all babies of unmarried mothers before discharge.

(7) To be closely concerned with the management of babies where blood incompatibility is suspected or known and of babies of diabetic mothers.

(8) To examine all babies born to mothers with previous unexplained fruitless pregnancy or congenitally diseased or defective babies, or after fœtal exposure to adverse influences such as rubella, vaccinia or heavy irradiation.

(9) To advise about feeding problems; here specially trained nursery staff are most useful.

(10) To conduct an infant welfare clinic in conjunction with local authorities[1] and a follow-up clinic for special cases, such as congenital heart disease or cerebral palsy following neonatal difficulty.

(11) To advise about antenatal problems.

(12) To teach the midwives and the residents.

(13) To keep records in such a way as to allow of clinical research into the progress of special groups of neonates.

(14) To initiate or participate in laboratory research into normal and abnormal conditions.

In these activities the pædiatrician works with all the other hospital services and comes in contact with the local authority service outside.

Perhaps the pædiatrician's main contribution to the philosophy of a maternity hospital comes from his absolute need, which he shares with the almoners' department, to view the baby in the context of the parents and family. Never for him can the mechanics of delivery outweigh the human factor.

The conduct of a case of hæmolytic disease gives a good illustration of the team at work, with the whole staff represented. The authority given to the obstetrician to try to time the delivery demands from him in return a sense of responsibility towards the rest of his team.

In an advertisement for a pædiatrician for newborn work certain qualities are necessary—tact and discretion, to be able to work in a team, great patience and humility. He ought to be a source of knowledge, and if he is, he ought to be a well rather than a fountain.

[1]In 1917 a Physician was appointed to an infant consulting centre, quite early in this field.

A Historical Note on Queen Charlotte's Maternity Hospital and its Pædiatricians

By L. E. TURNER, F.H.A.

RESEARCH into old records has shown that Queen Charlotte's Maternity Hospital originated in 1739 when Sir Richard Manningham founded a hospital in a seventeen-roomed house in Jermyn Street, known as The General Lying-In Hospital. Its name was changed in 1810, when Queen Charlotte became its Patron, to The Queen's Lying-In Hospital, and after her death the title of Queen Charlotte's Lying-In Hospital was assumed. A Royal Charter of Incorporation was granted in 1885 and when this was amended in 1924, the present name came into use.

The following extracts from the Minutes of meetings of the Committee of Management tell the story of the pædiatricians:

November 21, 1916: "The Sub-Committee reported that after conferring with the medical staff they recommended that an Infant Consultation Centre be established at the new out-patient department of the hospital and that a Physician be appointed to take charge of it, that the qualifications be the same as those for the Physician to the ante-natal department, that in the first place attendance be required on one afternoon weekly at 2.30 and that an honorarium be paid if necessary which may be from £30 to £50 per annum."

January 16, 1917: "A report was received from the visitors and medical staff on the appointment of a Physician to the Infant Consultation Centre. They had considered the applications for the post and unanimously recommended the appointment of Miss M. G. Thackrah."

Record of Attendances at the Infant Consultation Centre

1917 (9 months)	265	new patients—attendances were not recorded for these three years
1918	171	
1919	237	
1920	1,764	
1921	2,324	
1922	2,359	
1923	2,546	
1924	2,693	
1925	3,667	
1926	3,483	
1927	4,288	

Record of Attendances at the Infant Consultation Centre (contd.)

1928	4,546
1929	3,721
1930	3,964
1931	4,008
1932	4,493
1933	4,132
1934	4,291
1935	4,408
1936	2,949
1937	2,592
1938	2,465

The records for succeeding years are not available.

Dr. Thackrah resigned in 1931 and was succeeded by Dr. Gibbens, the Assistant Pædiatrician, who had been appointed to that office in 1930; thereafter the posts of Assistant Pædiatrician and Physician-in-Charge of the Infant Consultation Centre were combined.

November 18, 1929: "It was resolved that the proposal for the appointment of a Pædiatrician be approved and that the appointment be offered to Dr. Eric Pritchard. It was understood that Dr. Pritchard would be willing to accept the post for at least a year during which time he would organise the proposed department. It would be necessary to appoint an Assistant but it was decided to leave this to a later date."

NOTE.—Dr. John Hartley Gibbens was appointed Chief Assistant to the Pædiatrician in 1930. He resigned in 1933 whereupon Dr. Alan A. Moncrieff was appointed Assistant to the Pædiatrician with effect from May 1, 1933, succeeding Dr. E. Pritchard as Pædiatrician at the end of 1936 and resigning in November 1950.

Hæmolytic Disease of the Newborn

(I) **Serology.**—By JOHN MURRAY, M.D.

THE organization for the treatment of hæmolytic disease at Queen Charlotte's Hospital was discussed by *Dr. John Murray*, Director of the Bernhard Baron Research Laboratory. He said: At their first attendance blood is taken from all patients and tested for blood group Rh type and irregular antibodies. Rh-negative patients are retested for antibodies at

30 and 35 weeks. The finding of antibodies brings the patient into a special group with an additional separate system of notes and note filing. A wall chart, accessible to all staff, notes the expected date of delivery and all concerned are alerted when labour is expected or induced. This minimizes emergency arrangements and allows for the use of fresh blood for exchange transfusion. A consultant is in charge of the exchange, and has at least two other doctors in the hospital experienced in the method, together with some special members of nursing staff. The 24-hour pathological service enables bilirubin levels to be measured at 12-hourly intervals when necessary. Such arrangements are only possible with units dealing with a number of cases each year and probably 50 is the minimum for efficiency. The extra experience and skill of nurses and doctors in teaching hospitals counterbalance the usually small number of cases.

Control of bilirubin levels by exchange transfusion cuts down loss of life. In 1956 60 Rh-negative women with antibodies had 61 pregnancies. The 13 babies lost included 1 miscarriage, 3 abortions, 6 macerated hydropic stillbirths and 3 neonatal deaths. The present problem is to save intra-uterine loss by early induction at 35 or 36 weeks where it is expected that the baby will be seriously affected. Induction at 36 weeks should be considered when the mother has had a previous stillbirth or kernicteric or a baby requiring an exchange transfusion, or in any case where the antibody titre rises rapidly, even in a primigravida. Cæsarean section should be carried out at 32 weeks when the mother has had two intra-uterine deaths if the father is homozygous. Eight years' experience has shown only a 20% chance of survival when this type of case is allowed to go beyond 36 weeks. Efficient pædiatric treatment has lowered the neonatal death rate in prematures, especially of 4 lb. birth weight and over, and this is probably a normal weight for a healthy fœtus at 32 weeks.

If the baby is affected, the factors leading to the decision to exchange at birth are: a birth weight under 5½ lb., a cord blood Hb below 105%, a rise of bilirubin of 10 mg. per 100 ml. within twenty-four hours, and a history of previously badly affected infants. A repeat or late exchange is indicated when the bilirubin rises steeply and reaches or seems likely to reach 20 mg. per 100 ml., the levels being estimated twelve-hourly.

Early induction, which should be done by artificial rupture of the membranes, is only safe in units where bilirubin may be tested at regular intervals.

(2) Clinical Aspects of Exchange Transfusion.—By A. P. NORMAN, M.D., F.R.C.P.

MY intention is to describe briefly the technique of exchange transfusion used at Queen Charlotte's Hospital, to discuss the indications for secondary exchange, and to describe one case of special importance.

This hospital is fortunate in the interest which Dr. Murray and Dr. Lathe take in the problem of exchange transfusion, and the credit for our good results must go to them. My part is to co-ordinate and oversee the transfusion, although the exchange itself is usually carried out by the pædiatric resident, once the latter has the knack of doing it and has learnt our methods. These are more complicated because we gather information from individual samples of blood collected during the exchange.

We consider it important to use blood not more than twenty-four hours old. The blood is grouped and spun down, and plasma removed to give a hæmoglobin concentration of about 100%. We recommend that the blood be never heated, because of the risk of overheating, and we believe that it reaches an adequate temperature during preparation for the transfusion and during its passage along the tubing.

The baby is given oral digoxin, 0·125 mg. or 0·0625 mg. according to its weight, over or under 4½ lb., as soon as it is decided to carry out an exchange. We take a cord blood hæmoglobin of 105% as the critical level, but consider such other factors as the previous maternal history and antibody rise. Chloral 1 grain was given routinely until recently. The baby's legs are bandaged to a crucifix, the arms left free.

Blood is given in quantities of 10 c.c. at the rate of 10 c.c. per minute timed by a stop watch. In the hands of an expert 20 c.c. may be perfectly safe and I recently met a pædiatrician who completes his exchanges in thirty minutes by taking and giving 40 c.c. at a time. It would seem safer to transfer small rather than large amounts and 10 c.c. allows a good exchange. We aim at a total of 80 c.c. per pound. An advantage of a relatively slow and leisurely exchange is that time is given for the metabolism and excretion of possible harmful substances.

As a cause of death during transfusion, the laboratory staff suggested overloading of the heart and demonstrated gross errors in the estimates of blood given and removed, leading in general to overloading, though in one case to exsanguination.

Now, the blood is poured into a tall graduated container, against the level in which the estimated volume of blood given can be checked. The amount of blood removed is accurately weighed after each aspiration. The weighing machine used for this is an expensive instrument, but should be bought for big centres, while smaller ones could use a second tall measuring flask in which to put and measure the discarded blood. A cumulative error of 1–2 c.c. at each extraction of blood may reach a considerable size, so big that no one ever believes it until it is demonstrated.

We believe that because of careful attention to all points described, we no longer get deaths resulting from exchange transfusion, nor even real trouble. The use of the soft plastic catheter from Pharmaseal Laboratories, California, has made the operation both simpler and safer. This catheter is easy to insert and remains very comfortably in position without being held.

Apex beat rate and respiratory rate are recorded throughout the exchange by a *senior* nurse, who is responsible for reporting to the operator changes in the baby's condition. Formerly, we noticed that a slow rise in apex beat rate preceded the baby's collapse; not a sudden rise from crying, but a gradual increase of 20–30 beats per minute. The recording now is almost always flat, probably a beneficial effect due to the digitalisation. The venous (umbilical vein) pressure, always taken before the exchange begins, determines the size of the initial negative balance and the caution with which we proceed thereafter. There need be absolutely no urgency in the exchange and one should always stop and start again after a rest if the baby has appeared at all upset.

What is the critical level of bilirubin above which kernicterus may occur? First of all, in the best hands there is a potential error of 1–3 mg. in the estimate. Secondly, drugs, for example gantrisin, and perhaps other unknown changes such as physico-chemical differences in the baby, may lower the level of bilirubin at which cell damage occurs.

It is, therefore, unwise to dogmatize on the exact critical level. We know that kernicterus can occur with a level not much higher than 34 mg. per 100 ml.

Apart from one untreated case in a premature infant, we have had only one likely kernicterus in the past 3½ years. He is now aged 6 months, makes doubtful response to sounds and is backward in development. His case illustrates two points. Firstly, his known bilirubin did not rise above 29 mg., but his actual level may have been up to 32 mg. Secondly, the tragedy here was really the result of failure to check the bilirubin level until twenty-four hours after the exchange and of a further delay of about four and a half hours before doing the second exchange. This emphasizes the occasional need for urgency in starting these late exchanges and the necessity for an organization with sufficient personnel to carry out an exchange at any time and without delay.

Professor G. H. Lathe discussed the biochemical aspects of bilirubin metabolism as it affected the management and treatment of hæmolytic disease. His basic work has already been published elsewhere: BILLING, BARBARA H., COLE, P. G., and LATHE, G. H. (1954) *Brit. med. J.*, ii, 1263; (1957) *Biochem. J.*, **65**, 774. LATHE, G. H. (1954) *Biochem. Soc. Symposia*, **12**, 34; (1955*a*) *Brit. med. J.*, i, 192; (1955*b*) *Proc. R. Soc. Med.*, **48**, 271.

[*March* 22, 1957]

Sexual Precocity, Advanced Bone Age and Skin Pigmentation. ? McCune-Bruch-Albright Syndrome.—BRUNO GANS, M.D., M.R.C.P.

S. C., girl, aged 4½ years.

Family history negative.

Past history.—No neonatal jaundice, no exposure to œstrogens. Skin pigmentation first noticed in infancy. Normal development until the age of 3, when enlargement of the left breast was first noticed.

At 4½ her height, weight and mental development were normal for her age. Breast tissue was present on the left, but not on the right. There was a fine pubic down, but no proper pubic or axillary hair, and she had not menstruated. Rectal and abdominal examination was negative.

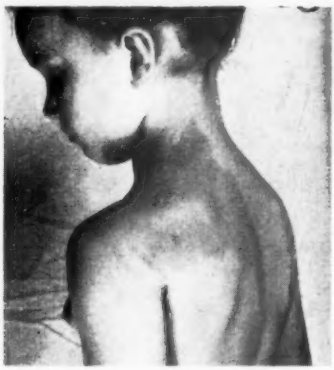


FIG. 1.—Aged 4½. Showing pigmented nævus and breast development.

A flat café-au-lait nævus was present over her left upper arm, her shoulder and her shoulder blade (Fig. 1).

A skeletal survey showed her bone to be at least two years in advance of her chronological age, this being a characteristic and constant finding in the syndrome. There was no evidence of polyostotic fibrous dysplasia. This type of osteitis fibrosa often does not make its appearance for several years after other features of the condition have been noted (Freedman, 1932; Peterman, 1956; Caffey, 1956).

17-ketosteroid excretion and F.S.H. production were normal. A vaginal smear stained by the Papanicolaou technique showed some pink squames, evidence of increased œstrogen production.

Eosinophilic Leukæmia in Eosinophilic Family. ? Larva Migrans Syndrome.—A. A. CUNNINGHAM, M.D., M.R.C.P., and F. R. ELLIS, M.D.

J. W., girl, born 15.8.54. Birth weight 6 lb. 2 oz. Premature delivery at 36 weeks after uneventful pregnancy. No pre-natal radiological investigation of the mother. Normal birth. Admitted to hospital 5.11.56.

History.—Listlessness, general irritability, poor appetite and disturbed sleep for one month, dating from a cold in the head. For some time the child had been in the habit of eating earth, coal dust, etc. Seen by family doctor on 2.11.56 and sent for blood count: Hb 76%. R.B.C. 5,000,000. C.I. 0·76. W.B.C. 89,400 (polys. 6%, lymphos. 23%, large hyalines 1%, eosinos. 69%). Some "basket" cells present. Very occasional "t[illegible]k" cells. The R.B.C.s show slight achromia and marked anisocytosis. This points to a possible diagnosis of eosinophilic leukæmia but all other forms of eosinophilia should first be ruled out.

Family history.—Father and mother alive and well. Mother has had iron deficiency anæmia. First child stillborn at 5–6 months. Brother of 5 was treated for anæmia, now well: sister of 4 had pica which disappeared at 2½ years of age: sister of 9 months alive and well.

General examination (5.11.56).—Temperature 98° F., P. 112, R. 24. Child very irritable and obviously anæmic. One gland was particularly noticeable in the posterior triangle of the left neck. Throat showed tonsils of moderate size without exudate. *C.V.S.* normal. B.P. 88/60. R.S.—normal. Abdomen—Liver enlarged 3 fingerbreadths below costal margin. Spleen not palpable.

6.11.56: *Stool:* No red blood cells, mucus, pus, ova or parasites seen. *Urine:* Clean specimen: faint trace of albumin. Deposit: occasional pus cell. *Mantoux* 1/10 — Negative.

7.11.56: Marrow puncture: Leucoblasts 6·0%, promyelocytes 4·0%; myelos: neut[illegible].

2·0% *eosino.* 18·0%, baso. —; metamyelocytes: neutro. 4·0%, *eosino.* 8·0%, baso. 0·2%; polymorphs: neutro. 6·0%, *eosino.* 28·0%, baso. 0·2%; lymphos. 14·0%, monos. 0·4%, reticulum cells 0·2%, megakaryocytes 0·1%, plasma cells 0·4%, proerythroblasts 0·4%, normoblasts: polychromatic 5·0%, pyknotic 3·1%; myeloid—erythroid ratio 9·4 : 1. "The marrow picture is either that of eosinophilic leukæmia or an eosinophilic leukæmoid reaction. The former would appear to be the more likely diagnosis."

8.11.56: *Throat swab:* Heavy growth of *M. catarrhalis* and pneumococci.
X-ray of chest: No abnormality.
9.11.56: *Blood Wassermann reaction* negative.
9.11.56: *Blood count:* Hb 56%. R.B.C. 3,800,000. W.B.C. 30,000 (polys. 7%, lymphos. 19%, large hyalines 2%, eosinos. 72%). Platelets 200,000/c.mm. There are a few eosinophilic metamyelocytes, but most of the eosinophils are well formed. No nucleated reds seen.

Treatment.—Prednisolone 10 mg. 6-hourly (=40 mg. daily).
16.11.56: *X-ray of long bones and skull:* No abnormality of bone structure.

On admission the child could not feed herself, but now takes food satisfactorily and feeds herself very well. Her whole temperament has changed. On clinical examination, however, the liver is still enlarged. Spleen not palpable.

18.11.56: *Blood count:* Hb 52%. W.B.C. 8,000.
19.11.56: Progress maintained. B.P. 100/60. Prednisolone reduced to 15 mg. b.d.
20.11.56: *Repeat marrow puncture:* myeloblasts 5·6%, promyelos. 6·0%; myelos.: neutro. 14·4%, *eosino.* 1·4%, baso. —; metamyelocytes: neutro. 27·4%, *eosino.* 2·4%, baso. 0·2%; polymorphs: neutro. 15·0%, *eosino.* 1·4%, baso. 0·2%; lymphos. 16·0%, monos. 0·8%, reticulum cells 0·2%, megakaryocytes 0·2%, plasma cells 0·4%, proerythroblasts 0·4%, normoblasts: polychromatic 4·0%, pyknotic 4·0%; myeloid—erythroid ratio 8·8 : 1. The marrow picture is now completely different as the eosinophilic series have reverted to normal.

At this stage the possibility of *Toxocara canis* infection was discussed. Samples of stools from the dog and from the dust of the patient's home yard showed no ova or parasites of any kind.

21.11.56: Good progress maintained. Liver still enlarged, but smaller: 2–3 fingerbreadths below costal margin. B.P. 120/80.
23.11.56: *Blood count:* Hb 54%. W.B.C. 10,000 (polys. 70%, lymphos. 23%, large hyalines 4%, *eosinos.* 3%). Film: R.B.C.s show extreme hypochromia and moderate anisocytosis. No abnormal W.B.C.s were seen.
29.11.56: Prednisolone reduced to 10 mg. b.d.
3.12.56: Good progress maintained.

Blood count: Hb 56%. W.B.C. 10,000 (polys. 72%, lymphos. 21%, large hyalines 2%, eosinos. 5%).

Fæcal specimens from W. family: No ova or parasites seen, in any specimen from father, mother, two sisters or brother.

6.12.56: *Blood chemistry:* Serum proteins 7·2, albumin 6·2, globulin 1·0 grams %. Alkaline phosphatase 10 King-Armstrong units. Thymol turbidity 2·5 units. Bilirubin: total less than 0·5 mg.%. Serum phoresis: Emphasis of alpha globulins and mucoproteins and virtually absent gammaglobulin. Alpha lipoprotein increased and beta lipoproteins diminished. No biochemical evidence of hepatic dysfunction.
11.12.56: Good progress maintained. B.P. 124/78. Prednisolone reduced to 5 mg. b.d.
15.12.56: *Blood count:* Hb 56%. W.B.C. 10,000 (*eosinos.* 13%).
20.12.56: *Blood count:* Hb 64%. W.B.C. 8,000 (*eosinos.* 7%). E.S.R. 16 mm. in one hour (Westergren).
24.12.56: B.P. 110/70. Prednisolone reduced to 2 mg. t.d.s.
29.12.56: Liver slightly enlarged 1–2 fingerbreadths. Child discharged from hospital.
9.1.57: *Blood count:* Hb 92%. W.B.C. 18,000 (*eosinos.* 32%, basos. 1%). Film: R.B.C.s show slight anisocytosis.

General report.—Child very well. Liver one fingerbreadth below costal margin. No enlargement of spleen. Eating and sleeping well. Up and about.

16.1.57: Prednisolone reduced to 1 mg. t.d.s.
4.2.57: *Blood count:* Hb 89%. W.B.C. 24,000 (polys. 20%, monos. 3%, *eosinos.* 60%). Film: R.B.C.s show slight anisocytosis. Child full of energy. B.P. 120/80.
20.3.57: *Blood count:* Hb 90%. W.B.C. 25,000 (*eosinos.* 40%). Occasional eosinophilic metamyelocytes. No "blast" cells or nucleated red blood cells seen.
Child remains very well. Prednisolone 1 mg. t.d.s. continued.

All the near relatives of this child were carefully investigated with complete blood counts:

TABLE I

	Leucocytes	Eosinophils
Maternal grandfather ..	9,300	280
,, grandmother ..	5,600	112
Father	10,200	102
Mother	6,000	360
Mother's sister	6,000	360
Brother aged 5	10,000	1,600
Sister aged 4	9,000	2,200
Sister aged 9 months ..	11,000	1,320

DISCUSSION

Some hæmatologists are reluctant to recognize the existence of eosinophilic leukæmia owing to the difficulty of differentiating it from an eosinophil leukæmoid reaction. Space does not allow a detailed discussion on this point, but when all evidence is considered it would appear that eosinophilic leukæmia is a definite and distinct entity, although exact diagnosis during life or before the terminal phase may be extremely difficult. The latter statement applies equally well to some cases of neutrophilic and lymphatic leukæmia and is not a valid argument against the existence of eosinophilic leukæmia.

Eosinophilic leukæmia in childhood on a basis of strict diagnosis is exceedingly rare and less than 10 cases, predominantly male, have so far been reported.

The original blood picture and myelogram in this case could be that of an eosinophilic leukæmia or an eosinophil leukæmoid reaction. The marked anæmia abnormal electrophoretic pattern, increased E.S.R., enlarged liver and the absence of evidence to date of other conditions known to cause eosinophilia are in favour of a diagnosis of eosinophilic leukæmia.

The differential diagnosis of disorders characterized by extreme eosinophilia covers various infections, allergic conditions and parasitic infestations. The possibility of parasitic infestation is being carefully examined. This condition, which has been described by Heiner and Kevy (1956) under the heading "visceral larva migrans" is becoming better known, particularly in the U.S.A., but so far we have not seen any cases reported in this country.

The syndrome is caused by the ingestion of embryonated ova of the dog or cat roundworm (*Toxocara canis* or *Toxocara mystax*) and similar syndromes are caused by other parasites. The infestation is widely prevalent in young cats and dogs and larval infestation in man is probably more widespread than has been generally realized to date. Patients present with enlargement of the liver, perhaps also of the spleen, in association with leucocytosis and marked eosinophilia, the eosinophils making up to 80% of the total count. The laboratory aids to diagnosis are in the process of development, but hypergammaglobulinæmia has been noticed in some cases. Liver biopsy has shown the presence of eosinophilic granulomata. Examination of the dust from the neighbourhood of patients' homes has produced the toxocara ova. Various immunologic tests have been found of value. In this patient frequent examinations of the dust from the neighbourhood of her home have produced negative results. The fæces of the dog have also been examined with negative results. The child has not been in contact with any other domestic animal, and the absence of hypergammaglobulinæmia is against the diagnosis. Blood serum has been sent to Dr. D. C. Heiner, U.S.A. (*see postscript*).

In addition, repeated examination of the stools of the family has been made for other infestation, but there has been no evidence to date.

The investigation of the family also points to another rare condition, familial eosinophilia. Gray and Shaw (1949) reviewed 15 cases, including their own, but in some of the families an alternative diagnosis could be suspected. Without other causation after routine investigation, this family with the relatively high eosinophilic counts can reasonably be regarded as coming within this category.

CONCLUSION.—This case is presented as one of eosinophilic leukæmia with familial eosinophilia. The immediate response to prednisolone, both in the peripheral blood and in the marrow are of particular interest. Both the patient and family will be carefully followed up and details reported at a later date.

PS. (30.8.57).—Report from Dr. D. C. Heiner: After careful testing of the serum supplied, the results point to a considerable likelihood that the patient is suffering from the "visceral larva migrans syndrome."

Diverticulum of the Heart. Ventricular Extension into the Abdominal Wall with Large Ventral Hernia.—PATRICIA WOOLF, M.B., B.Ch. (for R. H. DOBBS, M.D., F.R.C.P.).

M. B., female, aged 1 year. Admitted aged one day with a diagnosis of exomphalos.

On examination.—Weight 5 lb. 9 oz. Vigorous infant. Large ventral hernia with divarication of recti to just below umbilicus. Pulsating mass synchronous with apex beat, below xiphisternum, about 1 in. long, ½ in. wide, running slightly to right. Leading from its apex and running towards the umbilicus was a thin pulsating vessel lying superficially. No cyanosis. Respiration rapid 80–90, with some recession. Arterial pulsation in neck. Femoral pulses present. Blood pressure right arm 110/70. Heart enlarged, dullness to nipple line on both sides.

Screening (Dr. C. A. Neill): Heart centrally placed, markedly enlarged, apex probably on left. Vascularity increased.

Barium swallow: Left aortic arch.

ECG: Suggested dextroposition of heart. Balanced axis. Slight left ventricular preponderance. Record over diverticulum showed marked QRS complex, deeply inverted T-wave. The large complexes over the pulsatile swelling presented strong confirmatory evidence of myocardial diverticulum, not aberrant artery.

Progress.—Satisfactory except for some umbilical sepsis until aged 19 days, when shortly after strapping ventral hernia she developed pneumonia. Improved with digitalis and antibiotics. At this time she developed a blowing systolic murmer over lower præcordium.

Discharged at age of 1 month on Digoxin 0·025 mg. t.d.s. Progressed well and occasional mild upper respiratory infections resolved without antibiotic therapy.

Seen at 1 year. Weight 11 lb. 4 oz. No cyanosis, but generalized dusky skin colour. Dilated superficial veins over anterior chest. Præcordial systolic murmur, accentuated when supine. Pulmonary second sound accentuated and split. X-rays show progressive cardiac enlargement and the pulmonary circulation is now considerably increased. There is presumably a very large inter-auricular septal defect and possibly an interventricular septal defect.

Cardiac diverticula have been described communicating with the right and left ventricles. The majority communicate with the left ventricle, and are often associated with other lesions of the heart.

Skapinker (1951), reporting a case from Johannesburg, reviewed 12 cases, the earliest of which occurred in 1837. In this series only one survived infancy without surgical intervention and he died as a result of rupture of his diverticulum at the age of 4 years.

There appear to be two methods of dealing with this condition surgically; either by replacing the diverticulum into the pericardial sac and closing the opening in the diaphragm, or by resection of the diverticulum.

Snellen *et al.* (1952) reported another case from Holland, which was fully investigated during life, and in which the pericardial reflections were well demonstrated at autopsy. More recently Parsons (1957) described a further case and gave reasons for thinking that this anomaly arose during the ninth week of fœtal life.

Huntington's Chorea.—R. C. ROXBURGH, M.D., M.R.C.P. (for C. T. POTTER, M.D., F.R.C.P.).

B. H., girl aged 11 years 4 months.

History.—November 1952 (aged 7): sudden onset of dysarthria; previously well. Three months later developed ataxia and nocturnal enuresis, followed by a tendency to jerk her head to the left. First seen nine months after the onset of symptoms, in August 195 . Then appeared to have normal intelligence, but there was a gross slurring dysarthria; ataxia not apparent. C.N.S. normal. Speech therapist found that the main speech defect was due to poor lip movement, and started treatment. However, there was no improvement at all. By February 1954 (aged 8 years, 3 months) dysarthria worse and gait more unsteady. Once again, no definite abnormalities could be detected in the C.N.S., apart from a variable ataxia when walking. C.S.F. normal. W.R. and Kahn negative. X-ray of skull normal. Mantoux negative.

Referred to Psychiatric Department. I.Q. found to be 86. Diagnosis of hysteria was considered.

By October 1955 (aged 9 years, 11 months) showing more deterioration with increased dysarthria, and inco-ordination. Now coarse choreiform movements of the head and face. Her mentality appeared unaffected.

A course of lysivane was given for twelve months (Oct. 1955 to 1956) with slight temporary improvement.

Past history.—Normal developmental milestones. No relevant illnesses.

Family history.—Father died 1953 (aged 44) in a mental hospital, from Huntington's chorea complicated by miliary tuberculosis and meningitis. Diagnosis made at St. Bartholomew's Hospital eighteen months before death, despite the completely negative family history. Mother alive and well. 2 male siblings of patient aged 19 and 15 alive and well.

Present condition.—Nervous apprehensive child, showing coarse choreiform movements of head and face. Jerks her head frequently. Coarse intention tremor in both arms, but can still write her name with a pencil. Speech is almost unintelligible and slurred. Mentality: understands everything said to her and responds normally. Can read simple books.

Psychiatric report (Dr. Bowley): I.Q. 71 (Wechsler scale). Performance indicates intelligence considerably below average. Very possibly there has been some deterioration since last test, which was 86.

C.N.S.—Cranial nerves normal. Sensation normal. Arms: Tone is slightly increased, all reflexes normal, co-ordination very poor. Coarse intention tremor. Legs: Tone increased. Reflexes equal and rather brisk. Plantar responses flexor. Co-ordination fair, but gross ataxia on walking. Romberg's tests negative.

Comment.—It was with some reluctance that a diagnosis of Huntington's chorea was made in this girl, in view of the rarity of the disorder in children and the absence of a definite family history, preceding her father. In fact, it is only in the past six months that we have seriously considered Huntington's chorea in her case. Previously, a hysterical or functional disorder had been considered possible and latterly, when progress was for the worse rather than for the better, an extrapyramidal degenerative disorder seemed to be developing.

However, in view of the reports received from the hospitals concerned with the father's illness which showed that classical Huntington's chorea had been diagnosed confidently, we felt that no other diagnosis was really possible in this girl. Indeed, the girl's mother has recently told us that she is developing just as her father did, and makes exactly similar movements.

Huntington's chorea, which is so very uncommon in childhood, is genetically a dominant disorder and usually 50% of children of an affected parent will develop the disease. There is no sex linkage. The onset of symptoms is gradual, the commonest age of onset being 35 years. Only 2% of cases began in childhood (Bell, 1934). Most commonly, dysarthria is the earliest presenting symptom, inevitably followed by coarse choreiform and jerking movements, together with a peculiar ataxia. Mental deterioration is always a late development and is the beginning of the end. Death occurs 10–15 years from the onset.

This remarkable disease is generally regarded as a rarity in this country, but recent papers by Pleydell (1954, 1955) and by Bickford and Ellison (1953) have shown that in country districts, at any rate, there are 5–6 cases at any one time per 100,000 of population, from which they calculate a possible 2,000 cases in England and Wales alone.

Most early papers on Huntington's chorea emanated from the U.S.A. You may remember the fascinating studies which showed a positive family history in a family in the Eastern States going back 300 years to a small village in Suffolk from whence some affected persons had emigrated to America in the seventeenth century (Davenport and Muncey, 1916). In the U.S.A. the incidence is remarkably similar to ours, namely 5 per 100,000 of population (Lazarte *et al.*, 1955).

It is generally regarded as a disorder especially likely to be found in isolated country areas and a recent paper by Bickford and Ellison (1953) showed a high incidence in Cornwall. It is also common in Suffolk, Norfolk, Northampton and Devon.

Several writers have noted that the victims of this disease show heightened sexual activity and large families are commonly encountered (Pleydell, 1954). This activity may be the result of very early cortical degeneration.

The prevention of this disorder is naturally extremely difficult since most families have been started before the affected parent shows symptoms. The only effective measure would be to prevent marriage of all children in an affected family.

There is no good evidence of the disease skipping out a generation and reappearing later.

In our case it is possible that miscegenation may have occurred, but we have no proof or evidence.

Some families appear to have started up from a mutation.

Treatment is highly unsatisfactory. Some recent reports from U.S.A. have suggested that reserpine may benefit the hyperkinesis for a time (Lazarte *et al.*, 1955).

Neonatal Addison's Disease.—G. R. SPARROW, M.B., B.S., D.C.H. (for J. SAKULA, M.D., M.R.C.P., D.C.H.).

C. H., boy aged 3 months.

Past history.—Born 8.12.56 following normal pregnancy, labour and delivery. Birth weight 8 lb. 6 oz. First child.

Family history.—Healthy unrelated parents. No relevant history.

Progress.—Satisfactory, except for marked weight loss, until vomiting began on the eighth day, occasionally bile stained. Investigation for intestinal obstruction was negative.

The vomiting persisted and resulted in repeated episodes of severe dehydration, which responded to 0·9% saline subcutaneously or 0·18% saline intravenously. At one month it was found that there was gross sodium deficit and a raised serum potassium. Adrenogenital syndrome was suggested, but pigmentation was noted.

The electrolyte imbalance was corrected and controlled, at first with 3N saline which was given intravenously, and subsequently oral doses of salt of 7·5 gm. daily.

Investigation of adrenocortical function showed that the 17-ketosteroids were not elevated. ACTH intramuscularly produced no fall in the eosinophil count, nor an increase in the 17-ketosteroid excretion.

Cortisone was then added to the daily salt intake. Growth proceeded satisfactorily and the pigmentation was diminishing. In an attempt to control the continued salt loss, 9 alpha-fluorohydrocortisone has been added to the regime.

(To be published in greater detail elsewhere.)

Hepato-Lenticular Degeneration (Wilson's Disease).—J. J. KEMPTON, M.B.E., M.D., M.R.C.P., D.C.H.

V. S., boy aged 13.

History.—In August 1956 he fell and fractured a tibia. When the plaster was removed two months later he was noticed to be slow and stiff in his movements. Later his speech became indistinct, and it was on account of this that he saw his doctor in December 1956.

Four other children (half-brothers) and the father are healthy. The mother died of pneumonia in his early childhood.

On examination.—He shows all the appearances of hepato-lenticular degeneration. This is a striatal limb rigidity and fixity of facial expression. He adopts odd fixed postures, and has a tremor of tongue. His speech is slurred and indistinct. There are outbursts of spontaneous "thalamic" laughter. His tendon reflexes are normal. There is some gynæcomastia, and he has early clubbing of the fingernails, and very many spider nævi. The liver edge is hard and a little tender, and easily felt. Kayser-Fleischer rings are present in his corneæ.

Investigations.—Liver function tests indicate a severe degree of damage. Paper partition chromatography shows an excess amino-aciduria. His serum copper is abnormally low, 45 micrograms per 100 ml., with absent oxidase.

Treatment and progress.—Treatment has consisted of two courses of dimercaptal, and potassium sulphide given continuously in doses of 20 mg. thrice daily. He appears to have improved a little during three months' treatment.

Investigation of relations has shown that a great-aunt and great-uncle died of the disease. One cousin, aged 13, has amino-aciduria, minimal chemical evidence of liver damage, and very early pigment deposit in the cornea, shown on slit-lamp examination. Her serum copper is normal. She is quite symptom-free.

Cutis Laxa.—M. E. CASHMAN, M.B., Ch.B., D.C.H. (for J. J. KEMPTON, M.D., M.R.C.P.).

I. S., girl aged 18 months.

She is a first child of healthy parents, a full-term baby born following a normal pregnancy. The skin condition was noted at birth. There is no significant family history.

She was admitted to hospital at the age of 5 months with pneumonia, and has had

repeated respiratory infections since then. She has been in hospital five times in all, and there are persisting X-ray changes in the right lung.

Investigations show a normal blood picture and serum cholesterol, radiologically normal bones and epiphyses, and a normal ECG; fæcal trypsin is present, and sweat electrolytes are normal. A barium swallow shows free reflux, but no hiatus hernia.

At 18 months she is developing well. She walks and runs, feeds herself, says a few words and plays happily,

The appearance of the skin is grotesque (Figs. 1 and 2) but the texture is essentially normal. It is not hyperelastic, does not show any hæmorrhagic tendency and is not unduly friable.

FIG. 1.

FIG. 2.

Cutis laxa was first described by Alibert in 1832. In most standard textbooks of dermatology it is not clearly differentiated from cutis hyperelastica. Andrews (1946) described the two conditions separately. He says cutis laxa may occur as an isolated congenital anomaly, or in association with and secondary to Von Recklinghausen's disease or acromegaly. It is, of course, in some degree part of the facies of old age. The best clinical description of the condition is found in the standard French text book of dermatology by Dugos (1953). "La dermatolysie se caractérise par une flaccidité considérable de la peau (cutis laxa) qui forme de larges plis, flasques, mous, retombant en 'tablier'. La peau est de couleur normale. Elle est mobile, n'adhérant pas aux plans profonds. Elle a perdu toute élasticité et les plis produits par la traction ne se défont que lentement."

This child is presented both because of the intrinsic interest of a rare congenital abnormality, and because it is questioned whether there may be some association between the skin condition and the recurrent chest infection.

PS. (27.8.57).—Operation for inguinal hernia revealed an opportunity for skin biopsy and we are grateful to Dr. I. W. Whimster for the following report on histology:

"This shows a quite remarkable degree of elastic tissue abnormality, consisting of gross fragmentation, clumping, and curious granular degeneration. I have seen this kind of thing once or twice before but never on quite such a gross scale. The changes seem somewhat similar to those seen in senile skin, but much more exaggerated."

PROCEEDINGS

of the

ROYAL SOCIETY OF MEDICINE

GOLDEN JUBILEE NUMBER

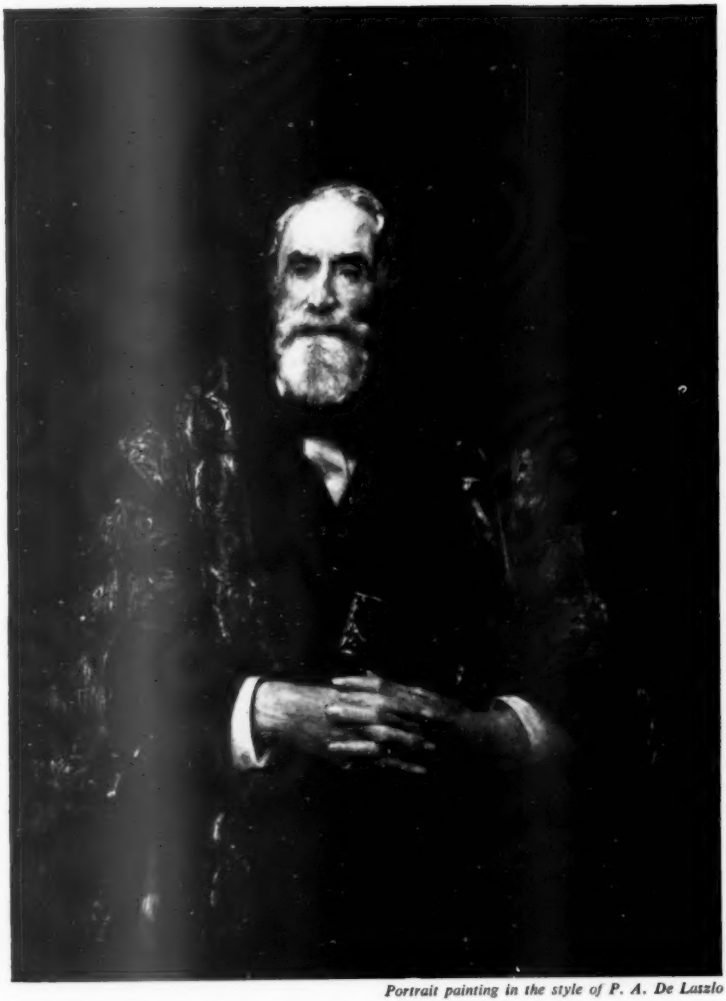
OCTOBER 1957

FOREWORD

by SIR FRANCIS WALSHE, O.B.E., M.D., F.R.S.

FELLOWS of the Society know that the Royal Society of Medicine arose from the amalgamation of some fourteen medical societies, and that fifty years ago, with a Royal Charter, it started on its new career. All this has been admirably described by Dr. Maurice Davidson in his recently published history of the Society—"The Royal Society of Medicine: the Realization of an Ideal"—and need not be recapitulated here.

What, perhaps, is less generally known is that many of the constituent societies published their own *Proceedings* or *Transactions* and that many, though not all, of these became merged in the *Proceedings* of the Society with which we are familiar. Comparisons are invidious, but it must be said that some of these earlier *Transactions* bore a high prestige and had been of primary importance in periodical medical literature for many years. Not a few major original contributions first saw the light in their pages, and references to some of them may still be encountered from time to time in modern papers. The *Transactions* of the Medico-Chirurgical Society, for example, formed an important element in world medical literature. To turn over some of the earlier nineteenth century volumes of the Society's *Transactions* is not only to encounter some classic original papers, but also to meet the predominance of a clear, concise and rhythmic English, written by men for whom the form of their papers was scarcely less important than their substance, and for whom to clothe their observations and ideas in worthy English was an ideal not forgotten.

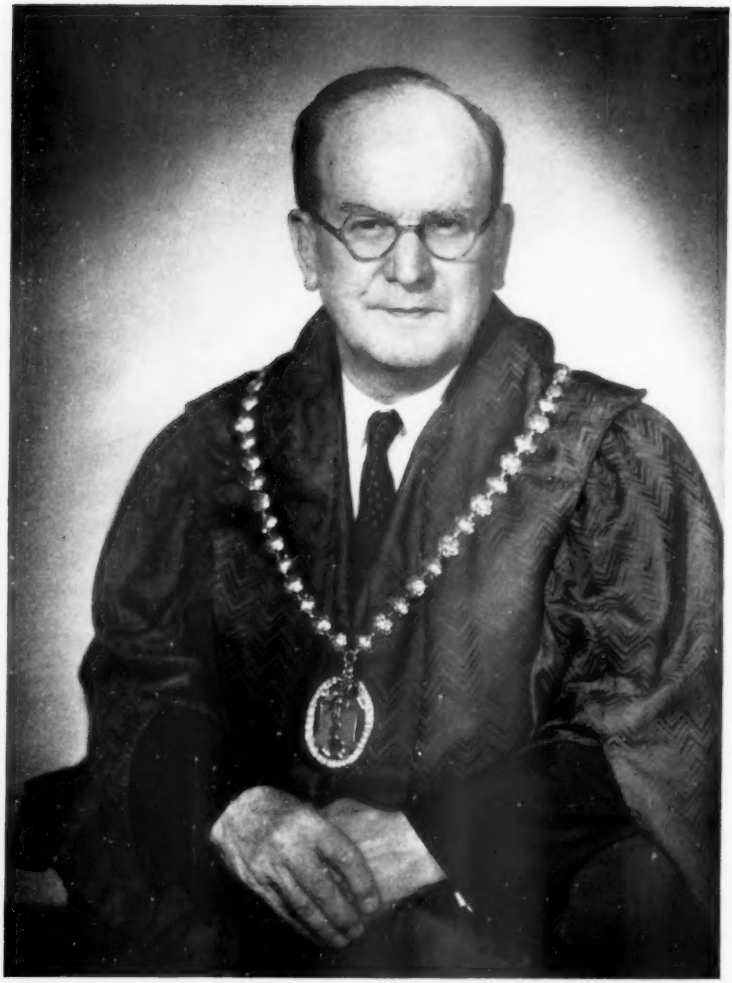


Thus, the *Proceedings* of our Society to-day has a distinguished tradition of scientific and literary excellence, the preservation of which has been the care of a long succession of devoted Honorary Editors, and also of the permanent editorial staff of the Society.

The expansion and increasing diversity of Medicine and Surgery have made the field of knowledge covered by the *Proceedings* almost more than they can adequately cope with, and the twenty-six Sections of the Society have to submit to limitations of space that, while regretted, have so far been inevitable.

Nevertheless, within these limited bounds, the *Proceedings* presents a balanced picture of the activities of its Sections, and if it be sometimes said that not every contribution breaks new ground in knowledge, the same is true of even the specialist journals, and it may be urged that no journal could continue in regular publication if it restricted the papers and communications it accepted to new discoveries of the first order. In fact, we know of no such journal.

Thus, the *Proceedings* reflects the different orders of medical and surgical work and thought: the original, the purely descriptive and clinical, the technical and methodological, and, at times, the critical review. These are the balanced diet of the medical reader, if we may use this simple metaphor, upon which he thrives.



So to speak of our *Proceedings* betrays no spirit of complacency, for we can never be satisfied until it reflects the highest level of medical and literary excellence which the combined efforts of contributors and editors can achieve. It is in this spirit of determination to enhance the value and the appeal of our *Proceedings* that the Society enters upon its second half-century.

INTRODUCTION

by E. C. WARNER, M.D., F.R.C.P., and SELWYN TAYLOR, M.Ch., F.R.C.S.
HONORARY EDITORS

THE present Number of the *Proceedings of the Royal Society of Medicine* celebrates the completion of fifty years of publication. It will therefore be of interest to Fellows, Members and Associates of the Society to have a short account of the development and growth of this Journal.

The first number was published in November 1907. In a report of a meeting of the General Committee of Representatives of the Societies held on July 17, 1906, we read:

> There shall be ten monthly issues of a publication to be called "The Proceedings of the . . . Society".
>
> The "Proceedings" shall contain as full a record as possible of the society's work during the previous month.

The first pages of Volume 1 are devoted to the Presidential Address of Sir Thomas Barlow to the Clinical Section of the Society—a Section which was the lineal representative of the Clinical Society of London which had already been in existence for nearly forty years. The presentation of patients of particular clinical interest to the Fellows of the Society, and the subsequent discussions in which all can join, has always been a particularly interesting feature of the work of the Society.

The production of these earlier volumes reveals the great care which was taken not only with the text but also with the reproduction of photographs and drawings; this set a standard which has been adhered to even in times of World Wars and which compares very favourably with the pages of any journal being published to-day.

There is, however, one noticeable difference between Volume 1 and Volume 49: Volume 1 contained 2,548 pages, for in 1907 it was possible to publish almost verbatim the whole of the transactions of the 13 Sections of the Society. The large print of Volume 1, which gave 500 words per page, is still much more pleasing to the eye than the closely printed pages which, perforce, have had to be adopted since. In contrast to this, Volume 49 contains 1,080 pages and gives an account of the work of 26 Sections, which in the course of the year have held some 185 meetings. Regrettably this has meant that only about three-quarters of the meetings can now be reported, and the published account of each meeting has to be carefully scrutinized beforehand by the Sectional Editor and by the Honorary Editors, to save space whenever possible.

The selection of papers to be published to-day is necessarily a difficult and often an invidious task. Particular attention is paid to the fact that the majority of readers are in active clinical practice and cannot possibly attend more than a small number of the meetings held. The *Proceedings* enables them to keep in touch with the views of those who are expert on a particular subject, as well as with recent advances in our knowledge. The papers which do not see the light of day in the *Proceedings* are usually of a very special nature which are more suitable for publication in specialist journals.

The number of copies printed has steadily increased. In the first few years about 3,000 copies were distributed; after thirty years this rose to 5,000 copies and

now to 10,400 copies per month. The distribution is not only to Fellows of the Society in Great Britain; some 2,500 copies are sent overseas, including 70 presented to other institutions, 340 exchanged for other journals and 500 to outside subscribers.

Clearly the Royal Society of Medicine can enter the second fifty years of its publication of the *Proceedings* with every confidence. In the near future an innovation will be to publish the accounts of the special conferences to be organized by Council, at which leading authorities from at home and abroad will debate clinical topics of wide interest. Those engaged in original work will be encouraged to discuss their results in the various Sections of the Society with a view to obtaining early publication in the *Proceedings*.

The success of this publication over the years, and the success of this our Jubilee Number is largely due to the keenness and high standards of work of our permanent editorial staff, and it is to them that we give thanks for the production of this Number.

WALTER ERNEST DIXON MEMORIAL LECTURE

[Number 8]

Ion Movement and Cardiac Fibrillation

By J. HAROLD BURN, M.D., F.R.S.

Department of Pharmacology, University of Oxford

Acetylcholine and atrial fibrillation.—In 1907 Walter Ernest Dixon, in whose memory this lecture is given, described experiments which he had carried out on the heart. In pithed animals he stimulated the vagi for half an hour and then extracted the heart. The extract possessed the power of inhibiting the frog's heart, and the inhibitory effect was abolished by atropine. He said also that "hearts treated in an identical manner, but in which the vagus nerve had not been excited, also gave a supply of this inhibitory substance, but in a smaller degree than in the excited heart". In the past few years we also have obtained evidence that the isolated heart, not receiving vagal impulses, liberates acetylcholine, and have described a series of observations which indicate further that acetylcholine has an action which is excitatory, though normally this action is not seen. It can be demonstrated in the isolated atria in the presence of drugs like quinidine, or when the atria are approaching exhaustion after long immersion in the organ bath, or when they are cooled (for references, *see* Burn, 1956). Recently, however, we have observed that in the heart-lung preparation of the dog where conditions are close to normal, acetylcholine can maintain the state of excitation commonly described as fibrillation. During experiments in which we infused acetylcholine at a constant rate, we discovered that when the right atrium was stimulated, the atria fibrillated. This fibrillation persisted after the stimulation stopped for as long as the infusion continued. Fibrillation was always recognized from the ECG, but evidence of the arrhythmia could also be seen in the record of the blood pressure. Fig. 1

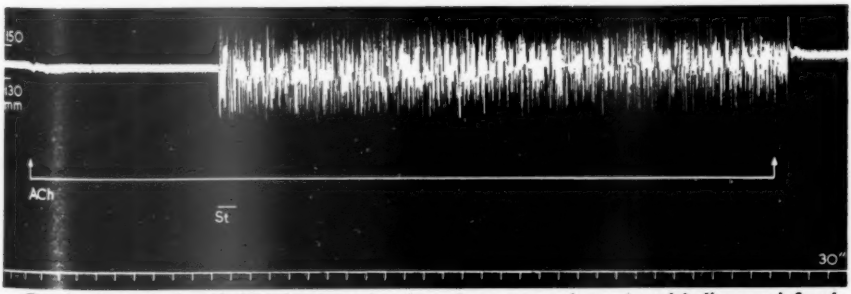

FIG. 1.—Record of aortic blood pressure in a heart-lung preparation. Acetylcholine was infused at a rate of 1 mg. per min., during the period shown. The tip of the right atrium was stimulated at a rate of 750/min. for 30 sec. at St. This produced atrial fibrillation which persisted until the acetylcholine infusion was stopped.

shows that the infusion of acetylcholine did not cause fibrillation until stimulation was applied; the application was for 30 sec. only, but the fibrillation continued until the infusion of acetylcholine was stopped 14 minutes later (Burn, Vaughan Williams and Walker, 1955*a*).

We have found that, to be certain of obtaining fibrillation, stimulation is required at a rate of 750 per minute. We use square wave pulses of 1 mA strength and 0·9 msec. duration. The length of time for which stimulation is applied appears to be relatively unimportant; 2 sec. may be long enough but we commonly use 30 sec. The amount of acetylcholine which

must be infused per min. to maintain fibrillation indefinitely varies in different preparations from 40 μg. to 4 mg. The effect of infusing different amounts in one preparation is shown in Table I, from which it is seen that if the rate of inflow of acetylcholine is less than a certain

TABLE I.—ATRIAL FIBRILLATION PRODUCED BY ELECTRICAL STIMULATION DURING INFUSION OF ACh

figure, the fibrillation established by stimulation does not last more than a few minutes. Our observation that under certain circumstances acetylcholine precipitates atrial fibrillation is not in itself new. Nahum and Hoff (1940) produced atrial fibrillation by applying acetyl-β-methylcholine to localized regions on the atrial surface, and it has long been known that vagal stimulation, which releases acetylcholine, favours the occurrence of atrial fibrillation.

Fibrillation in the presence of an anticholinesterase.—The addition of an anticholinesterase to the heart-lung preparation causes the accumulation of acetylcholine in the blood, and this accumulation was observed to be greater when the heart was driven electrically by stimuli applied either to the atria or to the apex of the ventricle (Burn, Vaughan Williams and Walker, 1956). We therefore tried stimulation of the atria in the presence of eserine and also of paraoxon (Mintacol) to see if fibrillation would occur when cholinesterase was inhibited. Most of our experiments were made with paraoxon, which is an organic phosphate having an action of longer duration than that of eserine. We found that fibrillation was induced by stimulation, and lasted after stimulation for a time which was proportional to the amount of paraoxon present, as shown in Table II. In one trial fibrillation was maintained for 25 min. (Burn, Vaughan Williams and Walker, 1955*b*).

TABLE II.—PRODUCTION OF ATRIAL FIBRILLATION BY ELECTRICAL STIMULATION WHEN PARAOXON WAS ADDED TO THE BLOOD IN DIFFERENT CONCENTRATIONS

Experiment	Molar concentration	Rate of stimulation per min.	Duration of fibrillation when stimulus stopped
1	9×10^{-6}	556	1 min.
	$1{\cdot}8 \times 10^{-5}$	556	3·3 min.
	$3{\cdot}6 \times 10^{-5}$	562	9·6 min.
2	9×10^{-6}	330	5 min.
	$2{\cdot}7 \times 10^{-5}$	750	25 min.
	10^{-4}	1,256	(Stopped by atropine)
3	9×10^{-6}	708	(Flutter 10 sec.)
	$2{\cdot}7 \times 10^{-5}$	875	1 min.
	$6{\cdot}3 \times 10^{-5}$	865	10 min.

Fibrillation due to aconitine.—The substance aconitine was introduced by Scherf *et al.* (1948) as a means of causing atrial fibrillation. An amount of 25 μg. is injected under the epicardium of the tænia terminalis, or a 5% solution in benzene is applied to one small area of the atrial surface. In the anæsthetized dog where vagal control is present, atrial fibrillation occurs. In the heart-lung preparation in which the vagi are cut, we found that the injection of aconitine alone did not cause fibrillation in the few experiments in which we tried, but that it did so with regularity after the addition of eserine to the blood. On the other hand, it never caused fibrillation in the presence of atropine; its effect then was to produce a tachycardia, accompanied by some degree of A–V block. These findings led us to conclude that atrial fibrillation due to aconitine depended for its occurrence on the presence of acetylcholine, the aconitine producing an ectopic focus from which a series of impulses arose, corresponding to the electrical stimuli which were required to start the fibrillation in the absence of aconitine.

Conversion of tachycardia into fibrillation.—In a series of experiments we stimulated the atria during the infusion of adrenaline or noradrenaline into the blood at a constant rate. In the majority of trials, normal rhythm was observed when the stimulation stopped. In some trials, however, a tachycardia was established, which either reverted to normal rhythm after some minutes or persisted. When it persisted we observed that if an infusion of acetylcholine was given, atrial fibrillation then promptly developed.

Factors required for atrial fibrillation.—We thus produced atrial fibrillation (1) by brief electrical stimulation of the atria during the infusion of acetylcholine, (2) by electrical stimulation of the atria after the addition of eserine or paraoxon to the blood, (3) by the injection of aconitine into the tænia terminalis after the addition of eserine to the blood, and (4) by the infusion of acetylcholine after establishing a tachycardia. The common factors in these different circumstances were the presence of acetylcholine in the blood and a high rate of stimulation. The acetylcholine produced a condition in the atria in which fibrillation occurred whenever a rapid succession of stimuli was applied; these might be electrical or they might arise from an ectopic focus set up by aconitine or they might be the tachycardia set up by stimulation during the infusion of adrenaline.

Fibrillation in isolated atria.—Fibrillation has also been established in isolated atria by my colleague W. C. Holland (Holland *et al.*, 1957). He dissected the atria from a freshly excised rabbit heart and suspended them in an isolated organ bath at 29° C. in which they were well oxygenated. A pair of electrodes penetrated the atria through which stimulation could be applied at one time and an ECG record could be taken at another. Holland failed to establish fibrillation by stimulating the atria in normal Locke's solution even in the presence of acetylcholine. However, when the K^+ concentration was reduced from 5·6 mM/l. to 1·4 mM/l., he then found that fibrillation occurred as shown in Fig. 2 and that the fibrillation stopped when the acetylcholine was removed from the bath. He demonstrated further that the fibrillation was arrested by atropine.

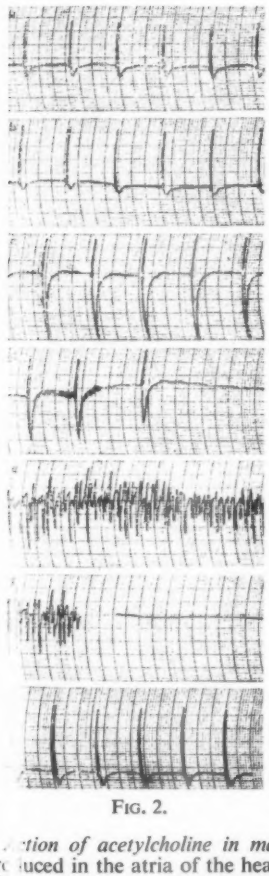

FIG. 2.

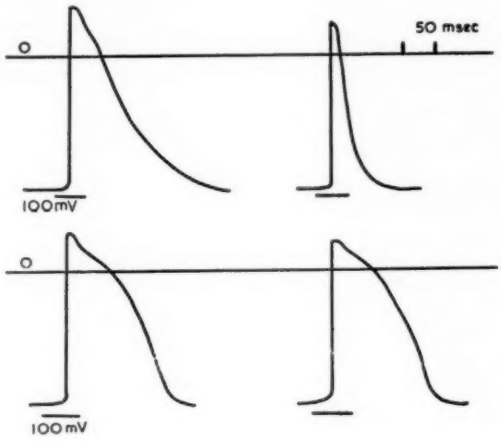

FIG. 3.

FIG. 2.—ECG records taken from isolated atria in bath of Ringer's solution. a, in normal Ringer's solution; b, in Ringer containing 1·4 mM/l. potassium; c, after stimulation for 2 min., d, after addition of acetylcholine which arrested the beat; e, after stimulation in the presence of acetylcholine; f, fibrillation stopped by atropine; g, in normal Ringer. (Holland and Burn, 1957.)

FIG. 3.—To show the effect of acetylcholine on the action potential. The upper records are from the atria and the lower records from the ventricles. Records on the left are control records; those on the right are in the presence of acetylcholine. (Drawn from records of Hoffman and Suckling, 1953, *Amer. J. Physiol.*, 173, 312.)

Action of acetylcholine in maintaining fibrillation.—As has been stated, the fibrillation produced in the atria of the heart-lung preparation by brief stimulation during the infusion of acetylcholine, was maintained until the infusion was stopped. This indicated that acetylcholine by itself maintained some change in the atria responsible for the continuation of

fibrillation. That acetylcholine shortens the refractory period of atrial tissue has long been known, and recent observations have provided more information about this effect. To understand it, the movements of ions into and out of the cell require consideration.

The membrane of a cell is relatively impermeable to sodium ions and is the seat of chemical processes which drive Na^+ out of the cell, so that the concentration inside is less than that outside. These processes constitute what Hodgkin (1951) has called the sodium pump. For potassium ions the situation is reversed and the concentration inside the cell is much greater than that outside. As a consequence the cell membrane bears an electrical charge which is negative internally and positive externally. Thus, if a micro-electrode is placed inside an atrial cell of the dog during diastole, a negative charge of about 90 millivolts is recorded.

When a stimulus arrives at the cell membrane the membrane becomes permeable to sodium ions. In consequence Na^+ moves into the cell rapidly, and the internal negative potential falls abruptly being reversed to a positive potential of about 30 mV. This fall of the internal potential is spoken of as the rising limb of the "action potential". About the time that the entry of Na^+ has neutralized the internal charge on the membrane, at which point the membrane is said to be depolarized, K^+ begins to diffuse out of the cell, and by doing so begins to restore the charge on the membrane. Cardiac muscle cells differ from those of nerve because the restoration of the charge on the membrane takes place slowly, so that the descending limb of the action potential is not abrupt, but is gradual. In its early course the limb may not descend at all, but may appear as a plateau, at the end of which repolarization takes place rapidly, and the action potential is then complete. For the greater part of the period of the action potential the cell is inexcitable; towards the end, however, the refractory period finishes. The Na^+ which enters the cell when a stimulus arrives is afterwards driven out by the sodium pump. Similarly, the K^+ which leaves the cell during repolarization is carried back into the cell by chemical processes which are in part at least linked to the sodium pump, occurring only when the sodium pump is working.

The first evidence that the action potential in the atrium was affected by vagal inhibition was obtained by Samojloff (1914) who showed that it was shortened. More recently Burgen and Terroux (1953) and Hoffman and Suckling (1953) have studied the changes by the use of intracellular electrodes. They are shown in Fig. 3. Both investigations revealed that the effect of acetylcholine upon the action potential was to accelerate the rate of repolarization, that is, to make the downstroke much steeper. Burgen and Terroux suggested that acetylcholine made the membrane more permeable to K^+, since the downstroke is determined by the exit of K^+ from the cell. Trautwein *et al.* (1956), working on isolated strands from frog auricles, have shown that during inhibition by acetylcholine the conductance of the muscle membrane is increased. Harris and Hutter (1956) have found that when the sinus venosus and the atria of the frog or tortoise heart were loaded with ^{42}K, the rate of loss of the isotope was increased by acetylcholine two or three times. Furthermore, they showed that the rate of uptake of ^{42}K was also increased. In the investigation already mentioned Holland has studied the loss of K^+ in isolated rabbit atria when he applied stimulation at increasing rates. In control observations the rate of K^+ rose only from 3·8 to 4·7 mM/kg. wet tissue per 5 min. when the stimulation was raised from 200 to 1,200 per min. In the presence of acetylcholine ($3{\cdot}0 \times 10^{-4}$g./ml.), however, the rate of loss rose from 6·8 to 10·5 mM as the rate of stimulation increased from 200 to 800 per min., and fibrillation occurred when the loss of K^+ exceeded a value about 10·5 mM/kg. wet tissue per 5 min. This was observed when the rate of stimulation was 600 per min. or more (Holland, Burn and Schümann, 1957).

Hence the maintenance of atrial fibrillation appears to be linked to the diminution in membrane resistance, to the increased permeability to K^+ and to the increased rate of loss of K^+ which acetylcholine causes. Thus it seemed likely that fibrillation would be arrested by measures which retarded the outflow of K^+ from the cells and which prolonged the repolarization of the action potential.

Effect of raising the extracellular K^+.—The simplest method of retarding the outflow of K^+ seemed to be to raise the concentration of extracellular K^+. (Whether this idea was justified will be discussed later.) In a series of experiments in which we established atrial fibrillation in the heart-lung preparation as already described, we infused a solution of KCl slowly at a constant rate. We found this infusion arrested the fibrillation after amounts from 50 to 410 mg. had entered the blood, the mean amount being 227 mg. There was approximately 1 litre of blood in the system, so that the K^+ concentration was raised from 5 to 8 mEq./l. Not only was fibrillation arrested in spite of continued infusion of acetylcholine, but when attempts were made to re-establish it by further stimulation it was found impossible to do so (Burn, Gunning and Walker, 1956).

Effect of adrenaline.—Having supported the hypothesis by showing that infusion of KCl would arrest fibrillation, we turned our attention to a study of the effect of adrenaline. The injection of adrenaline into animals anæsthetized with chloroform was shown by Levy (1912)

to precipitate ventricular fibrillation, and anæsthetists have long regarded adrenaline as a substance which is dangerous for this reason. However, it seemed possible that a different relation might be revealed in the atria. Webb and Hollander (1956), having confirmed that acetylcholine shortened the duration of the action potential in the isolated atria, found that adrenaline prolonged it by a mean figure of 14%. The effect of adrenaline in the heart-lung preparation is certainly complex, and we were not surprised to find that in different experiments different results were obtained. However, out of a total of 16 experiments, we observed that an infusion of adrenaline or noradrenaline prevented atrial fibrillation from being established in 9. In 2 experiments we observed the opposite result, and in 5 experiments we observed no effect.

An example of the prevention of fibrillation is given in Fig. 4, taken from the kymograph

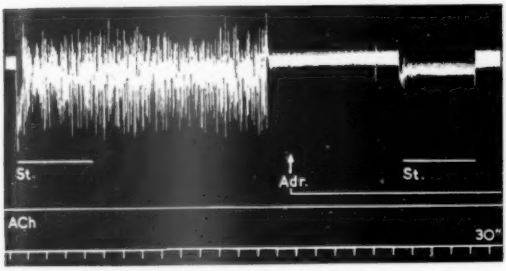

FIG. 4.—To show the action of adrenaline in preventing fibrillation. Acetylcholine was infused throughout the record. Stimulation was applied to the right atrium at "St", and this caused fibrillation which reverted to normal rhythm after 4·5 min. Adrenaline was then infused in addition to acetylcholine. Stimulation now failed to cause any fibrillation.

record. During infusion of acetylcholine alone, stimulation of the right atrium produced an arrhythmia which the ECG showed to be fibrillation. During the infusion of adrenaline and acetylcholine together, there was no arrhythmia. This result and the similar results in 8 other experiments were consistent with the view that adrenaline prevented acetylcholine from causing fibrillation by preventing repolarization from being sufficiently rapid, and the refractory period from becoming sufficiently short.

Arrest of fibrillation by quinidine.—The action of quinidine in arresting atrial fibrillation has long been attributed to a lengthening of the refractory period, in other words, to an increase in the duration of the action potential. Recent observations by Armitage (1957) indicate that this increase may be due to a decrease in the permeability of the membrane to K^+, though this is not yet proved. When the isolated atria are suspended in a bath, the addition of quinidine to make a concentration of 10^{-5} causes a progressive diminution in amplitude and rate of beat until it stops. The beat can be started again in two ways; either by adding acetylcholine to the bath, or by reducing the concentration of K^+ in the solution. Since we know that acetylcholine increases the permeability of the membrane to K^+ it would appear that quinidine may act by diminishing the permeability of the membrane to K^+. This is supported by the evidence that reduction of the K^+ in the external fluid also neutralizes the effect of quinidine, for this reduction by increasing the concentration gradient from inside to outside would offset the diminution in permeability.

VENTRICULAR FIBRILLATION

The study of ventricular fibrillation.—In the whole animal or in the heart-lung preparation, the onset of ventricular fibrillation brings the circulation to a standstill. To study fibrillation it was necessary to use a system in which the coronary flow continued although fibrillation had begun, and for this the simplest arrangement was the isolated rabbit heart perfused through the aorta, by Langendorff's method. Grumbach *et al.* (1954) have used this preparation and observed that in it ventricular fibrillation occurred spontaneously when it was perfused with a solution free from potassium, though not if calcium was also absent. They also observed fibrillation if they injected large doses of calcium. In our experiments we produced fibrillation by electrical intraventricular stimulation. When the heart was perfused with a modified Krebs' solution containing 5·6 mM/l. K^+ and 2·2 mM/l. Ca^{++} and the ventricles were stimulated at increasing rates, fibrillation began at a rate near 600 per min. If this rate of stimulation was then maintained for a fixed period of 5 min., when the stimulation stopped, the ventricles continued to fibrillate. This might be for a short period, reversion to normal rhythm occurring within 5 min. or it might be for 30 min. after which observation was discontinued. An arbitrary distinction was made between these hearts, the former being said not to fibrillate and the latter being counted as fibrillating. Of 28 hearts studied at 36°–37° C., perfused with the solution described, 11 were found to fibrillate in this sense.

Effect of carbachol and atropine.—Since acetylcholine produced a condition in the atria in

which stimulation caused fibrillation, the effect of adding carbachol (the carbamic ester of choline) to the perfusion fluid was studied. Experiments in 11 hearts failed to show any effect of carbachol in a concentration of $1{\cdot}25 \times 10^{-6}$g./ml. A similar negative result was obtained when atropine was added in concentrations up to 10^{-6}g./ml. Thus the ventricles differed from the atria in this respect. Hoffman and Suckling (1953) found that acetylcholine did not shorten the duration of the action potential in the ventricle.

Changes in potassium ions.—Because of the results obtained with atrial fibrillation, observations were first made to determine the effect of changes in the concentration of K^+ in the perfusion fluid. The proportion of hearts which fibrillated fell when the concentration of K^+ was raised; at twice the normal concentration no heart fibrillated even during the period in which the stimulation was applied. As the concentration of K^+ was reduced the proportion of hearts which fibrillated rose as shown in Table III until at a concentration one-quarter the normal, 5 out of 6 hearts fibrillated spontaneously without electrical stimulation.

An illustration is given in Fig. 5.

TABLE III.—EFFECT OF CHANGES IN K^+ CONCENTRATION ON PROPORTION OF HEARTS FIBRILLATING

K^+ concentration mM/l.	Proportion of hearts fibrillating	Percentage
11·2	0 out of 7	0
5·6	11 „ „ 28	39
4·2	20 „ „ 26	77
2·8	10 „ „ 11	91
1·4	6 „ „ 6	100

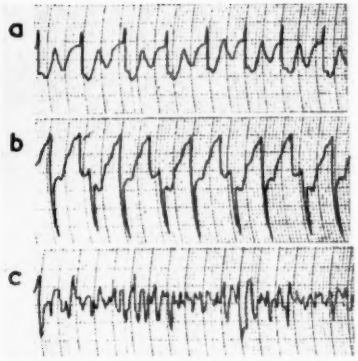

FIG. 5.—ECG record from ventricles of isolated heart. a, taken after changing to perfusion fluid with only 1·4 mM/l. potassium; b, taken 20 min. later; c, showing spontaneous fibrillation 5 min. after b.

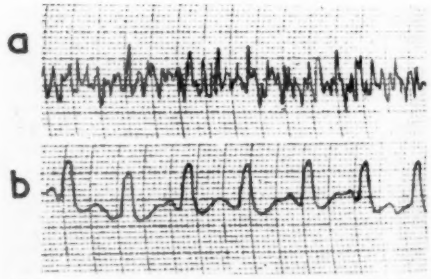

FIG. 6.—ECG record from ventricles (a) fibrillating in low calcium Ringer 0·07 mM/l. The Ringer was then changed to calcium-free Ringer, when the fibrillation stopped, as shown in (b).

The effect of reducing the potassium concentration was abolished by a simultaneous reduction of the calcium concentration. When the perfusing solution contained one-quarter calcium as well as one-quarter potassium, fibrillation did not occur, but on raising the calcium to normal, fibrillation occurred once more. The results with low potassium were of special interest since they showed that normal rhythm could change to fibrillation without the intervention of electrical stimulation.

Changes in calcium ions.—Observations were then made to determine the effect of changes in the concentration of calcium. In general it was found that the proportion of hearts which remained in persistent fibrillation was affected in the opposite direction to that in which it was affected by changes in potassium. When the concentration of calcium ions was raised to twice the normal, all hearts fibrillated. At the other extreme, when the solution perfusing a heart which was fibrillating was changed to one which was Ca-free, the fibrillation was arrested as shown in Fig. 6. Between these extremes there was no simple gradation of the calcium ion concentration changed, as is shown in Fig. 7. Up to concentrations of 0·3 mM/l., the proportion of hearts fibrillating steadily increased; above this concentration, however, the proportion declined until the concentration reached 2·2 mM/l.; finally, as already stated, at 4·4 mM/l. all hearts fibrillated. A similar change with rise of calcium ion

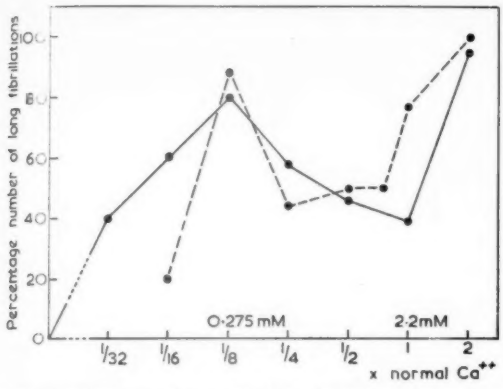

FIG. 7.—Chart showing the relation between the proportion of hearts fibrillating for 30 min. after stimulation and the amount of calcium in the perfusion fluid. The full line shows the relation with 5·6 mM/l. potassium. The broken line shows the relation with 4·2 mM/l. potassium. The full line was determined on larger numbers of hearts than the broken line.

concentration was observed when the solutions contained 4·2 mM/l. K^+ as when they contained 5·6 mM/l. K^+.

Effect of reducing sodium ions.—Experiments were carried out in which the sodium ion concentration was reduced by one-half, and it was found that in all of them stimulation caused persistent fibrillation. In 13 experiments the tonicity was maintained by the addition of sucrose; this meant that the concentration of chloride ions was reduced as well as that of sodium ions. In 7 further experiments the tonicity was maintained by choline chloride, giving atropine to prevent A–V block. The concentrations of potassium and of calcium ions were normal. Thus, reducing the sodium ions to half increased the proportion of hearts fibrillating from 40 to 100%.

Loss of potassium during fibrillation.—An increased loss of potassium ions during fibrillation was directly observed. By the use of a Beckman flame photometer the potassium content of the fluid leaving the heart was determined before fibrillation was induced, during fibrillation and then again when a normal rhythm had been restored for 15 min. It was found that the loss of potassium was greater during fibrillation whether this was induced in the presence of a lowered potassium content of the perfusing fluid, a raised calcium content or a lowered sodium content. Results are shown in Table IV.

TABLE IV.—INCREASE IN K^+ LOSS DURING FIBRILLATION

Perfusion fluid	No. of hearts	Mean K (mg./l.) of perfusing fluid leaving the heart		% increase in K concn. during fibrillation
		Before and after fibrillation	During fibrillation	
½× normal K^+	5	112·5	121·9	8·0
2 × normal Ca^{++}	5	203·1	207·9	2·3
½× normal Na^+	5	217·2	221·9	2·2

Action of adenosine triphosphate.—The addition of adenosine triphosphate to the solution perfusing the heart was found to arrest fibrillation in a high proportion of hearts as is illustrated in Fig. 8. This substance (A.T.P.) was tested because it is known to be an energy

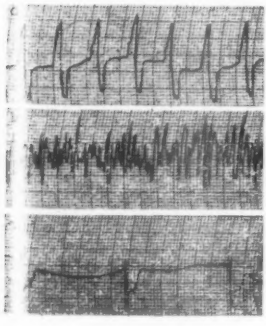

FIG. 8.—ECG records of ventricles. a, in normal Ringer; b, after production of fibrillation by stimulating in fluid containing 4·2 mM/l. potassium and 3·3 mM/l. calcium. The fibrillation persisted after stimulation stopped for 14 min. until A.T.P. was added to the perfusion fluid. This arrested the fibrillation, as shown in c.

donor, and by its means the rate of replacing potassium ions within the cell might be increased. The addition of A.T.P. to the perfusing solutions would not, however, increase the amount of A.T.P. *within* the cell, so that it is unlikely that it could act in this way. Fortunately, this was not realized before it was discovered that A.T.P. did, in fact, arrest fibrillation. In one experiment in which a heart was fibrillating in a solution containing normal concentrations of potassium and calcium, the addition of A.T.P. in a concentration of $2{\cdot}5\times10^{-5}$M converted fibrillation to a tachycardia; the solution was then changed to a solution without A.T.P. and the fibrillation was resumed; with a higher concentration of A.T.P. ($6{\cdot}4\times10^{-5}$M) the fibrillation reverted to normal rhythm, and on changing back to a solution without A.T.P., the normal rhythm once more gave place to fibrillation. Finally, the solution with A.T.P. again restored a normal rhythm. It seemed in this experiment that A.T.P. was a key substance in controlling fibrillation.

Action of magnesium ions.—The observations with solutions containing varying proportions of calcium ions had shown that an excess of calcium ions caused fibrillation. Since A.T.P. can enter into combination with calcium ions and thus neutralize their activity, it was possible that A.T.P. arrested fibrillation by such a combination, which might occur within the pores of the cell membrane. If this were true it seemed that it should be possible to demonstrate that magnesium ions potentiated the action of A.T.P. since magnesium ions might be required to link the A.T.P. to the protein in the membrane. Experiments were carried out on hearts in which fibrillation was produced by stimulation during perfusion with a solution containing 4·2 mM/l. of K^+ and 0·275 mM/l. of Ca^{++}. It was found that when the solution was changed to one containing $6{\cdot}4\times10^{-5}$M A.T.P., the fibrillation was not arrested, but on changing to a solution containing $1{\cdot}6\times10^{-6}$M Mg^{++} in addition, the fibrillation was arrested in 4 out of 7 experiments.

Effect of Versene and A.M.P.—A substance which is known to bind calcium ions, and thus to inhibit their activity is ethylenediamine tetra-acetate or Versene. It was found that Versene would also arrest fibrillation, but this occurred only when the amount of calcium ions in the perfusion fluid was low and the concentration of Versene sufficient to remove all calcium ions from the solution.

Other phosphates, adenosine monophosphate or A.M.P. and inosine triphosphate were tested, and they also were found to arrest fibrillation in some experiments, though again only when the amount of calcium ions in the solution was low. We did not discover in these experiments whether all calcium ions were removed from solution, and whether the arrest of fibrillation was due to this cause. The results are shown in Table V.

TABLE V.—EFFECTS OF ADENOSINE TRIPHOSPHATE (A.T.P.), ADENOSINE MONOPHOSPHATE (A.M.P.), INOSINE TRIPHOSPHATE (I.T.P.) AND ETHYLENE DIAMINE TETRA-ACETATE (VERSENE)
Fractions are the proportion of hearts in which fibrillation was arrested

	Molar concentration	Millimolar calcium concentration 2·2–4·4	0·275–0·55
A.T.P.	$1{\cdot}6\times10^{-4}$	7/10	5/7
A.M.P.	$2{\cdot}9\times10^{-4}$	0/3	0/2
	$5{\cdot}8\times10^{-4}$	0/1	1/3
	$8{\cdot}7\times10^{-4}$		1/1
I.T.P.	$1{\cdot}6\times10^{-4}$	0/5	2/2
Versene	$3{\cdot}2\times10^{-4}$	0/4	5/7

The effect of dinitrophenol.—In the hope of obtaining a clue to the meaning of the results with A.T.P., to learn, that is, whether A.T.P. normally plays a role in the cell membrane, we investigated the action of 2,4-dinitrophenol which is said to uncouple oxidation and phosphorylation. The energy derived from oxidation is used in part to convert A.D.P. or A.M.P. into A.T.P. by adding one or two phosphate groups. In the presence of dinitrophenol (D.N.P.) the energy derived from oxidation cannot be used in this way, and A.T.P. cannot be formed. In consequence, if A.T.P. normally plays a part in preventing fibrillation, the addition of D.N.P. to the perfusion fluid should cause persistent fibrillation in conditions in which it would not otherwise occur.

In a series of experiments, shown in Table VI, carried out on hearts which did not fibrillate for more than 4 min. after stimulation, the addition of D.N.P. in a concentration 5×10^{-5}M caused them to fibrillate for periods from 15 to 35 min.; at the end of this time the perfusion was continued without D.N.P. and the hearts then reverted to normal rhythm. These results were obtained in solutions containing calcium both in higher and lower concentrations (Armitage *et al.*, 1957).

DISCUSSION

The theory of auricular fibrillation which was almost universally accepted for about thirty years was that of a circus movement of an excitation wave around the large veins; this movement persisted so long as the refractory period of the auricular muscle was short (*see* Lewis *et al.*, 1918–20, 1921). In 1948 and 1950 Scherf and his colleagues published papers suggesting that rapid impulse formation in one or more centres was rather to be regarded as the underlying cause, and a similar conclusion was reached by Prinzmetal and his colleagues (1950). Ventricular fibrillation was studied by Moe *et al.* (1941); it was precipitated by a D.C. shock and was believed to be due to a re-entry of impulses attributable to a progressive decrease in refractory period combined with a progressive increase in conduction time.

All workers are bound to interpret phenomena in terms of the observations their methods allow them to make, and our study of the fibrillation in the ventricles of the isolated rabbit heart has led us to emphasize different aspects of fibrillation. Our general method has been to induce fibrillation by rapid stimulation of the ventricular muscle, and then to see how long it persisted when perfusion fluids of different composition were used. In the course of this work we have observed that rapid stimulation or indeed stimulation of any kind is not an essential factor in the production of fibrillation. Thus we have found that when the potassium concentration is reduced to 1·4 mM/l. the ventricles fibrillate spontaneously. The normal rhythm suddenly disappears and fibrillation begins. This result was obtained earlier by Grumbach *et al.* (1954). The fibrillation can be arrested by changing to a solution with a higher potassium concentration. Further, we have found that when the potassium concentration is 11·2 mM/l., no rate or duration of stimulation has ever produced fibrillation even while it was applied. Next we have observed that when fibrillation has been established, perfusion with A.T.P. caused reversion to normal rhythm, and subsequent return to a solution without A.T.P. once more brought back fibrillation. Finally, observations (Burn and Goodford, 1957) have shown that when fibrillation was established at 37°, cooling to 32° C. caused reversion to normal rhythm, and re-warming to 37° again caused fibrillation. Thus by lowering potassium concentration or by removing A.T.P. or by raising temperature the change from normal rhythm to fibrillation was induced, and the reverse procedures restored the normal rhythm. These results indicated not only that fibrillation is reversible, as was already known, but that it can be produced and arrested alternately by changing the composition of the fluid perfusing the heart without the use of electrical stimulation.

An attempt can be made to interpret these changes in terms of the movement of ions across cell membranes, or in terms of the part played by ions. We may first consider the effect of reducing potassium. There is normally a much greater concentration of potassium within the cardiac muscle cell than there is without, and the potential difference on the two sides of the membrane depends on the difference in concentration. When the external potassium concentration is reduced to one-quarter, this difference must be greatly exaggerated, so that perhaps because of this the insulating properties of the membrane break down, and it becomes unstable; thus the condition of fibrillation arises. However we have recently observed that this spontaneous fibrillation does not occur when calcium is also reduced to one-quarter, so that the spontaneous ventricular fibrillation may be due to a rise in the Ca/K ratio rather than to the fall in potassium.

Fibrillation can be arrested by adding A.T.P. to the perfusing fluid, and it can then be re-established without electrical stimulation by withdrawing the A.T.P. The part played by A.T.P. cannot be related to metabolic processes inside the cell since A.T.P. does not penetrate the interior of the cell. A.T.P. is known to combine with calcium ions, and it is possible that in abolishing fibrillation, A.T.P. is combining with calcium ions not within the cell but within the pores of the cell membrane. This idea assumes that fibrillation is caused by an excess of free calcium ions in the membrane and that it stops when this excess is removed.

The arrest of fibrillation by cooling from 37° to 32° C. is likely to be due to a lengthening of the refractory period. It has been observed by Hollander and Webb (1955) that a fall of

temperature prolongs the duration of the action potential in the atrium, which means that it prolongs the period in which the cardiac cells are inexcitable and so terminates the fibrillation. When the temperature is raised again we have observed that fibrillation reappears without electrical stimulation.

These examples illustrate in what terms three conditions may be discussed in which fibrillation can be converted to normal rhythm, and normal rhythm back again to fibrillation without intervention of electrical stimulation.

We may now consider atrial fibrillation produced by applying stimulation at a rate of 750 per min. during the infusion of acetylcholine. Attention has already been drawn to the evidence that acetylcholine can diminish the duration of the action potential (from between 150 and 200 msec. down to periods as short as 10 msec.), that it increases the membrane conductance and the permeability to potassium. Hoffman and Suckling (1953) also found that when a stimulus was applied in the presence of acetylcholine fairly early in the relative refractory period, it caused not one but a succession of action potentials of very short duration, sometimes lasting for 10 min., at rates of 700 to 1,500 per min. This has been confirmed by Dr. M. H. Draper (1956). In our experiments the rate of stimulation used was 750 per min., so that there was an interval of 80 msec. between stimuli, which might well arrive early in the relative refractory period, and so set up such a succession of action potentials.

The cause of the succession of action potentials has been discussed by Segers (1947) who stressed the importance of the supernormal phase of excitability first demonstrated in cardiac tissue by Adrian (1920). Segers pointed out that when several contractions follow one another sufficiently rapidly, each stimulus arriving during the supernormal phase following the preceding contraction, the supernormal phases pile up, the excitability steadily increases and the threshold of excitation falls until it disappears. Continuous depolarization and repolarization may then occur without a further stimulus.

Fibrillation persisted in the atria only so long as acetylcholine was infused, and the changes produced by acetylcholine were therefore essential for fibrillation. Of these the increased permeability to potassium would seem from Holland's observations to be of importance since he found that fibrillation occurred in the isolated atria only when the exchange of sodium and potassium ions exceeded 10 mM/kg. wet tissue per 5 min. This value was reached when stimulation was applied at rates of 600 per min. or more in the presence of 5×10^{-4}g./ml. acetylcholine. The addition of quinidine to the system inhibited both the fibrillation and the increase in the ion exchange.

The short duration of the action potential is clearly important for fibrillation, for if fibres in a given area are out of phase, they may stimulate one another so long as the duration of the action potential is short and the recovery of excitability is rapid. They may thus maintain the fibrillation. Hoffman and Suckling (1953) have suggested that the normal long action potential is maintained by metabolic processes which may delay repolarization, and that they are inhibited by acetylcholine. Since adrenaline increases the duration of the action potential and can prevent fibrillation due to stimulation in the presence of acetylcholine, it may do so by increasing these metabolic processes.

While it has been seen that ventricular fibrillation can be produced without electrical stimulation, most of our observations were made by inducing fibrillation by stimuli at the rate of 600 per min. upwards. Moe *et al.* (1941) observed that when they produced fibrillation by the application of a D.C. shock, the onset of fibrillation was preceded by discrete deflections at progressively decreasing intervals. The succession of action potentials evoked in the atria which have just been discussed seem to be a similar phenomenon.

The factors which have been shown to modify the proportion of hearts in which persistent ventricular fibrillation was observed are factors known to modify the duration of the action potential. Dinitrophenol, which shortens the action potential in the frog ventricle as shown by Macfarlane and Meares (1955) causes ventricles to fibrillate when they otherwise do not. A fall in temperature which has been shown to lengthen the action potential (Hollander and Webb, 1955) causes ventricles to cease fibrillating.

The action of calcium requires special consideration. As long ago as 1936 Schütz stated that in high-calcium solutions cardiac muscle becomes re-excitable at a relatively early stage of repolarization. This was confirmed by Weidmann (1955). Hoffman and Suckling (1956) found that in papillary muscle when the amount of calcium was high repolarization occurred at a faster rate, while when the amount of calcium was low the action potential was longer, due to a prolongation of the plateau. We found that high calcium solutions raised the proportion of hearts which fibrillated on stimulation.

The observations of Hoffman and Suckling (1956) on the effect of changes in calcium concentration on excitability in the auricles were of particular interest. They showed that when the calcium concentration was lowered, the change in auricular excitability was biphasic; at first the auricular tissue was more excitable, and then, below 0·27 mM/l, it was

less excitable. These changes are very similar to those in the proportion of hearts in which the ventricles fibrillated on stimulation (*see* Fig. 7). In skeletal muscle calcium stabilizes the membrane, and when calcium is reduced, spontaneous activity develops in the fibres. The increased tendency to fibrillation which is seen when calcium is lowered from 2·2 mM/l. to 0·27 mM/l. may be the corresponding change in cardiac muscle, occurring because the membrane becomes more permeable and its diminished resistance gives rise to greater excitability. If, however, the calcium is reduced below 0·27 mM/l., the leak of ions through the membrane perhaps becomes so great that many of the fibres are inexcitable, and so there is a decreasing tendency to fibrillation. The view that calcium is mainly concerned in stabilizing the membrane in cardiac muscle does not, however, explain why raising the calcium to 4·4 mM/l. causes fibrillation in a much larger percentage of hearts.

Of the observations so far made the effect of changes in potassium concentration are the most difficult to understand. Potassium may cause fibrillation, and also may arrest it. Thus Grumbach (1956) has shown that, after an injection of adrenaline, the injection of KCl into the fluid perfusing an isolated heart caused fibrillation. A discussion of the opposite effects of potassium on arrhythmias whether produced experimentally or occurring clinically is given by Scherf and Schott (1953).

In atrial fibrillation in the heart-lung preparation a slow infusion of KCl into the blood sufficient on the average to raise the plasma K^+ concentration from 5 to 8 mEq./l. arrested the fibrillation. Similarly, in ventricular fibrillation when the potassium concentration was doubled, fibrillation did not occur in any heart, and, on the other hand, a diminution of potassium in the perfusing fluid increased the proportion of hearts fibrillating. Now several observers have found that an increase in extracellular potassium concentration shortens the duration of the action potential (Yoshida, 1926; García Ramos and Rosenblueth, 1947, who worked on the dog auricle, and Weidmann, 1956). Weidmann's observations showed that the shortening could be obtained without preceding depolarization. Thus it seems that an increase of K^+ ions externally can hasten repolarization in some way, and if the rate of repolarization is indeed concerned with fibrillation we would expect that potassium would increase the tendency to fibrillation rather than oppose it. The amounts of potassium used by us to arrest atrial fibrillation seem to have been less than the smallest amount used by Weidmann, and it may be that the amounts necessary to arrest fibrillation have another action. Hodgkin and Keynes (1954) have shown that in *Sepia* nerve the sodium pump is depressed both by dinitrophenol and also by a low external potassium concentration. If this is true for heart muscle the effect of low potassium in inducing fibrillation and that of higher potassium in preventing it may be related to its effect on the sodium pump. Since dinitrophenol increases the tendency to fibrillation it is probable that this is because it depresses the sodium pump, and if so the antifibrillatory action of the amounts of potassium we used may be explained by an increase in the action of the sodium pump. Fortunately this can be tested experimentally.

The main results of the investigations are in the first place methods for the study of both atrial and ventricular fibrillation which are relatively simple to use; in the second place observations which indicate that an approach to fibrillation in terms of the movement of ions is likely to be very fruitful. On the whole, the attempt to explain fibrillation in terms of the factors affecting the action potential has had considerable success; indeed, what failure there has been does not suggest that the approach is wrong, but rather that through a study of fibrillation more light may be thrown on the ion movements in cardiac tissue when a normal rhythm is being maintained.

Summary

Hitherto no methods have been available for the quantitative study of factors influencing fibrillation in either the atria or the ventricles of the heart. Three methods are now described. Atrial fibrillation has been produced in the heart-lung preparation of the dog by applying brief stimulation to the atrium during the slow infusion of acetylcholine. Following this observation fibrillation has been produced in the isolated atria by stimulation in the presence of acetylcholine. Fibrillation occurs when the exchange of sodium and potassium ions reaches a certain value per unit of time.

Ventricular fibrillation has been studied in the isolated rabbit heart. When electrical stimulation at a rate of about 600 per min. is applied to the ventricles until they fibrillate, the continuance of fibrillation after the stimulation has stopped has been shown to depend on various factors. Fibrillation is more likely to continue the lower the potassium concentration of the perfusing fluid, and the higher the calcium concentration. The effect of variation in the calcium concentration is, however, triphasic. Fibrillation is more likely to continue in the presence of dinitrophenol, and on the other hand, fibrillation is arrested in the presence of adenosine triphosphate. Fibrillation is attended by an increased loss of potassium ions

from the ventricles. These and other observations represent the early stages of an investigation of the factors involved, but they already suggest that fibrillation is closely related to the rate and extent of exchange of ions across the cell membrane.

I am indebted to Dr. M. H. Draper and to Dr. E. M. Vaughan Williams for suggestions which they have kindly made.

Section of Pædiatrics

President—D. V. HUBBLE, M.D., F.R.C.P.

[*May* 24, 1957]

DISCUSSION ON THE PROBLEMS OF SPINA BIFIDA CYSTICA

Dr. D. MacCarthy and Dr. Mary Lindsay:

Spina Bifida as a Pædiatric Problem

When a child presents multiple problems it is best if he can be looked after as a whole by a pædiatrician who co-ordinates the work of the specialists. Cerebral palsy is an obvious example but spina bifida, if the child survives, requires the same sort of care; fortunately there are much fewer cases. We would like to emphasize that care of the whole child in spina bifida, as in other diseases, includes care of the parents, and even if the infant dies in the first few weeks the pædiatrician has still a responsibility.

Though we cannot here discuss the causation and pathology of spina bifida, the question of its incidence and its heredity does concern us. Reports in the literature show a considerable variation in different parts of the world. Record and McKeown (1949) showed a falling incidence in Birmingham in 158,000 births in the course of seven years. It was 3·35 per 1,000 in 1940 and 1·63 per 1,000 in 1947, the average being 2·45 per 1,000. McMahon *et al.* (1953) record 2·53 per 1,000 in Rhode Island and Harris and Steinberg (1954) 2·4 per 1,000 in Rochester, Minnesota. The highest published figure of the incidence of spina bifida in England after Birmingham 1940 is that of Malpas (1937) in Liverpool who, in 13,964 births, found an incidence of 2·8 per 1,000, i.e. approximately 1 in 350 births. A still higher figure is recorded by Coffey and Jessop (1955) in Dublin, who in 12,552 births found an incidence of spina bifida of 4·2 per 1,000, i.e. approximately 1 in 240. Professor L. S. Penrose (1957) thinks that a geographical distribution of high or low incidence is probably definable in Europe.

Inquiry into the incidence of spina bifida in Buckinghamshire shows a figure comparable to Liverpool, one of the highest recorded in England. This part of England may even be one of these areas of high incidence suggested by Professor Penrose. In the course of this inquiry we have learnt many facts about the fate of these infants and the sufferings of their families. Taking all births in our two hospital maternity units (including unbooked cases) and three general practitioner maternity units in the course of six years, there were 11,300 births and 32 cases of spina bifida, an incidence of 2·8 per 1,000. The incidence among hospital births is about 30% higher than in the general population if unbooked cases are included, as cases of spina bifida and anencephaly tend to go with complications of pregnancy and labour which lead to admission as emergencies (Penrose, 1957). 11 of our series were still-births and 21 live births. This means that a pædiatrician who sees 1,000 newborn infants a year will see between 2 and 3 live-born cases a year in maternity homes or hospitals. In addition, cases born at home will be brought to his notice and may double this number. Many pædiatricians see 2,000 or 3,000 newborn infants a year and with cases born at home will be confronted with spina bifida problems twelve times a year.

The fate of our 21 live births can be briefly told. 11 died in hospital under twenty-eight days. 6 died elsewhere between the ages of two months and two years, leaving disturbing memories in their families. They all developed hydrocephaly and parents who could not keep them at home were relieved of the burden (by various expedients) either temporarily in our hospital beds or permanently elsewhere. The remaining 4 are still alive. A boy, aged 4½, is intelligent, walks and has sphincter paralysis. A girl, aged 6, is intelligent, walks, or rather waddles, and has sphincter paralysis. A girl, aged 2, is intelligent, walks on one strong leg and one weak leg, has a very deformed back, but tight sphincters. A boy of 9 months is intelligent, has a sacral skin-covered tumour with slight neurological involvement of the lower limbs. We have also, from another county, a 4-year-old girl with a skin-covered myelomeningocele, intelligent, and complete paraplegia at D.12, incontinent, and rejected by her family from birth. She has spent all her life in a hospital and is soon going to a Barnardo home.

This group of cases is fairly representative of the conditions to be found in survivors who amount to 20% of the total. The first three had their myelomeningocele removed as newborn infants. If a policy of masterly inactivity had been adopted they might have developed meningitis and died, but more probably they would have survived as they did not develop any severe degree of hydrocephaly.

Salvage of apparently hopeless cases is now attempted in many fields with some worthwhile results. But when a child with myelomeningocele is born it is very difficult for the

parents to grasp fully what the child is in for and what they themselves are in for if it survives. The reaction of fathers very often is mentally to "write off" this child. Often the very first question he puts is, "Will the next child be all right?" But mothers who, one must remember, have known their child internally for several months feel different and instinctively wish for its survival, though occasionally they have a revulsion against it. When the parents do not feel alike about the child there is a danger to their relationship and we have seen this become serious when, as time goes on, a child becomes hydrocephalic. We have learnt from close follow-up of the children surviving for a few wretched years that mothers suffer far more over the hydrocephaly than over the raw area on the back. One cannot formulate any rules for the management of these bad cases. To adopt a policy of taking charge of the baby completely and removing it from the sight of parents to hospital, where they thrive, or to linger in quiet corners elsewhere till the end comes, would be utterly wrong for certain parents, who demand out of human feelings, or a moral or religious attitude, that the utmost be done to save their child.

The occurrence of other affected children in a family is familiar to everyone. We have met this three times in our small series. To generalize on the findings with regard to heredity of the grosser nervous system defects Penrose (1946) has shown that advanced maternal age gives an increased incidence. Polman (1951) in 105 cases of anencephaly found an incidence of 6·5% of gross nervous system abnormalities in sibs. Penrose (1957) from a similar study rates the likelihood of a second affected child at about 1 in 20 and of a third affected child 1 in 4. Malpas (1937) found in 39 fraternities containing a spina bifida, a still-birth and neonatal death-rate of 29%. Parents have a right to know these gloomy facts if they ask for them, and if they do not ask it is a matter for our private conscience whether we tell them or not. They often fear another abnormal child and wish to make the best life they can for the afflicted child.

If we are asked to salvage one of these severe cases, we and the parents ought to know about the failures as well as the successes and we should remember that even with arrested hydrocephaly individuals have a shallow cortex and may in character be shallow also. We doubt whether this Discussion will convert our pessimism about spina bifida cystica into optimism. We think it will be disquieting if it does.

Mr. G. H. Macnab:

I shall confine my remarks to my own observations in a series of 200 cases.

Pure meningoceles, in comparison with myelomeningoceles, occur in about a ratio of 1 in 5. Cervical meningocele must be distinguished from the occipital encephalocele, the latter often having a narrow neck in relation to a small defect in the occipital bone, the sac hanging down over the cervical spine. The occipital encephalocele always contains neural tissue in its neck and the fourth ventricle may be dragged out into the sac. On the other hand, the cervical meningocele has a narrow neck and contains no neural content. Ventriculography may show some dilatation of the ventricular system, but removal of the sac does not give rise to post-operative hydrocephalus. I operate on patients with meningocele when four to six months old, after ventriculography. Pure meningoceles are always covered by skin, even though it may be thinned out, but sacs present in the sacral region and covered by skin often prove to be myelomeningoceles. This is due to the fact that many branches of the cauda equina have passed out through their intervertebral foramina above the spinal defect so that the neural content of the sac is small. Pure cases of meningocele never produce clinical evidence of paralysis, but cases of sacral myelomeningocele covered by skin may show no evidence of paralysis in the lower limbs, as the nerve supply is intact, but at a later date control over micturition and defæcation is shown to be defective. The pure meningocele always has a narrow neck to its sac and in a few cases we have evidence of a shutting-off of the neck by fibrosis, but on the other hand, on clinical examination the narrow neck may be masked by the presence of a deposit of lipomatous tissue. It follows that the diagnosis of a pure meningocele is made at operation, so I always warn the parents that my operation is exploratory in character. No guarantee of cure can be offered until the findings show a sac with a narrow neck containing cerebrospinal fluid and not more than three to four fibrils which always prove to be fibrous and not neural.

My definition of the myelomeningocele is a sac lined by the membranes surrounding the

spinal cord which contains cerebrospinal fluid. Into the sac pass the spinal cord or nerves of the cauda equina. These nerves pass to the fundus of the sac wall and form part of its wall, true epithelium is absent and ulceration is seen at birth. Within a few days granulation tissue begins to form and healing takes place by fibroblastic reaction in four to eight weeks, leaving a scarred area in the fundus of the sac. The initial appearance of ulceration suggests infection and often a poor prognosis is given but only 18% have developed meningitis in my series. The sac is often loculated due to sheets of arachnoid fusing together, so that the cerebrospinal fluid in the spinal canal is shut off from the content of the sac and thus inflammatory reaction remains localized. The greater the loculation in the sac the greater is the neural content.

In 50% of cases that have come to post-mortem there have been pathological changes in the spinal cord proximal to the sac, mainly in the form of hydromyelia, and Dr. A. H. Cameron has shown that myelinization of the tracts has been retarded. These pathological changes in the cord account for the curious distribution of the paralysis in the lower limbs, e.g. a flaccid limb with movements present in toes, or a return of a degree of motor power to a limb that appeared completely flaccid at birth. The clinical appearance of the sac with its poorly-formed skin covering suggests the diagnosis of a myelomeningocele and the presence of paralysis confirms it, but 21% of my cases show a membranous covering with no paralysis and those in the sacral region show a skin covering with no paralysis in the lower limbs, though the bladder is usually involved.

Myelomeningoceles without clinical evidence of paralysis form a small but important group for they can be de-capped and the neural content replaced into the spinal canal and fascial flaps brought over the spinal defect. The timing of this operation is dependent on the fact that 47% of my cases of myelomeningocele developed progressive hydrocephalus within the first eight months of life due to the presence of an Arnold-Chiari malformation. The onset of hydrocephalus may be slow, or even arrest in a few cases, so the de-capping operation for myelomeningocele is not carried out under eight months. An Arnold-Chiari malformation varies in size but does not act as a plug to the foramen magnum and cervical canal. In these cases there is usually a communication of cerebrospinal fluid between ventricle and spinal canal. The cause of slow development of hydrocephalus appears to be venous congestion over the deformity, setting up arachnoiditis and blocking of the sub-arachnoid space.

Fate of the Child with a Myelomeningocele—the Early Case

Hydrocephalus.—46 cases showed evidence of hydrocephalus at birth, and 23 cases showed onset of hydrocephalus between the second and eighth month of life. Ten cases were kept under observation for one year before I could satisfy myself that progressive hydrocephalus was not present. Rapid progressive hydrocephalus with raised ventricular pressure over 250 mm. occurring in the first three months will lead to death within one year. Slow onset with low pressure may arrest. If ventricular and spinal dye absorption is high, there is a communicating hydrocephalus with a proportionate degree of absorptive surface. I carry out a subdural dye absorption study and if the result is over 50% I connect the ventricle with the subdural space by the use of a plastic disc.

Meningitis.—The clinical state of so-called ulceration seen in the first week of life would suggest that meningitis was inevitable in all cases. An analysis of 150 cases showed 23 with large thin membranous ulcerated sacs that did not develop meningitis during their life. 28 with ulceration developed meningitis during conservative treatment, and 15 with severe ulceration developed dense fibrosis without meningitis so that healing of the sac took place without operation. The remaining cases had a mild degree of ulceration that healed in a period of four to eight weeks. If I see a thin membranous ulcerated sac I cover it with skin flaps if the size of the spinal defect permits.

Leaking of the sac.—53 cases out of the 150 developed a leakage of cerebrospinal fluid within the first six months, and 30 cases survived. The high survival rate from rupture of the sac is largely due to loculation of the sac shutting it off from full communication with the spinal canal.

Fate of the Child with a Myelomeningocele—the late Case

Incontinence of urine.—This type of paralysis is such that the urine dribbles away continuously, so back-pressure does not occur. Acquired hydronephrosis is a late development, and urinary infection is usually low-grade as there is no stagnation, and can be kept under control with the use of sulphonamides or antibiotics for many years. Trophic ulceration around the vulva in the female with secondary infection is a severe complication, and in my cases I have had to resort to diversion of the urinary stream by uretero-ileal anastomosis. Where motor paralysis in lower limbs is slight or non-existent the psychological problem of the wet, smelly child at normal school arises about the age of 8 years. If, after the first year of life, you can cause dribbling of urine by pressure on the bladder, no form of conservative treatment will give satisfactory control in later life.

Incontinence of fæces.—It is interesting to note how these children can gain a measure of control with poor sphincter tone. They form a plug of fæces which blocks the anal canal. The child soon finds the correct diet and fluid intake to produce a mild constipating effect. In such a case ureters cannot be transplanted into the colon to control incontinence of urine. In severe cases I carry out colostomy in the adolescent.

Trophic ulceration occurs around the vulva and anal canal in association with incontinence. A period of in-patient treatment will often clear up the anal ulcers, but where urinary incontinence is severe the stream has to be diverted. Trophic ulceration on the dorsum of the foot or toes, due to pressure by shoes, may respond to conservative measures, and sympathectomy is of great value if the response is poor, but where ulceration occurs on a weight-bearing surface like the heel it usually ends in amputation. In such cases the motor paralysis is usually slight and sensory loss confined below the level of the knee-joint so that amputation can be carried out.

Motor paralysis.—Most infants retain some power in the quadriceps, so that contractions suggest to the mother that the whole leg moves. A fair proportion of those children who survive beyond the age of two years have sufficient tone to stabilize the knee-joint, so that boots and calipers may give them locomotion. These children have never walked and their chief difficulty is learning to walk is flexion contractures at the hip-joints set up by pain on attempted movement. De-capping of the myelomeningocele, covering of spinal defect with fascia, and closure of wound with healthy skin relieves pain on movement and allows the hip-joints to be extended. Attempted walking is greatly assisted at this stage by the supply of stiff leather boots with uppers to mid-calf, and without toe-caps. These boots keep the feet at right-angles to the tibiæ where the paralysis is greatest and give a firm base for weight-bearing.

SUMMARY.—Pure meningoceles only form a small percentage of cases of spina bifida cystica. Their removal results in a normal child. There is also a small group of myelomeningoceles without clinical evidence of paralysis that can be restored to normality by de-capping. Early onset of hydrocephalus will lead to a rapid death and 47% of cases of myelomeningocele are associated with hydrocephalus. The complications of meningitis and leakage of cerebrospinal fluid from myelomeningoceles account for 26% of deaths. In the late cases, incontinence of fæces is more easily controlled than that of urine. Trophic ulceration in relation to a toe will usually heal with rest or rest and sympathectomy. Trophic ulceration on a weight-bearing surface usually leads to amputation. If motor paralysis is confined to below the level of the knee-joint walking with the aid of instruments will usually be possible provided that the myelomeningocele has been de-capped allowing extension of the hip-joints.

Mr. D. F. Ellison Nash:

The Management of Fæcal and Urinary Incontinence and the Associated Hazards

There are two distinct, but nevertheless, related clinical problems. The first is that of the neglected case which requires full investigation, assessment and probably a good deal of salvage work before one can set about an effective rehabilitation programme. The second is that of the management of the sphincter deficiency from birth, and the prevention of retention damage.

The first group has really been the basis of my personal experience. Most children have come between the ages of 5 and 10 years without previous urological investigation. A considerable number already had advanced renal disease. In addition, many of the children had gross orthopædic deformities, penetrating ulcers, a severe educational deficit and a background of dismay and depression. Our urological programme has always had to be fitted into the general plan of management of the other complications.

Considerable variation in sphincter and viscus involvement, both on the motor and sensory side, is produced by growth of the child, by change of posture, by increased activity and by the development of the prostate and uterus at puberty.

Whichever group we are considering—the neglected late case, or the neonate—it is necessary to see clearly our ultimate goal. It is not only survival, but a full education, leading to employment and a satisfactory social life. Though in many cases we cannot hold out hope that there will be a normal adult life, one knows both men and women who have so overcome their total disability, even with amputation, that they can go swimming, or enjoy an adequate game of squash, in spite of unreliable sphincters.

Bowel control.—Even in those who seem to have a fairly good anal sphincter mechanism, there is a variable lack of rectal sensation. This leads to constipation and to the development of a megacolon which requires rehabilitation by regular enemas, neostigmine and training.

Those children who have a patulous anus, similarly lack sensation. There is therefore no spontaneous evacuation of the rectum. The initial task is to remove the inspissated faeces by various means—manual evacuation, judicious enemas using bile, or manoxyl as a solvent. Subsequently the general principles of management are those of a colostomy.

Some children can be trained to regular evacuation by the use of a glycerin suppository if the anus is tight enough to keep the suppository in position. A warning must be given about manual evacuation and enemas since it is possible to injure the insensitive rectum and produce a pelvic abscess, or peritonitis. Fæcal incontinence is not inevitable, and training leads to the stage when there is nothing more than a slight stain on the underclothes at the end of a strenuous day.

Micturition.—The management of micturition is concerned with two things; retention, with pressure damage on the kidneys and infection, and urinary incontinence. The normal, automatic bladder of the baby prevents our assessing whether the bladder is distended, or whether there is residual urine. You must know—"is the urine leaking out *all* the time?" or "does it come in squirts with dry intervals of even a minute?" If there is no residual and the urine is clear, excretion pyelography can be postponed until nine months or a year. If the bladder is distended or if there *is* residual urine, then full urological and instrumental investigation is imperative. If the bladder is being emptied continuously or intermittently the infant should be "pot" trained at set times with increasing intervals to educate what may remain of the neuro-muscular mechanism.

After an adequate period of observation and full urological investigation, the cases may be separated into one of three main groups. It must, however, be emphasized that the intellectual and physical capacity is of paramount importance in planning the treatment. (Table I).

TABLE I.—URINARY INCONTINENCE: CLINICAL CLASSIFICATION

Group 1.	Complete incontinence *without* residual urine.
Group 2.	Continuous or intermittent incontinence *with* residual urine.
	(*a*) without sacculation or upper tract dilatation.
	(*b*) with sacculation and/or upper tract dilatation.
Group 3.	Retention with overflow incontinence.
	(*a*) without back pressure structural change.
	(*b*) with back pressure structural change.

Group 1: A continuous leak, or an automatic bladder with no appreciable residual urine. This is the state of affairs found in the normal newborn baby. Many spina bifida babies have this relatively normal bladder behaviour when born, and only develop complications as the months pass, possibly from superadded infection. The treatment of this group is the control of infection, if it arises, and careful observation for deterioration.

Group 2: Incontinence *with* residual urine. The obstruction must be relieved. In the boy this is done by transurethral bladder-neck resection, and this may be adequate to allow normal control to develop. A moderate amount of sacculation in the urinary tract does not seem to matter once the obstruction has been relieved. If diverticulum formation is severe, or if the ureters have become grossly dilated and rigid, the relief of the obstruction must be really radical and undoubtedly in some of these patients the immediate diversion of the urine from the bladder to an isolated ileal loop is preferable. A number of patients with only a moderate amount of residual urine may overcome their disability by regular manual expression of the bladder, but if they *are* able to express the bladder satisfactorily, it is likely that they have stress incontinence when the bladder is only moderately full. If infection persists in the presence of residual urine a diversion operation is necessary.

Group 3: This represents the really dangerous group—those with retention-overflow, and in all probability, irreversible pyelonephritis.

This broad basis serves as a guide in planning treatment, details of which have already been published (Nash, 1956*a*, *b*, 1957).

First, there is time training. In this the mother needs to find out how long the child can go without leaking, and she then trains the child to micturate by straining at set times. With an intelligent mother and a co-operative child complete control may be obtained and strict time training forms an essential part of management even in those who have had various operations.

The second aid is manual expression and this is necessary if there is resistance at the bladder-neck due to alteration of angle, or simple muscle inco-ordination.

If manual expression is not possible retention is relieved by resection of the bladder-neck. This is a difficult procedure performed with a miniature resectoscope. All those patients who have a residual urine of more than 60 ml. after manual expression require resection to allow manual expression to be effective. In boys, overdoing the resection produces continuous incontinence necessitating the use of a urinal and if the resection is insufficient the obstruction recurs as the prostate grows. In girls, resection frequently leads to a vesico-vaginal fistula.

Urethral plication was originally devised for the treatment of post-prostatectomy incontinence. It consists of the insertion of supporting and partially compressing mattress

sutures of silk or nylon between the ischiocavernosus muscles in the perineum. The bulbocavernosus muscle is frequently atrophic and sometimes completely absent. The cases particularly suitable are those boys who have some degree of control. It is an operation with very little risk and tremendous dividends; in my hands it has failed several times, but in five out of twelve it was completely successful. It can be used after bladder-neck resection to restore control in certain cases.

Pudendal neurectomy.—I have very little experience of it. I have used it once to reduce very severe priapism which was preventing manual expression and use of a urinal.

Urinals.—No effective urinal has been devised for the girl, and an indwelling catheter is thoroughly undesirable. For boys with no appreciable residual urine, modern plastic lightweight urinals are worth a trial, but in many cases something more is needed. One of the main difficulties is that wearing a urinal night and day leads to a cauliflower-like penis, risk of meatal stenosis and urethral fistula.

Ileo-cutaneous ureterostomy.—The complete diversion of urine from the bladder by means of an isolated ileal loop—i.e. an ileo-cutaneous ureterostomy—is an operation which has come to stay. It is a major operation which carries a little risk, but a major reward. It is an irreversible procedure to be undertaken only when it is clear that the degree of incontinence or damage to the urinary tract is such that the patient will be unable to enjoy a full education, profitable employment or a moderately happy social life (Table II).

TABLE II.—ILEO-CUTANEOUS URETEROSTOMY

Conversions from suprapubic cystostomy (renal failure)	7
For vesico-vaginal fistula	3
For infection and incontinence	2
Total	12

Male—2.
Female—10.
Operative deaths—nil.
Subsequent deaths—2 (1 renal: 1 unconnected).
Selected cases awaiting operation—4.
Operation indicated in 16 cases out of 78 observed=20·5%.

The dramatic change in the general health of those children who have been submitted to this radical operation has been almost unbelievable.

In boys, bladder-neck resection, and wearing a penile urinal is appropriate treatment for the majority; those who exhibit back-pressure would probably do better with a diversion operation. In girls, bladder-neck resection should be tried when training and manual expression have failed, but it seems likely that an ileo-cutaneous ureterostomy is the ultimate treatment of choice.

There is no place in my opinion for suprapubic cystostomy, penile clamps or sling operations.

If we take a long-term view we are now in a position to say that urinary or fæcal incontinence must not be accepted as a barrier to the child's intellectual, occupational and social progress; we might fairly speak of spina bifida "*sicca*".

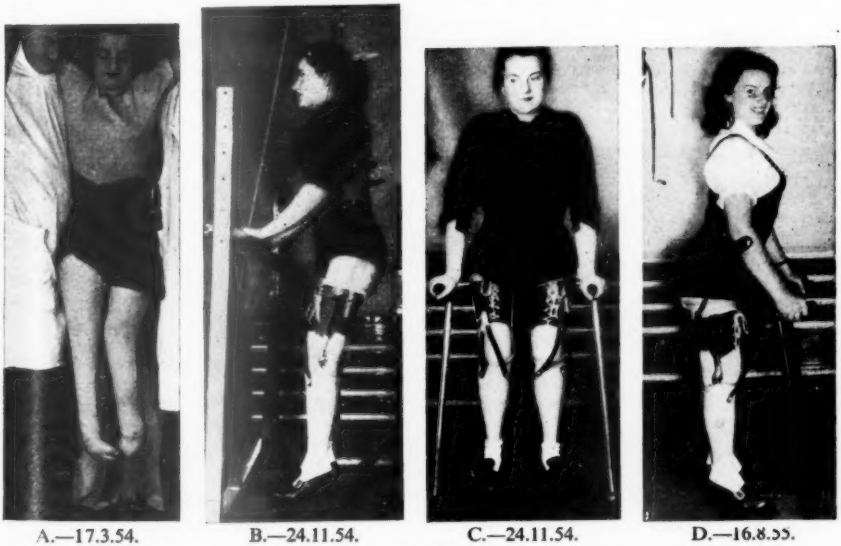
Dr. L. Guttmann [*Summary*]:

The remarkable results achieved in recent years, in the treatment and rehabilitation of traumatic paraplegics, have had their effect on our approach to the management of other forms of spinal paraplegia. No longer is it a question of whether the majority of spinal paraplegics can be returned to useful life but how soon.

In this paper, something is said about the plight of patients with spina bifida who have survived for many years, and complications are discussed which could have been avoided with adequate management from the beginning. It is impossible to cover here the whole ground of this complex problem, and only a few of the pertinent points are mentioned, which have emerged from observation on 40 patients with spina bifida, studied at the National Spinal Injuries Centre, Stoke Mandeville.

Over 50% of the total material reached adolescence, the eldest patient being 41 years old. In most of the patients, the symptoms of paralysis were discovered either immediately following birth or shortly afterwards. In only a few cases did the symptoms develop later and one man with retained myelomeningocele developed a transverse spinal syndrome at the age of 22—below T.11 on the right and L.1 on the left—shortly after his "Dodgem" car bumped into another car at a fair and he was hit at the site of the myelomeningocele.

Skeletal Abnormalities Due to Mal-development and Muscular Contractures



In analysing the skeletal abnormalities found in these patients, one has to distinguish between those due to mal-development of the spine and other parts of the skeletal system and those which develop later, as a result of inadequate management of the patient. Neglect of either may have serious consequences for the later activities and health of the patient. Special attention is drawn to the equinovarus deformity of the feet. If overlooked or neglected in the early stages following birth, this deformity may take grotesque forms and contractures result, which make standing and walking impossible, although the neurological lesion may be only that of a distal cauda equina lesion—say below L.4—where the quadriceps and gluteus maximus are intact. This deformity of the feet is frequently combined with a postural deformity of the pelvis and lumbar spine, due to prolonged positioning of the pelvis in hip flexion. This leads to contracture of the iliopsoas and quadratus lumborum, especially in lesions below L.1, where these muscles are more or less intact, while their antagonists are paralyzed. The result of the contractures of these muscles is a hyper-lordosis with backwards distortion of the pelvis. The following case is a good example:

Case I.—Girl, aged 17. Spina bifida, partial paralysis both legs, talipes equinovarus; several unsuccessful operations to correct deformity. Never able to stand though quadriceps and glutei good both legs. Gradually developed hyper-lordosis and backwards distortion of pelvis through constant sitting in bed or chairs (*see* Fig. 1).

On admission.—Complete cauda equina syndrome below L.4. Having regard to the uselessness of the feet, on the one hand, and the good quadriceps and gluteus maximus function on the other, I felt that below-knee amputation and the provision of artificial legs might enable this girl to stand and walk. Amputation carried out (Mr. Geoffrey Platt).

Iliopsoas contractures and spine and pelvis deformities gradually overcome by hanging in harness (Fig. 1). Aged 18, patient able to walk with elbow crutches. Subsequently, with bladder training, correlating intake of fluid with regular voiding, she became absolutely dry.

Readmission follow-up: walking on elbow crutches improved, health very good, urine sterile, regular function of both bladder and bowels, now employed in a factory.

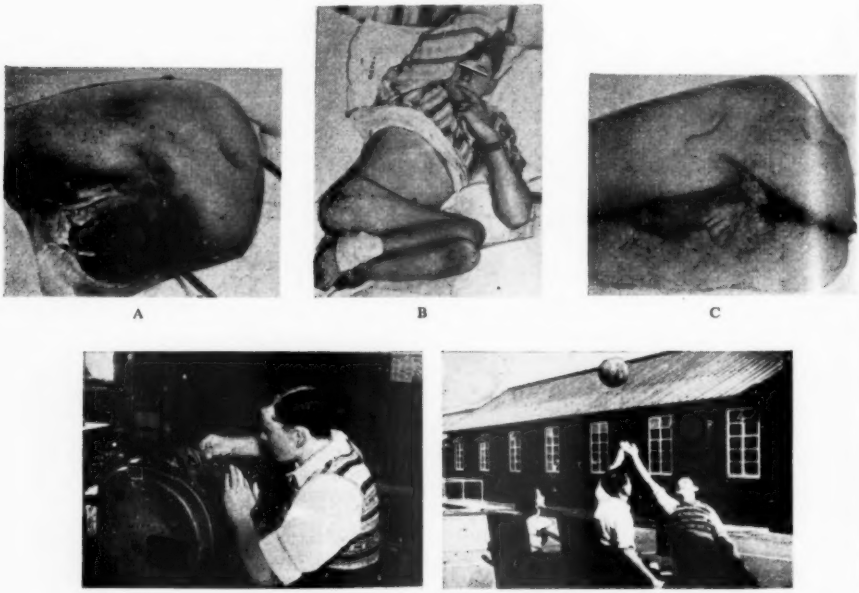
A.—17.3.54. B.—24.11.54. C.—24.11.54. D.—16.8.55.

FIG. 1.

Skeletal Deformities Due to Pressure Sores

Another skeletal deformity, as a result of inadequate management, which may cause most serious consequences, is osteomyelitis, as a result of neglected pressure sores. This complication develops particularly over the trochanteric and ischial areas but may also develop over the ankles and sole of the feet. The infection may penetrate into the deeper tissues and involve, if not checked, the ischial ramus, spreading into the hip-joint, which eventually completely disintegrates (Guttmann, 1954, 1955).

Such serious complications can definitely be avoided, if proper precautions are taken from the beginning. The most important of these is prevention of pressure, at all costs—in particular, by not allowing the patient to sit, once a sore has developed, until it is soundly healed.



However, the best cure for pressure sores in spina bifida, as in other forms of paraplegia, is prevention, and both the patient and his attendants have to be well instructed about the mechanism of formation of sores and the factors promoting them (Guttmann, 1956).

Bladder Paralysis

The value of detailed examination by cystometrogram, cystogram and intravenous pyelogram cannot be overstressed in these patients. These investigations are invaluable for the differential diagnosis between the abnormalities of the urinary system, caused by neurological lesion and infection, on the one hand, and congenital abnormalities of the renal system, associated with spina bifida, on the other. In this connexion, attention may be drawn to the fact that vesical incontinence, which is one of the most predominant clinical symptoms in these patients, may not always be due to paralysis of internal and external sphincters but to overflow, as occurs in paraplegics from other causes. Training the patient, by correlating his fluid intake and output by going to the toilet at regular intervals, which are gradually increased, can be very successful indeed (*see* Case I). It is true that this training is particularly difficult in children with low intelligence or lack of concentration, but, with great patience on the part of the attendants in hospital, institution or at home, encouraging results can be achieved.

Various methods of artificial drainage have been introduced to combat retention and incontinence. Of all the methods used, the most unsatisfactory is the perineal urethrostomy. The disastrous effects resulting from this method are best illustrated in the following case:

Case II.—Patient, now 23, with an incomplete cauda equina syndrome below L.2, following a spina bifida and myelomeningocele, suffering from urinary incontinence, had a perineal urethrostomy done at the age of 17. He very soon developed a sore in the perineal area, which never healed and gradually worsened. He was admitted in a most pitiful condition and, in addition to profound contractures in hips and knees and deformities of feet, he had a large pressure sore, involving the whole perineal area (Fig. 2) and penetrating into the urethra. He was highly septic, with a hæmoglobin of 62%. However, we succeeded in obtaining healing of the sore and fistula. Following circumcision, the frontal part of the urethra was gradually dilated and a catheter passed. Eventually, the urethral fistula was closed by plastic operation and the patient trained in self-catheterization. Fig. 2 also shows the later stages of this patient's successful rehabilitation.

A B C

D E

FIG. 2.

In many spina bifida patients with incontinence, the wearing of a rubber urinal is necessary, to make them socially acceptable. The patient must be thoroughly instructed in the proper wearing of rubber urinals and informed of the risks involved in producing pressure over the posterior surface of the penis.

Care of the Bowels

Incontinence of the bowels in spina bifida patients is easier to combat than urinary incontinence. Rectal incontinence may be due to overflow from overloading of the colon, as the result of chronic constipation. The aim is to develop, in these patients, as is done in other paraplegics, a habit of regular emptying of the bowels, which eventually makes them socially acceptable. Colostomy should be reserved for very selected cases only.

Finally, the importance of systematic education, training, regular work, and employment must be emphasized for the social integration of spina bifida patients. The defeatist attitude of the past, on the part of the medical profession, as well as the public as a whole, is unjustified in many of these patients, and a more optimistic and dynamic approach towards these unfortunate people is imperative. It has been proved that many of them can eventually master their disability and be gainfully employed, in one way or another, and several of the patients of this Centre are now employed in full-time factory work.

Dr. K. M. Laurence:

Hydrocephalus developing in cases of cystic spina bifida can satisfactorily be accounted for by co-existent intracranial malformations or the occurrence of ascending infection. Early surgery may prevent the latter, and a brief survey of 183 unselected cases at the Hospital for Sick Children, Great Ormond Street, suggests in fact a much lower incidence of hydrocephalus in operated cases (40%) than in those treated conservatively (75%). The operation of choice would appear to be deflation of the sac and covering by skin flaps rather than radical excision, as this avoids the risk of damage to the spinal cord.

Mr. A. N. Guthkelch:

The essentials of the management of a case of spina bifida cystica in infancy are to preserve the maximum of neurological function and, if possible, to diminish the risk of hydrocephalus. It is important to enquire whether the timing of the operation upon a case of myelomeningocele can affect either of these.

As to the eventual degree of neurological deficit one might have thought that operation in the neonatal period would prevent any tendency to infection in the exposed cord, and therefore to ascending myelitis with a consequent further loss of neurones, but the results in a personal series of cases have not really fulfilled expectation. As to hydrocephalus, since local infection of the sac sometimes leads to a more generalized involvement of the meninges, and since bacterial meningitis is one of the commonest causes of infantile hydrocephalus, one might suppose that early closure of a myelomeningocele would be helpful in preventing this. Of course, however early one operates the area granulosa is always contaminated, and from time to time a flare-up of infection (and therefore increased intracranial pressure) in the post-operative period must be anticipated—this may have been the origin of the belief, now generally abandoned, that removal of the sac in itself precipitates hydrocephalus. But I have the impression from a group of recent cases too small to be statistically significant that operation in the neonatal period decreases the risk rather than the reverse.

None the less the state of any child with both paraplegia and progressive hydrocephalus is so pitiable that everyone will sympathize with the instinct to postpone repair of the spina bifida until is is fairly clear that the head is not enlarging unduly, and it is certain that no particular timing of the operative procedures is applicable to all cases. Each must be judged as a separate problem.

Finally, we should not forget the possible risks of operation. In a series of over 300 cases I have found the direct operative mortality negligible. In 3 cases the child's neurological deficit was significantly increased by operation, doubtless because in a chronically infected case the identification and preservation of all functioning neural tissue may be very difficult, but the deterioration was never catastrophic. We might reasonably conclude that the benefits of operation outweigh the risks.

Mr. C. H. Macnab (in reply to Mr. Guthkelch):

The venous congestion over the Arnold-Chiari malformation setting up a closure of the subarachnoid space is only one form of cause of the development of hydrocephalus where a myelomeningocele is present. I put it forward as an explanation of the slow development of hydrocephalus, the ventricular pressure usually being low, as there is not a congenital intraventricular block. With regard to the question of early closure of the defect set up by a myelomeningocele to prevent the onset of meningitis or leaking of the sac, I find it is

only in a small proportion of cases that the skin coverage is adequate, and unless you can close the defect in the spine with fascia there is no guarantee that you will avoid leakage of cerebrospinal fluid. As 47% of cases of myelomeningocele develop hydrocephalus within the first eight months of life I do not carry out the early operation unless the defect is a small one and the covering is so thin that leakage and meningitis are imminent.

With regard to the question of active treatment or no treatment, the point I would stress is that these children should not be abandoned by the medical practitioner. It is my experience that when the child is born with the defect the parents often wish it to be removed by the State, but later on they come to enjoy the presence of the child and gain solace by the devoted care they can give to the infant. During this period they must always have the backing of the medical practitioner and specialists so that a little hope for the future can be given to them. The ideal is to encourage the parents to look after the infant and only admit to hospital or institution when the child gets beyond the management of home nursing, or where a definite programme of active specialised treatment is to be carried out.

Dr. Hugh Jolly (*summing up*)**:**

Those who have taken part in this Discussion have shown that they all feel the same uncertainty as to the correct treatment for children with spina bifida and have raised the question when, if ever, they should withhold treatment. Dr. MacCarthy's figures illustrate the frequency of the condition which is indeed a challenge to all of us and can only be tackled by team work. They were obviously depressed by the problem and this depression, which must be common to most paediatricians, was in contrast to the enthusiasm of the surgeons who are tackling the problem. Admittedly, many of the infants we see die before reaching the surgeons and we have had to cope with the emotional problems surrounding their life. At the same time it is obvious that we must be influenced by the fact that the surgeons feel they can do much to help these children.

Dr. MacCarthy emphasized the rift which could so easily develop between the father who was prepared to "write off" the child and the mother, who, with her normal maternal instincts, could never bring herself to think in this way. Mr. Macnab's figures drew attention to the much greater frequency of the meningomyelocele as compared with the meningocele and I am sure that we have all been guilty of diagnosing a meningomyelocele as a meningocele. His statement that the meningocele is always covered by intact skin is a useful diagnostic aid.

Turning to the correct time for operative treatment, it was agreed that the meningocele should be tackled between four to six weeks of age but there was a difference of opinion with regard to the meningomyelocele. In general, Mr. Macnab would leave this until the age of 8 months in order to avoid those who were going to develop hydrocephalus. Mr. Guthkelch felt that earlier operation in cases without gross neurological defect had the advantage of preventing recurrent infection of the sac, even though a flare-up of infection in the post-operative period might precipitate a hydrocephalic episode. It was agreed that the development of hydrocephalus was unrelated to surgery and occurred in about 50% of cases, except in so far as Dr. Laurence's figures suggested that removal of the sac diminished the risk of recurrent infection. The important question as to whether surgery might increase the degree of paralysis of the legs and sphincters was answered by Mr. Guthkelch who showed that such a risk did exist and had occurred in three of his cases. He believed that one should not be influenced against surgery because of it. The frequency of meningitis as a complication was only 18% in Mr. Macnab's large series.

Mr. Nash showed that many of these children could be helped by time training and manual expression and if these methods failed it was essential to determine whether residual urine was present. If this was the case the help of a urologist was essential. His term "spina bifida sicca" as the natural outcome of surgery should encourage us all to do our utmost for those who survive but have urinary incontinence.

Dr. Guttmann showed how much could be achieved by modern methods of rehabilitation and his photographs were most impressive. His figures showing the frequency with which these patients could be employed emphasize that we should not adopt an attitude of hopelessness.

The President asked the searching question as to what we know of the prognosis for these children, and of course at the moment the answer is that we have a very incomplete idea as to their future. Possibly one result of this meeting might be to set in motion some form of machinery to correlate the figures from all over the country, particularly in order to determine the place for surgery. At the same time I would agree with Mr. Macnab that the parents of a child who has been treated surgically are immediately helped emotionally, whatever the result of the treatment.

This meeting has strongly emphasized the value of bringing together paediatricians and those who have to deal with the results in adult life of problems we have to treat in childhood.

Section of Odontology

President—J. A. S. WRIGHT, A.F.C., F.D.S. R.C.S.Eng., H.D.D., F.D.S. R.C.S.Ed.

[*October* 22, 1956]

A Hundred Years of Dentistry

PRESIDENT'S ADDRESS

By J. A. S. WRIGHT, A.F.C., F.D.S. R.C.S.Eng., H.D.D., F.D.S. R.C.S.Ed.

DURING the forthcoming session we will be celebrating the centenary of the Odontological Society, as well as the jubilee of the Royal Society of Medicine of which it was a foundation society.

This is, perhaps, an occasion upon which I may be forgiven for referring to my own special and personal interest in the Section. The practice which I joined in 1923 was started in 1840 by Sir John Tomes, secretary of the Odontological Society of London at its foundation in 1856. He became President in 1862 and for the second time in 1875.

He was succeeded in the practice by his son, Sir Charles Tomes who was President of the Society in 1887. He was followed by Mr. E. G. Betts (President 1905) and then by Sir Harry Baldwin and Mr. Carl Schelling. Baldwin was secretary in 1896 and President in 1915. Schelling was secretary in 1904–5 in the years during which the negotiations were taking place which led to the amalgamation with the other societies to form the Royal Society of Medicine in 1907. He was President of this Section in 1930 and I had the honour to be one of the Honorary Secretaries during his year of office. On his retirement he presented the Presidential badge to the Section.

Prior to 1856 there was no organized professional education for dentists. The only method of obtaining any training was by apprenticeship to a private practitioner. There was, of course, no Dentists Register and clinical instruction was limited to occasional visits to the master's surgery. The pupil might, indeed, gain a good knowledge of dental mechanics, but unless he obtained a medical qualification his chance of having any training in dental anatomy or surgery was remote.

There were a few books available, notably John Hunter's "Natural History of the Teeth" (1771); "The Anatomy, Physiology and Diseases of the Teeth", by Thomas Bell (1829); and in 1847 was published John Tomes's "Dental Physiology and Surgery". Lectures on Dental Surgery were given at Guy's by Joseph Fox in 1799 and by Thomas Bell, who succeeded him.

In 1855 and 1856 two separate efforts were being made to organize dentistry upon a scientific and professional basis. On August 25, 1855, a letter from Samuel Lee Rymer, a 22-year-old dentist, practising in Croydon, was published in the *Lancet*, calling attention to the need for proper dental education and suggesting that the College of Surgeons might examine candidates who might well be termed Licentiates in Dental Surgery, and further suggesting the formation of a Dental College. This letter was favourably received by a large number of the profession, but a small group of perhaps the more eminent dentists, most of whom were Members or Fellows of the Royal College of Surgeons, or Fellows of the Royal Society, were quietly making approaches to the Royal College of Surgeons.

In December 1855 they met privately, and eighteen practitioners signed a "memorial" to the College of Surgeons, suggesting that a course of education should be held, and an examination in dental surgery instituted. This did not produce any immediate result, and while the paper was lying at the Royal College of Surgeons the memorialists agreed to constitute themselves a scientific society. A notice appeared from Rymer in the public press calling a second meeting of the profession on Tuesday, November 11, 1856, and the profession was then made aware that on the previous day (November 10) the Odontological Society of London had been formed, its by-laws framed and invitations sent to those members of the profession who were known personally to the memorialists and were deemed anxious to promote the well-being of the Society. The first ordinary meeting of the Odontological Society was held on Monday, January 5, 1857, under the presidency of Mr. Samuel Cartwright. It may be noted that he was not a Member of the Royal College of Surgeons, but was, in fact, a Fellow of the Royal Society. In the following year the Society acquired No. 32, Soho Square, and there established the first dental hospital and school, and, indeed, provided most of its staff from among the members of the Committee.

There was, unfortunately, considerable irritation in the profession generally at the

manner in which the Society had been started. A large number of highly respectable practitioners felt that the promoters had been both selfish and unjust in instituting the society in a private and clandestine manner.

The rival parties continued to work independently, and in 1857 the College of Dentists was formed, largely as a result of Rymer's campaign. Lecturers were appointed and commenced on February 18. This College opened the Metropolitan School of Dental Science in 1859, and two years later the National Dental Hospital of London. Students were examined and the successful candidates were entitled to use the letters M.C.D.E., Member of the College of Dentists of England.

The promoters of the College of Dentists were endeavouring to build up a dental profession which would be independent of medicine or surgery, while the memorialists were working to the same end through the College of Surgeons. The antagonism between the two was bitter and undisguised.

The year 1856 also saw the appearance of a monthly professional journal—the *British Journal of Dental Science*. In its opening number (July) the Editor assured his readers that its columns were open for free discussion, and at the disposal of any and every member of the profession requiring a medium for the extension of accumulated knowledge. The number for September 1856 warmly supported Rymer's plan, and there was already discussion on the title to be used by dentists, the editor feeling that it was an error, even for those who were members of the Royal College of Surgeons to call themselves Surgeon Dentists. By the end of 1856 the ownership of the *Journal* changed hands. It was offered to the committee under Mr. Rymer, which offer was refused, and then became the property of some gentlemen in the profession who supported the Odontological Society. From being the friend of the College of Dentists it became its foe and was apparently unwilling to publish its proceedings. Undaunted, the College decided to publish its own proceedings and in April 1857 appeared the first number of the *Quarterly Journal of Dental Science*.

In 1857 efforts were being made to bring about a fusion of the College of Dentists and the Odontological Society. These were unsuccessful, mainly as a result of unwillingness on the part of members of the College to follow the lead of its more far-sighted President and officers. Most of the latter resigned, and from then on the College appears to have diminished in numbers and importance, while the Odontological Society increased. The Royal College of Surgeons obtained its Dental Charter in 1859 authorizing examinations in Dental Surgery and the issue of certificates of fitness to practise. The first examination for the Licence in Dental Surgery was held by the College of Surgeons on March 13, 14, and 20, 1860, when 43 gentlemen, most of whom were distinguished members of the profession, were candidates. Among them were Samuel Cartwright, John Tomes, Thomas Bell, and Arnold Rogers, the last three being the dental members of the first Board of Examiners in Dental Surgery. They are reported in *The Times* of March 15, 1860, as "having undergone the necessary examinations", although by whom they were examined I have been unable to ascertain. In 1871 the status of the profession was further improved when the council of the College agreed to give its certificate the form of a diploma bearing the College arms and signed by the President.

In 1862 Rymer appreciated the fact that the Dental College was not going to succeed in getting a charter and so establish on a firm basis, either itself or its examination and diploma, especially as the Royal College of Surgeons had by then been empowered to admit dentists to examination and licence. He therefore approached the Odontological Society with a view to making another attempt at amalgamation.

When the first approach was made in 1857, the proposals came mainly from the Odontological Society, and, although agreed by the officers of the College, were rejected by its members. It was therefore considered desirable that the College of Dentists should, this time, formulate the proposals. On December 22, 1862, representatives of the College met Arnold Rogers, Samuel Cartwright and John Tomes for the Odontological Society, and agreed upon terms for the embodiment of the members of the College of Dentists with the members of the Odontological Society of London, under the new name of the Odontological Society of Great Britain. The amalgamation of the two bodies took place at a meeting of the Odontological Society held on May 4, 1863.

Even at this period dentists were concerned about status. The College of Surgeons had instituted in 1843, a Fellowship which carried with it a share of the responsibility for the control of its affairs. It was feared that the Licentiates in Dental Surgery might also expect a voice in the affairs of the College, but the memorialists denied any such intention. Tomes considered that education for the diploma should be equal in degree to, but different in kind from that for the Membership of the Royal College of Surgeons and may even have visualized a Fellowship in Dental Surgery.

The examination and licence in Dental Surgery were permissive and there was still no register, or limitation of the right to practise. The Medical Register was started in 1858,

but the General Medical Council refused to register the L.D.S. and this refusal was an important factor in the starting of a campaign in 1870 by Charles Fox for compulsory education and registration. This led to the election of the Dental Reform Committee in 1875 and to the passing of the Dentists Act of 1878. John Tomes was the first to inscribe his name on the Dental Register and in 1879 the Dental Reform Committee resolved itself into the Representative Board of the British Dental Association.

It is interesting to see that, in 1876, during this period of agitation for the formation of a Dentists Register the Association of Legally Qualified Dental Surgeons was formed under the chairmanship of Samuel Cartwright, Junior, with his nephew, Samuel Hamilton Cartwright, as Secretary. It appears to have been limited to Members of the Royal College of Surgeons. Both John and Charles Tomes refused to join, and it petered out after a few years. In 1900 its funds were handed over to the Royal College of Surgeons to be administered for the Cartwright Prize, and, to quote Dr. Lilian Lindsay, "as a Parthian shot from its founders, this can only be competed for by a member of one of the Colleges of Surgeons".

We must not overlook the developments which were taking place on the scientific side, as distinct from what might be called the administrative or even the political side of the profession.

It was not long before this period—in fact in 1844—that Horace Wells, an American dentist, showed that teeth could be extracted painlessly after the inhalation of nitrous oxide. A committee was appointed by the Society in conjunction with the Dental Hospital to investigate its merits and a careful report was issued based on 1,380 cases.

In 1846 Dr. Morton, a dentist of Boston, U.S.A., gave ether as an anæsthetic. Tomes took this up at once and used ether in the out-patients' room for dental operations.

During the early years there were frequent papers, letters and discussions on the relative merits of chloroform, ether and nitrous oxide for dental anæsthetic purposes. It was a long time before the safety and the easy administration of gas ousted the others from general use in dental practice. I remember being told by a doctor patient of mine that when he needed an extraction he usually gave himself chloroform. He sat upright in the dental chair, administered the chloroform to himself on an open mask, and told the dentist that, when his hand dropped and he was no longer able to hold up the mask he was ready for the operation to start. Happily for me he did not then require any extractions.

At a meeting of the Odontological Society held in March 1859 a paper was read by Dr. Blandy of New York advocating the use of cast base metal denture bases as better than swaged metal, ivory, or the relatively new vulcanite, and at the following meeting in April, Mr. Putnam, also of New York, spoke of the use of vulcanite.

This had been introduced in the United States by Mr. Goodyear in 1855, although Mr. Evans of Paris claims to have made some experiments for Goodyear in 1851 or 1852, and to be the first to make a practical "piece" as dentures were called.

Tomes was busy designing, not only the extracting forceps for which he was so well known, and which have, in many cases, remained unchanged to the present day, but also instruments for the insertion of fillings.

W. D. Miller of Berlin propounded in 1884 his chemico-parasitic theory of dental caries. Although it has been hotly disputed ever since, and certainly is not the whole story, it has not yet been generally discarded.

Non-cohesive gold had come into general use as a filling material early in the nineteenth century, and about 1855 Dr. Robert Arthur of Baltimore invented the method of cold welding pure gold in the cavity. Incidentally, he became a corresponding member of the Society in 1859.

In 1857 John Tomes read a paper describing a method of keeping teeth dry during filling, with a membrane of gutta-percha coated on one side with either gelatine or gum-arabic to make it adhere to the mucous membrane. Rubber dam was introduced by S. C. Barnum of New York in 1864.

The passing of the Dentists Act in 1878 and the starting of the Dentists Register, initiated a new era in dentistry. Before that time there was nothing to prevent anybody, with no surgical training whatever, holding himself out as qualified to practise, and advertising in the most blatant and outrageous manner. The new Act was designed to prevent unregistered and, ultimately, unqualified practice by prohibiting any unregistered practitioner from calling himself dentist or dental practitioner or by any name, title or description implying that he was registered or specially qualified to practise dentistry. The General Medical Council was entrusted with the duty of keeping the Register and maintaining, in the interests of the community a high standard of professional conduct. It is amusing to note that, in the discussions which took place prior to the passing of the Act there was considerable opposition to the imposition of duties of control by the General Medical Council. The *British Medical Journal* protested that "Medicine is a profession, Dentistry

is largely a business. To adjudicate upon charges likely to be brought against dentists involves some knowledge of trade matters as well as of professional matters". In spite of this, these duties were imposed upon the General Medical Council and carried out by them with the greatest care. There were at first no dental representatives on the General Medical Council and in May 1899 the British Dental Association requested the appointment of one or more. The Council replied that they had no power to do this, but the Privy Council nominated Charles Tomes as Crown nominee, in succession to Sir Richard Quain.

The Act of 1878 appears to have succeeded at first in controlling dental practice and no legal decision on it is reported until eight years later. Subsequently there were many prosecutions. Most of them were under the section which prohibits the use of titles implying registration or the possession of special qualifications. Convictions were followed by appeals, some of which were dismissed, and some allowed. Advertising by unregistered practitioners became general and blatant. The most important legal case under this Act was that of Bellerby *v.* Heyworth, which was taken to the House of Lords.

Their decision on April 15, 1910, that there was nothing in the Act which prevents any man from doing dentists' work and informing the public that he does such work, without being registered under the Act, was a statement of Law by the Supreme Court of Appeal of the United Kingdom and was unalterable except by Act of Parliament. From this time until the Act of 1921 it was quite clear that an unregistered man could not call himself a dentist or imply that he was on the Register; but that he might expatiate upon his skill in dentistry, employ any number of unqualified assistants, and advertise in the most blatant manner without hindrance.

The first Dentists Register, authorised by the 1878 Act, contained the names of 5,289 practitioners, of whom only 483 were licentiates, and it is a little surprising to find that, prior to the 1921 Act the numbers on the Register were almost the same—about 5,500. By this time, however, at least 75% were graduates or licentiates, and practically all the rest were those who had been admitted as being in practice in 1878. There were then added some 8,000 practitioners who, again, claimed to have been in practice at that time. Since then the number has increased a little, but of the 15,000 now on the Register only about 12,000 are actually practising. Very few of those registered as in practice in 1921 will remain on the active list after the next ten years, and it is probable that more than one-third of those now on the Register will have ceased to practise—a loss of about 5,000—while new registrations may number only 3,000.

It follows then, that, as our dental schools have scarcely been able to maintain the number of active practitioners, and as the Welfare State is irrevocably committed to the provision of a comprehensive dental service, there is an urgent need for steps to be taken to make good the rapidly increasing rate of loss to be anticipated in the next few years.

This is hardly the place to discuss the pros and cons of the use of ancillary workers and the provisions of schools and teachers to train them, but I cannot help comparing the era which is now beginning with the state of the profession a century ago. There was then a totally inadequate number of qualified dentists, and a large amount of the work was carried out by untrained or partly trained practitioners, and now, with the number of qualified dentists still inadequate, it is proposed to experiment with the use of partly trained operators, under the control of the General Dental Council which took over the Dental functions of the General Medical Council in 1956.

The training of the dental student in the early days of the Odontological Society was, as I have said, by apprenticeship to a dental practitioner. When the first regulations for the curriculum were laid down and training was started at the Dental Hospital of London, and the National Dental Hospital, great stress was laid upon the importance of acquiring manual dexterity. Before admission to a dental school the student had to be apprenticed for three years to a dental surgeon to learn dental mechanics. If a pupil was fortunate enough to be articled to a practitioner whose standard of work was high and who took pains to see that he was well instructed, the system was very satisfactory.

A most interesting description of the professional training of the time is to be found in the autobiographical notes of the late J. H. Badcock, published in the *British Dental Journal* in January 1954. He started in 1880, and was President of this Section in 1917.

Later the time spent at dental mechanics was reduced to two years, which could be spent either privately or in the pupils' laboratory at one of the dental schools. Before private apprenticeship was finally abolished, the regulations required either three years articles or two years at a dental school.

I did my own mechanical training with a practitioner who had a good middle-class practice at which he worked in the daytime, and in the evenings he had a dental dispensary in the Waterloo Road. Here, although the fees were low, the standard of work was good, and it had the great advantage, as far as I was concerned, that I was able, under supervision,

to take impressions, and make quite a number of dentures for patients. I was also permitted to do free extractions, without any anæsthetic, and often removed 70 or 80 teeth in one evening. We used only three pairs of forceps, as far as I remember—straights and bayonets for uppers and a pair of lower root forceps. We used to feel a sense of superiority when, as happened from time to time, patients came in who had had roots left in after attempts at extraction at Guy's. This was countered later, when I was a student at Guy's, by the appearance there of some of the failures of the Dental Dispensary.

Clinical teaching was done entirely by part-time honorary teachers, who spent the rest of their time in private practice. The first dental professor in this country was Samuel Cartwright (junior) who was appointed to the Chair of Dental Surgery at King's College, London, in 1860, but there was at that time no dental school there. The first professor to hold a Chair in a Dental School was Gilmour, who was appointed in 1920 at Liverpool. Since that time dental education has come more and more into the hands of full-time teachers.

The appointment of these teachers was a tremendous advance, as it provided opportunities for men of the highest ability in the profession to initiate projects of research, and to co-ordinate to a much greater extent the academic and clinical teaching. I would not like it to be thought that I underestimate the value of these full-time teachers. They are essential to the teaching of dental surgery as we know it to-day, but there has been, in recent years, a real danger of the clinical training becoming too academic. Of course it would be much easier administratively to organize the necessary sessions with full-time teachers, and there is still much room for improvement in the teaching, but it must never be forgotten that for a good many years to come graduates will have to spend most of their time putting in fillings, doing straightforward extractions, and replacing lost teeth with prosthetic appliances, and treating periodontal conditions. All these will be done the better for a wider knowledge of anatomy, pathology and surgery, but extension of education in this direction must never be at the expense of time spent acquiring operative skill in dentistry.

The part-time clinical teacher does, I think, still serve a useful purpose in relating the operative work of the student to the needs of private practice, an aspect difficult for him to appreciate while he is treating only hospital patients and with which the purely academic teacher is in danger of losing touch.

From the passing of the 1878 Act onwards, there was a period of scientific advance. This came mainly from the isolated efforts of individual workers, as there was little or no organized research until a much later date.

Sir John Bland-Sutton made many of his contributions to the study of dental pathology at the Odontological Society, his first paper in April 1883 being on the development of the mandible. From that time until 1905 his interests included problems of calcification of the jaws, the pathology of odontomes, of pyorrhœa alveolaris or Riggs' disease as it was then called, structure and development of ovarian teeth, treatment of caries, and after-treatment of extractions. The *Transactions of the Odontological Society* contain some 22 papers or discussions in which he took part between 1883 and 1905.

Cocaine was first introduced as a local anæsthetic about 1885, and in spite of its danger, soon came to be used extensively. Up to 1907 cocaine and the chemically related eucaine and Stovaine were the only local anæsthetics in general use. The *British Medical Journal* of March 1907 published a letter advocating the use of 20 minims of a 10% solution of cocaine, equivalent to 2 grains. On March 25, 1907, Dr. J. W. Pare gave a casual communication to the Society on Novocain, which he said had been introduced to this country in the previous June.

In February 1899 Dr. William Hunter read his paper on the Relations of Dental Diseases to General Diseases, which initiated what might be termed the era of focal sepsis. It was accepted with rather uncritical enthusiasm by the progressive members of both the medical and dental professions and for many years its validity was scarcely disputed. It was not at all unusual for the doctor who was at a loss to understand his patients' symptoms to send him to the dentist with instructions to have all his teeth out.

While dental sepsis is no longer regarded as the specific cause of the vast number of general diseases which used to be attributed to it, I think the pendulum may have swung too far in the opposite direction, and that there is some danger of the effect of oral infection being underestimated.

Dental radiographs were taken in America about 1896, and as far as I can ascertain were first shown here to the Odontological Society on January 28, 1901, when Carl Schelling read a short paper on "An obscure case of dental trouble diagnosed by X-rays". He had seen the patient 18 times, gradually dilating a sinus in the upper canine area, with bibulous paper. The patient had assured him that $\underline{3}2|$ had been extracted without fracture of the roots. The area was radiographed by Dr. Mackenzie Davidson with a piece of tinfoil in the sinus, and a root was shown to be present.

In 1895 occurred an event of major importance and interest to the dental profession, when the name of Lilian Murray appeared in the Register, the first woman to be registered. As Dr. Lindsay she is known to all of us and it would be difficult to exaggerate the debt owed to her by this Society, the British Dental Association and the profession as a whole. She was President of this Section in 1945 and of the Section of the History of Medicine in 1950.

At the end of the nineteenth century amalgam was coming into general use. It was first regarded as an inferior substitute for gold, to be used only by incompetent workers, but was not, as far as I can find out, ever held in such disrepute in this country as it was in the United States. There, at one time, the American Society of Dental Surgeons, the American Dental Association of its day, had a rule that "any member of this society who shall hereafter refuse to sign a certificate pledging himself not to use any amalgam, and moreover, protesting against its use under any circumstances in dental practice, shall be expelled from this society". Before very long, however, most members were using it surreptitiously and it seems to have become respectable there in the early 1870s. In both countries many materials were used. The alloys used were mostly proprietary, although a number of practitioners made their own. In 1895 Dr. E. V. Black published some work on amalgams, but from then until 1933, when Dr. Marie Gayler published the results of her investigations at the National Physical Laboratory, little scientific work seems to have been done on the subject. Thanks to the Dental Board, a very full study was then made, and most useful data obtained as to the factors controlling the setting of amalgams.

In 1903 Dr. Black described the fundamental principles of cavity preparation, which hold good to-day.

The special study of Orthodontics developed in the latter part of the nineteenth century, much of the interest in the subject being stimulated by the enthusiasm of Edward Angle and his followers. In this country it culminated in the foundation in 1908 of the British Society for the Study of Orthodontics, largely due to the work of the late George Northcroft, who was President of this Section in 1928.

Progress has been made in the treatment of periodontal disease, to which Sir Wilfred Fish has made important contributions.

The advances in anæsthesia which have come in the last twenty-five years, together with the general and discriminate use of antibiotics since the war, have improved enormously the results of oral surgery. When one thinks of the large numbers of impacted third molars and odontomes which we remove at the present time, one wonders what happened to them in the past. It may be that the odontomes were treated by the general surgeon and the impactions relieved by the extraction of the more easily accessible neighbouring teeth.

In the field of prosthetics, the use of acrylic resins has completely replaced vulcanite, and cast gold has taken the place of the swaged dental plate. Now the chrome cobalt alloys are to some extent replacing gold.

Advances in conservative dental surgery have been assisted by the increased use of local anæsthetics and of cold water jets for the prevention of pain. The development of painless dentistry which is at the same time safe has helped us to take advantage of the improvement which has taken place not only in plastic filling materials, but in the accurate casting of gold for inlays and bridges.

While great advances have been made during the hundred years of the life of the Odontological Society and of this Section, in the conservative, surgical and prosthetic treatment of dental disease, comparatively little has been learned about its prevention. The large-scale experiments with fluoridation of water would appear to offer some prospect of a reduction in the caries rate, but much more evidence is needed over many more years before this can be finally accepted or rejected.

A country-wide campaign of instruction in oral hygiene would bring about a great improvement, especially if, before starting it, the profession could agree upon its essentials. Nearly all of us are fully occupied in repairing damage already done, and it is only recently — since 1920—that our schools have had full-time teachers, and professors, one of whose main duties is the promotion of research, without which so little can be done in the field of prevention.

I venture to think that the next phase of dentistry, which may be only just over the brow of the hill, will be the era of preventive dentistry. The time may well come when the dentist willl examine his patient, advise, and prescribe treatment, both preventive and restorative, which will be carried out by others under his control, whose work would be analogous to that of the radiographer, the optician or the physiotherapist. The vastness of the task of controlling such widespread diseases forces us to envisage such a possibility.

It only remains for me to express my thanks to those who have helped me in the preparation of this Address, especially to Dr. Lilian Lindsay and Mr. Alan Shefford and to the Librarians of the Royal Society of Medicine, and of the British Dental Association.

JOINT MEETING No. 5

Section of Pathology with Section of Epidemiology and Preventive Medicine

Chairman—Professor JOHN W. S. BLACKLOCK, M.D.
(President of the Section of Pathology)

[*January* 15, 1957]

DISCUSSION ON ADENOVIRUS INFECTIONS

Dr. B. E. Andrews and Dr. J. C. McDonald (Central Public Health Laboratory, London):
Epidemiological Studies of Adenovirus Infection

In 1954 the distribution of serological types in a series of 143 adenovirus strains isolated in the U.S.A. was reported by Huebner and his colleagues. More recently Rowe and Huebner (1956) reviewed present knowledge of the clinical significance of these viruses. The purpose of this communication is to present the information we have obtained since 1954 on the natural distribution of adenovirus types in this country and on the illnesses with which they have been associated. Most of the observations on which our report is based were made in collaboration with others, in the course of planned surveys of acute respiratory disease in the Royal Air Force, and in the investigation of outbreaks and sporadic cases of respiratory and other febrile illness in residential schools and in the general population.

METHODS

In most of the investigations a systematic record was made of the symptoms and clinical signs in each patient. Laboratory diagnosis of adenovirus infection was usually serological and based on a fourfold or greater rise in complement-fixing antibody to the adenovirus group antigen, in paired blood samples. Virus isolation was attempted only on suitable specimens, taken from a sample of cases in each outbreak. In more than 70 patients on whom both isolation and serological tests were performed good correlation was obtained by the two methods between positive and negative results.

All but four virus strains were isolated in HeLa cell cultures, the presence of virus being detected by the characteristic type of degeneration caused, and by the production of the group complement-fixing antigen. The type of virus was identified by neutralization tests in HeLa cultures using type-specific rabbit sera. All strains were tested against sera to adenovirus types 1 to 8; when they were not neutralized by any of these they were tested against a serum to type 14, kindly supplied by Professor van der Veen. The laboratory techniques have been more fully described elsewhere (Kendall *et al.*, 1957).

DISTRIBUTION OF ADENOVIRUS TYPES

Results of typing of 85 selected adenovirus strains isolated in this country since 1954 are presented in Table I, classified into broad clinical and age groups. Some 200 strains were isolated in this period but it was not possible to undertake the typing of them all. In choosing those to be tested, strains were taken from as many different outbreaks and clinical conditions as possible and no attempt was made to examine all the strains available from any particular source. Of the 85 strains shown in Table I, 63 were from 14 outbreaks and 22 from sporadic cases. Most of the strains were isolated from throat swabs taken during the acute stage of illness, but some were from eye swabs and some from fæces; 4 strains were from tonsils and adenoids removed at operation.

The virus strains from the tonsils and adenoids were of types 1, 2 and 5. The only other type 1 strain was from the lungs of a baby aged 3 months that died from pneumonia. Type 2 virus was isolated from a fatal case of pneumonia in a child aged 3 months, from a child aged 6 weeks with acute bronchiolitis, and from 3 patients thought to be suffering from non-paralytic poliomyelitis—aged 2, 6 and 26 years respectively. Twelve strains belonging to type 3, representing 3 large outbreaks in schools and 2 sporadic cases, came from patients with the clinical features of pharyngo-conjunctival fever. Few strains of types 4 and 5, and none of type 6 were encountered. Type 7 was, in our experience, the most prevalent type; it was isolated under every clinical heading shown in Table I, except tonsils and adenoids. We have not found any strains of type 8 so far. Many of the strains tested were from patients with conjunctival inflammation, but only one patient was considered clinically to be suffering from epidemic keratoconjunctivitis. This disease has been reported by Jawetz *et al.* (1955) to be due to type 8 virus in North America. Type 14 was isolated from an airman in an outbreak of febrile catarrh and from 6 boys in a school outbreak of pharyngo-conjunctival fever. One strain from a case of febrile catarrh in a military outbreak proved untypable with the sera available and Dr. W. P. Rowe has reported that it is not of types 1 to 14 inclusive.

TABLE I.—ADENOVIRUS TYPES IN RELATION TO AGE AND CLINICAL GROUP
(85 virus strains from 14 outbreaks and 22 sporadic cases)

Clinical and age group	Virus type 1	2	3	4	5	6	7	8	14	Undesignated
Tonsils and adenoids removed at operation ..	1	2			1					
Acute respiratory disease without conjunctivitis										
0–2 years	1	2					1			
3–10 years							3			
Adults—civilian ..				1			1			
military ..				1			26		1	1*
Acute respiratory disease with conjunctivitis ..			12	1			16		6	
Febrile illness with meningism		3			1		4			
Total	2	7	12	3	2	0	51	0	7	1

*This strain was not neutralized by antisera to types 1–14 (Rowe, 1957).

CLINICAL GROUPS

Many outbreaks and sporadic cases of febrile illness of unknown ætiology—mostly with respiratory or nervous symptoms—were studied between 1954 and 1956. In almost all those in which evidence of adenovirus infection was found, respiratory tract symptoms and signs were prominent. A possible exception to this was a small outbreak in a country town in south-west England, and some scattered sporadic cases, reported as "non-paralytic poliomyelitis", during the summer of 1956. These illnesses were characterized by fever, meningism that was definite and persisted for several days, and the absence of respiratory symptoms, except for a few with sore throat.

Most of the respiratory illnesses associated with adenovirus infection occurred in outbreaks and fell into two distinct clinical groups, one apparently similar to the acute respiratory diseases in military recruits described by Hilleman *et al.* (1955), and the other to the disease named pharyngo-conjunctival fever by Bell *et al.* (1955). Our experience of pharyngo-conjunctival fever is based on outbreaks in residential schools in summer (Kendall *et al.*, 1957) and of the other syndrome on surveys in the R.A.F. in winter, when it was found to be highly prevalent in recruit camps but infrequent in other types of unit (Andrews *et al.*, 1956, and unpublished data). In both types of illness the patients had four or five days' fever and fairly severe sore throat, but whereas pharyngo-conjunctival fever was characterized by enlarged cervical lymph glands, conjunctivitis and the absence of respiratory tract involvement below the pharynx, in the recruit-disease the cervical glands and conjunctivæ were usually normal, but laryngitis, tracheitis or bronchitis were frequent, and evidence of pneumonia was present in about 10% of those admitted to hospital. The main clinical features of these two manifestations of adenovirus infection are set out in Table II, together

TABLE II.—CLINICAL FEATURES OF ACUTE RESPIRATORY ILLNESS ASSOCIATED WITH ADENOVIRUS, INFLUENZA VIRUS AND STREPTOCOCCAL INFECTION

Clinical features	Pharyngo-conjunctival fever (adenovirus)	Acute respiratory disease of military adults (adenovirus)	Streptococcal pharyngitis	Influenza (A and B)
Symptoms				
Sore throat	⊞	⊞	⊞	+
Cough		⊞		⊞
Nasal	+			+
Aches and pains				⊞
Sweating		+	⊞	⊞
Signs				
Conjunctivitis	⊞			
Enlarged cervical glands	⊞		⊞	
In pharynx	+	+	⊞	+
Below pharynx		⊞		⊞

+ = present in majority. ⊞ = prominent.

with those of influenza and streptococcal pharyngitis for comparison. It is our impression that in epidemics at least, it may often be possible to distinguish these 4 syndromes from each other clinically, though not necessarily from infections due to other agents.

SUMMARY AND CONCLUSIONS

From some 200 adenovirus strains isolated in England since 1954, 85 taken from 14 outbreaks and 22 sporadic cases were typed. Representatives of types 1, 2, 3, 4, 5, 7, 14 and an undesignated type were identified. 9 of the 11 strains of types 1, 2 and 5 were from tonsils and adenoids removed at operation or from acute respiratory disease in infants under 3 years of age. Of the remaining 74 strains, 51 belonged to type 7 and were isolated from patients of all age-groups in a variety of clinical categories.

With the exception of a small outbreak and some sporadic cases in which the main symptoms were fever and meningism, laboratory evidence of adenovirus infection has only been found in patients with acute respiratory disease. These respiratory illnesses fell into two clinical groups, both with fever and pharyngitis but one accompanied by conjunctivitis and cervical lymphadenopathy, and the other by tracheitis, bronchitis and sometimes pneumonia. The latter illness was almost confined to military recruits in the winter months, and the pharyngo-conjunctival illness to children in residential school outbreaks.

No constant relationship between adenovirus type and clinical syndrome has been apparent.

ACKNOWLEDGMENTS

We wish to acknowledge permission to use results obtained jointly with Drs. E. J. C. Kendall, R. W. Riddle, H. A. Tuck and K. S. Rodan; Air Commodore J. S. Wilson and Wing Commander W. B. Thorburn; Mr. Barrie R. Jones, F.R.C.S., and Dr. P. P. Fox. We are also grateful to colleagues in the Public Health Laboratory Service who have sent virus strains for identification, and to the many other doctors who have allowed us to help in the investigation of their cases.

Dr. H. G. Pereira and **Barbara Kelly** (Common Cold Research Unit, Harvard Hospital, Salisbury, Wilts): *Studies on Natural and Experimental Infections by Adenoviruses*

Adenoviruses have been associated with a variety of human infections occurring sporadically or epidemically, especially in military populations. Of the 14 serological types so far identified (Rowe *et al.*, 1956) some are more frequently associated with outbreaks of disease and others are found as "latent" viruses in adenoids or tonsils and occasionally causing sporadic infections.

The ætiological role of adenoviruses types 4 and 7 in acute respiratory disease (A.R.D.) or febrile catarrh (Hilleman *et al.*, 1955; Berge *et al.*, 1955) and of adenovirus type 3 in pharyngo-conjunctival fever (Bell *et al.*, 1955) has been clearly demonstrated. Some cases of primary atypical pneumonia have also been related to type 4 infections (Hilleman *et al.*, 1955; Berge *et al.*, 1955). There is some evidence that adenovirus type 8 is the cause of epidemic keratoconjunctivitis (Jawetz *et al.*, 1955). A number of less clearly defined respiratory infections have been associated with other types of adenoviruses and it has been suggested that these viruses may be related to some cases of mesenteric lymphadenitis (*see* reviews by Rowe and Huebner, 1956, and by Dingle and Feller, 1956).

Work on volunteers (Bell *et al.*, 1956; Southam *et al.*, 1956; Roden *et al.*, 1956) has confirmed the pathogenic action of several types of these viruses and demonstrated the relation between susceptibility to infection and pre-existing antibodies.

Our interest in this group of agents was initially stimulated by their possible ætiological relationship with the common cold. Clinical, epidemiological and experimental studies had previously established certain criteria for distinguishing the common cold from several different "entities" among the group of unclassified upper respiratory infections (Stuart-Harris *et al.*, 1938; Commission on Acute Respiratory Diseases, 1947). By means of the methods now available for the study of serological responses to adenovirus infections, Ginsberg *et al.* (1955) were able to confirm the identity of "acute respiratory disease" as a distinct entity and to demonstrate the ætiological relation of adenovirus type 4 (R.I.67) with this disease. No relation of this adenovirus to the common cold could be demonstrated by these authors. This last finding is substantiated by our own failure to recover

adenoviruses from nasal washings obtained from natural or experimentally induced cases of common cold. A total of 42 such washings tested in HeLa cells gave entirely negative results after prolonged observation of the test cultures and, in most cases, after several blind passages. Several instances of isolation of adenoviruses from cases diagnosed as common cold are recorded in the literature but in view of the diagnostic difficulties in this group of diseases these observations are to be expected and their relative rarity is in favour of an independent ætiology of the common cold.

Our studies on specially recruited volunteers (Roden *et al.*, 1956) provided both clinical and laboratory evidence of an ætiological relationship between adenovirus type 1 and a respiratory illness best described as acute pharyngitis. Clinical and subclinical infections were observed and susceptibility of volunteers to this virus was closely correlated with the absence of pre-existing homotypic serum neutralizing antibodies. The study of the serological responses revealed, as for other adenovirus infections, the group specificity of the complement-fixing antibodies. The serum-neutralization test was more type-specific but frequent heterotypic responses were observed indicating that in individual cases, the serological tests alone were insufficient to establish the identity of the infective virus type.

Our experience with infections by other types of adenoviruses include a few sporadic cases of respiratory illnesses caused by types 1 and 5 and a small outbreak of pharyngo-conjunctival fever caused by a strain related to type 7.

A strain of adenovirus type 1 was isolated in our laboratory from tracheal and lung swabs collected *post mortem* from a case of pneumonitis in a 4½-months-old child. A similar observation was made in the U.S.A. by Henle (quoted by Rowe and Huebner, 1956) and an adenovirus type 3 has been isolated in Holland by Dr. van der Veen (personal communication) from the lung of a fatal case of pneumonitis in an 8-months-old child. The ætiologic association of adenoviruses with these cases cannot be definitely established but these observations suggest the need for further study of the problem.

In December 1955–January 1956 a small outbreak of pharyngo-conjunctival fever associated with an adenovirus strain related to type 7 was observed in Salisbury. Most of the cases observed by us occurred among young children. 3 households were observed and at least 1 child from each house had prolonged and repeated contact with those of the other 2. Of a total of 15 members of the 3 households (7 adults and 8 children), there were 10 cases of infection, 3 in adults and the remainder in children between 1 and 7 years old. Most patients had fever, pharyngitis, rhinitis and cervical adenitis. 3 patients, 2 adults and 1 child, had unilateral conjunctivitis and pre-auricular adenitis. Virus isolations were attempted from 6 cases with positive results in all but one. The positive isolations were from nose and throat swabs in 2 cases, from throat swab in 1 case and from conjunctival swabs in 2 cases. Of the 3 cases of conjunctivitis, virus was isolated from conjunctival swabs in 2 and not attempted in the third. The sequence of events was suggestive of an incubation period of four to six days. All the viruses isolated from these cases were shown to belong to the same type provisionally designated as type 7-H. Comparison of a representative strain from this outbreak with adenovirus prototypes 1 to 11 by means of neutralization tests in cultures of HeLa cells using rabbit anti-sera revealed no cross reactions with any but adenovirus type 7. The cross reactions with this type are shown in Table I.

TABLE I.—CROSS REACTIONS BETWEEN ADENOVIRUS TYPE 7 AND TYPE 7-H BY SERUM-NEUTRALIZATION TEST

	Strain	
Anti-serum	Type 7	Type 7-H
Type 7	6,400	800
Type 7-H	400	1,600

Other strains of the same type were isolated by Dr. M. S. Pereira at the Salisbury Public Health Laboratory; 2 in May 1956—associated with cases of upper respiratory infections in Salisbury; and one in June 1956 from a case of conjunctivitis in a patient just arrived from Cornwall. Similar outbreaks caused by the same type of adenovirus were observed by Dr. D. A. J. Tyrrell in Sheffield during the same winter (Tyrrell *et al.*, 1956).

Two strains of adenovirus type 7-H were isolated from cultures of adenoids received during the first few months of 1956 from Mr. Brian Reeves, the E.N.T. surgeon in Salisbury. It may be worthy of notice that one of these was from the adenoids of a child who had had, four months previously, a type 7-H infection, confirmed by virus isolation, during the outbreak just described.

These findings confirm the association of adenovirus type 7-H with pharyngo-conjunctival fever, a disease previously related mainly to adenovirus type 3.

The limited studies so far reported do not allow us to make a judgment on the exact importance of adenoviruses as a source of disease in this country. Further knowledge in this field will be most valuable in view of the good prospects of artificial immunization against this group of agents.

Dr. R. G. Sommerville (The Virus Laboratory of the University Departments of Bacteriology and of Infectious Diseases, Ruchill Hospital, Glasgow): *Adenoviruses as a Cause of Epidemic Keratoconjunctivitis on Clydeside*

As an example of the amount of illness and morbidity which can be caused by one adenovirus I would like to describe an epidemic of keratoconjunctivitis which occurred in the west of Scotland between November 1955 and October 1956. A preliminary analysis of the details up to the end of August 1956 was made by Dr. J. Winning of the Eye Infirmary, Glasgow, and I am grateful to Dr. Winning and to other clinical colleagues for permission to quote from it. A full report of the outbreak will be published shortly.

The epidemic began in workers in one shipyard and quickly spread to involve most sections of heavy industry in the Clyde Valley. It is difficult to be certain of the total number of cases in an illness of this nature, due mainly to the fact that a choice of several ophthalmological clinics was available and also because many patients who were mildly affected, sought treatment from works ambulance rooms or general practitioners only. The figures on which this report is based were drawn from two clinics and the number involved in the nine months to the end of August 1956 was around 1,700. The total number of cases in the area was probably very much greater.

Analysis revealed that 83% of patients were male and a large proportion were workers with metal. One of the most puzzling features of the outbreak was the almost complete lack of spread from the infected male to his family, despite the highly infectious nature of the illness. Approximately 50% of cases involved the right eye, 30% the left and 20% both eyes. The incubation period of the disease was calculated to be between seven and ten days.

Few patients developed fever during the illness and a typical case might be represented as follows: the onset was abrupt with a gritty feeling in the eye and lacrimation. These were rapidly followed by conjunctivitis, chemosis, follicle formation and in some cases membrane formation in the lower conjunctival fornix. Pre-auricular adenitis was present in the majority of cases and often was the presenting sign associated with earache. Four or five days later subepithelial corneal opacities developed and these are a typical feature of the disease. Within a few days these ulcerated and corneal sensation was lost. Re-epithelialization occurred within two to four weeks and thereafter resolution gradually followed. With re-epithelialization the pain and irritation frequently returned and lasted perhaps for some months.

Many different treatments were tried and most were unsuccessful, but chloramphenicol ointment, probably merely by suppressing bacterial contaminants, was the treatment which appeared to confer most benefit. Relapse occurred in about 4% of cases, and usually the same eye was affected with a rather more severe attack than the first. Diminished visual acuity was troublesome, especially where both eyes were affected and about 10% of cases were ill for more than three months altogether.

As a result of this preliminary analysis 2 cases have been discovered where a rheumatoid type of arthritis developed during the early weeks of keratoconjunctivitis. One of these patients is a medical practitioner, and both illnesses have since cleared up.

Laboratory Studies

Virus isolation was attempted from conjunctival swabs in tissue culture. Each swab was extracted in a few millilitres of buffered saline with added antibiotics and the fluid was examined in tissue culture of HeLa cells. Forty-nine such swabs yielded negative results. One swab produced an adenovirus. No virus was isolated when the swab extract material was

inoculated into eggs and suckling mice intracerebrally. Extracts of fæcal specimens from 8 patients were examined in tissue culture of HeLa cells and from one an adenovirus was isolated. A conjunctival swab from this case was negative in tissue culture.

Both adenoviruses belonged to type 3 and unfortunately it was not subsequently possible to contact these patients to obtain serum for neutralization tests. Complement-fixing (C.F.) antibody for the adenovirus group antigen develops rapidly and increases in amount as the disease develops. The rising titre of C.F. antibody in a representative group of cases is shown in Table I. Acute specimens were all collected in the first ten days of illness and the convalescent sera were collected at the intervals shown.

TABLE I.—COMPLEMENT-FIXATION TESTS WITH RI-67 ANTIGEN

Case	Acute*	Convalescent	Interval (weeks)
3	<8	16	4
6	<8	32	4
7	16	16	1
8	<8	16	2
11	<8	16	2
12	16	64	3
16	8	16	1

* Acute sera collected during first ten days of illness.

TABLE II.—NEUTRALIZATION TESTS WITH ADENOVIRUS TYPES 3 AND 8

Case	Type 3 Acute*/Conv.	Type 8 Acute*/Conv.	Interval (weeks)
3	8/8	<8/16	4
6	4/8	<4/256	4
7	4/4	8/16	1
8	16/16	<8/64	2
11	<4/<4	<8/32	2

* Acute sera collected during first ten days of illness.

Serum virus neutralization tests were performed in tissue cultures of HeLa cells against adenovirus types 3 and 8 only. All sera tested to date have developed neutralizing antibody to type 8 virus after the first ten to fourteen days of illness. A representative selection of results is shown in Table II. A small rise in titre of neutralizing antibody to the type 3 virus has also been observed in some cases, but despite the isolation of two type 3 viruses, no cases have been found with significantly rising titre of neutralizing antibody to this virus.

From the evidence which I have reviewed this epidemic of keratoconjunctivitis appears to have been caused by adenovirus type 8 and this finding is in agreement with recent experience of the disease by Jawetz *et al.* in U.S.A. (1955) *Amer. J. Ophthal.*, **40**, 200.

Dr. P. K. Hopper: In view of the evidence that adenovirus is formed as aggregations within the cell nucleus, I would be interested to hear if any intra-nuclear inclusion bodies were found in smears taken from the cases with conjunctivitis.

As this virus seems to persist as a latent infection in adenoids and tonsils, and thereby act as a continual antigenic stimulus, it would be interesting to know if children who have had their tonsils and adenoids removed are more susceptible to infection with different types of virus of this group.

(Reply: No observations on this point were made in the studies described.)

Whilst considering the possible role of trauma in conjunctival infections with this virus, I think some observations made in America by Dr. R. J. Huebner (personal communication) two years ago are very relevant. Several types of adenovirus were tested in volunteers by the conjunctival route, and it was found that in many cases infection could not be initiated unless some degree of trauma was caused with the inoculating swab.

Dr. C. H. Smith, in reply to Dr. Hopper, said that in his experience inclusions were not found in scrapings taken from human conjunctivæ in these infections, although the nuclei of the conjunctival cells often showed a marked degenerative change.

Mr. Barrie R. Jones (Moorfields Eye Hospital): *Sporadic Ocular Disease Associated with Adenovirus Infection in London*

During 1950 over 80 cases of a rather distinctive conjunctivitis, resembling that which Dr. McDonald has just described, presented in the Ophthalmic Department of the Dunedin Hospital in New Zealand. This was found to be associated with a glandular fever-like illness which was epidemic at the time (Jones *et al.*, 1952, *Proc. Univ. Otago med. Sch.*, **30**, 1). The conjunctivitis was usually preceded, accompanied or followed by upper respiratory infection, fever, malaise and pre-auricular or cervical adenitis. In some cases the adenitis was widespread, the abdominal nodes being not infrequently involved. These cases were characterized by the development of a total mononucleosis of more than 50% with 5% or more of abnormal lymphoid cells, and negative Paul Bunnell tests. Similar sporadic cases were seen at Moorfields Eye Hospital in 1952, 1953 and 1954. Although a few abnormal lymphoid cells were usually present some cases did not show an increase in total mononuclears.

In 1955 when Dr. R. W. Riddle invited me to see some of his boys at Lancing College who were suffering from adenovirus infection, I was impressed by the very great clinical similarity and fully expected that this would be the answer to a great deal of our previously unidentified ocular infections.

During 1956, working with Dr. B. E. Andrews at the Virus Reference Laboratory and Drs. G. A. Henderson and P. B. Schofield at the Institute of Ophthalmology I have investigated a proportion of the acute conjunctivitis and keratoconjunctivitis presenting at Moorfields and the London Hospital. Evidence of adenovirus infection was obtained in 7 of the first 60 cases (Table I). In 4 cases there was at least a fourfold rise in titre to the

TABLE I.—LABORATORY FINDINGS IN 8 CASES OF OCULAR ADENOVIRUS INFECTIONS

Case No.	Day of ocular disease	Day of systemic disease	Adenovirus C.F.T.	Systemic illness	Virus isolation and day of disease in that site	Type of adenovirus

	17		1 : 8			

complement-fixation test (C.F.T.) and adenovirus was isolated from the affected eye of 3 of these. In 2 further cases adenovirus was isolated from the inflamed eye of patients who had some complement-fixing titre but did not show a fourfold rise. These were cases with minimal systemic disease. Virus was isolated from the throats of 4 of the 5 cases in which there were signs of pharyngitis accompanying the conjunctivitis. Virus isolation was not successful in 2 further cases which showed a fourfold rise in C.F.T. titre. Types 3, 7 and the "Dutch type" of virus at Lancing College produced a pharyngo-conjunctival fever resembling that reported from America in type 3 virus infections, and type 8 virus was responsible for the Glasgow epidemic keratoconjunctivitis. Hence it is of interest to know whether there is any correlation between the virus type and the pattern of illness in the sporadic London ocular cases (Table II).

With each type of virus the conjunctivitis was similar; there was some ptosis and slight swelling of the lid, but no purulent discharge. The inflammation was most marked in the lower palpebral conjunctiva with the bulbar and upper lid conjunctiva rather less involved. In all except Cases 53 and 32 the inflammation was follicular and the pre-auricular node was always palpable and usually tender. The differences lay chiefly in the nature of corneal and systemic involvement. The type 3 infection did not affect the cornea and was associated with a moderately severe upper respiratory infection with headache and cervical adenitis, leading on to abdominal pains and tenderness with some diarrhœa. Fever, malaise and abdominal symptoms persisted intermittently for two months. In the type 4 virus infection the cornea was not affected and it was accompanied by moderately severe upper respiratory disease with pre-auricular and cervical adenitis, headache and myalgia which went on to abdominal, inguinal and cervical adenitis with episodes of slight diarrhœa. His white cell count rose steadily to 24,000 in the fourth month and has now subsided to 12,000. Early on there were abnormal lymphoid cells although the response was chiefly polymorphonuclear. Although the glandular and abdominal symptoms have been recurrent and the patient has shown a gradual improvement, he has not been apyrexial for more than a day at a time since this glandular fever-like illness began eight months ago.

One case in which no virus was isolated was accompanied by coryza, sore throat, cervical adenitis and palpable spleen. The lymphadenitis, fever and malaise took one month to resolve. A further case in which no virus was isolated was accompanied by a fine punctate epithelial keratitis in which the lesions were not visible until stained by fluorescein and they cleared completely. The ocular infection was followed by sore throat, headache, soreness of neck muscles, anorexia and vomiting. Cough and central chest pain persisted for a month and there was a return of abdominal pain with tenderness and diarrhœa. The cervical, inguinal and abdominal nodes were enlarged in a patchy way and the spleen became palpable. There are close resemblances between these 4 cases and those of the Dunedin epidemic of 1950. The type 7 virus infections showed less systemic illness and more corneal disease. One

TABLE II.—CLINICAL FEATURES OF 8 OCULAR ADENOVIRUS INFECTIONS

Virus type	Case No.	Sex Age	Conjunctivitis	Keratitis	Systemic illness
3	61	F 26	L. follicular	Nil	Preceded by coryza, accompanied by sore throat and cervical adenitis, followed by headache, muscle pains, abdominal pain, tenderness and diarrhœa, fever and malaise for 2/12
4	25	M 26	L. follicular	Nil	Accompanied by coryza, sore throat, headache and cervical adenitis, followed by muscle pain, abd. pain and tenderness and diarrhœa, inguinal, axillary and cervical adenitis, fever and malaise for 3/12
?	53	F 21	R. and L. finely granular	Fine epithelial punctate staining with fluorescein	Followed by headache, neck soreness, sore throat, cough and chest pain, anorexia, vomiting, tender colon, palpable spleen, malaise, mild cervical and inguinal adenitis for 1/12
?	80	F 10	L. follicular and bulbar	Nil	Accompanied by coryza, sore throat, cervical adenitis and palpable spleen. Lymphadenitis, fever and malaise for 1/12
7	49	F 32	L. follicular	Nil	Mild fever and malaise for five days
7	57	M 21	L. follicular	Fine epithelial S.P.K. on ninth day progressing to subepithelial opacities of E.K.C. type on fourteenth day	Preceded by coryza, and fever for two weeks
7	81	M 33	R. follicular	Fine epithelial S.P.K.	Nil
?	32	F 6	R. finely granular	Nil	Accompanied by upper respiratory infection and fever for two weeks
			R. acute dacryoadenitis		

patient showed no systemic signs, another had mild malaise with fever for a few days, and the third had an upper respiratory infection with fever for two weeks.

In one case the cornea was not involved. In another there was a moderately severe fine epithelial punctate keratitis. The lesions could be seen only with the corneal microscope; they stained faintly with fluorescein, were associated with minimal subepithelial infiltration and cleared completely.

The third case ran a course which was clinically extremely similar to the Glasgow epidemic keratoconjunctivitis. As the conjunctivitis was subsiding on the ninth day there was fine epithelial punctate keratitis. Some of these lesions developed subepithelial infiltrations which, by the fourteenth day, had hardened to the typical disc-like opacities. Two months later these two subepithelial opacities could be seen easily with the naked eye and were exactly like the epidemic cases which Dr. J. Winning had shown me in Glasgow. Had the patient not been closely questioned and examined he would not have complained of any systemic upset.

It will probably never be decided whether the Dunedin epidemic was an adenovirus infection, but since dacryoadenitis was a feature of some cases I have also been investigating patients with inflamed lacrimal glands. Of the first 7 cases 1 showed a rise in adenovirus C.F. titre from 1 : 2 to 1 : 16 during the illness (*see* Table I, Case 32). When swabs were taken the inflammation was starting to wane, and no virus was isolated.

It is thus apparent that adenovirus infections should be considered in the differential diagnosis of glandular fever-like illnesses and that the adenoviruses are an important cause of external ocular inflammation among those cases which are severe enough to reach ophthalmic clinics, but many more cases will have to be seen before one could predict which type was responsible for a given infection.

Furthermore I should like to emphasize that several very similar cases of ocular and systemic illness have been seen in which there has been no evidence whatever of adenovirus infection. Hence whilst an adenovirus infection may be suspected clinically it can be diagnosed only in the laboratory.

Major R. J. C. Hart said that low titre complement-fixing antibodies to the adenovirus group were present in the sera of many soldiers and he suggested that these antibodies might therefore be comparatively long-lasting.

[*November* 28, 1956]

DISCUSSION ON CUSHING'S SYNDROME

Dr. R. I. S. Bayliss: *Diagnosis of Cushing's Syndrome*

There may be difficulties in establishing a diagnosis of Cushing's syndrome and, having established the diagnosis, in deciding whether the cause is hyperplasia, an adenoma or a carcinoma of the adrenal gland or even one of the other conditions (carcinoma of the pancreas, thymus or bronchus) which may rarely be present. In his original description Cushing (1932) included only patients who were severe examples of the syndrome. All had adiposity of the trunk with sparing of the limbs, kyphosis with rounding of the shoulders, amenorrhœa or impotence, hypertrichosis, purple striæ, a plethoric complexion, hypertension and backache, abdominal pain, fatigue or weakness. But even in long-standing cases several of these features may be absent, and in the earlier stages the clinical picture is less obvious. Although Cushing considered the condition a pluriglandular disorder, all its clinical and biochemical and most of its pathological features can be induced with hydrocortisone, and we now believe that increased secretion of adrenocortical hormones is the cause. Thus it is logical to seek confirmation of the diagnosis by obtaining biochemical evidence of increased adrenocortical activity. The adrenal cortex secretes many different hormones, and those that produce Cushing's syndrome belong to the glucocorticoid group having a hydroxyl group at the C-17 and usually a hydroxyl or ketone group at the C-11 positions. Large amounts of hydrocortisone were first isolated from a patient with Cushing's syndrome by Mason and Sprague (1948), and subsequently excess of cortisone and compound S (17-hydroxy-11-desoxycorticosterone) has been found in the urine of other patients (Dohan *et al.*, 1955). Theoretically excessive formation of corticosterone might cause Cushing's syndrome but no instance of this has yet been reported although increased amounts may arise in parallel with overproduction of hydrocortisone (Sweat, 1955). In some cases increased secretion of glucocorticoids is accompanied by enhanced production of androgenic steroids, and the clinical features of hyperadrenalism may range from classical Cushing's syndrome at one end of the scale to virilization at the other with intermediate forms in between. If retained at all, the term Cushing's syndrome should be reserved for patients with the clinical features of excess glucocorticoid secretion, but wherever possible, especially in mixed cases, the disorder should be classified in terms of the particular steroids secreted in excess.

Clinical cases.—In 36 patients suspected clinically of having Cushing's syndrome, the diagnosis has been confirmed by clinical and hormonal assessment in 19, most of whom have undergone total or partial adrenalectomy. In 14, excess glucocorticoid secretion was not found and the diagnosis was discarded. In 3 patients the diagnosis has remained uncertain.

Fig. 1 shows the principal features in the 19 patients with Cushing's syndrome, of whom 12 were women and 7 men. Of diagnostic importance was the alteration in skin texture which is difficult to quantitate and which was first stressed by Parkes Weber (1926). The skin loses its elasticity and can be picked up in the fingers with an absence of the normal underlying fat. The lack of elasticity and resistance is particularly noticeable when doing a venepuncture. This atrophy, which may be associated with increased bruisability and ecchymoses, is probably due to loss of body protein. The development of purple striæ seems to depend on the combination of this with truncal obesity.

Radiological evidence of osteoporosis, difficult to detect in its early stages, was found in 11 of the 19 patients. 4 patients with particularly long-standing or florid disease had fractures of the ribs, vertebræ or femur. In 1, fractures were the presenting symptom, and this patient had the highest level of 17-hydroxycorticosteroids yet encountered—88 μg. per 100 ml. All but one of the women had facial hirsutism, and of the 10 who were pre-menopausal and had not had a hysterectomy, 6 had amenorrhœa. Hypertension was a common finding,

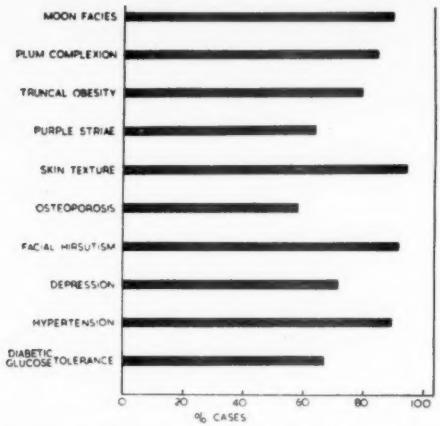

FIG. 1.—Frequency of chief manifestations in Cushing's syndrome (19 cases).

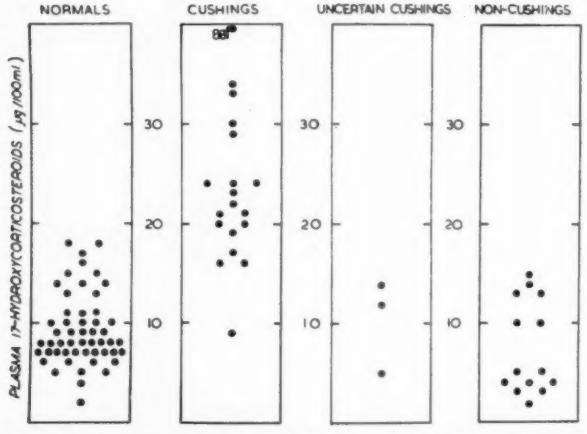

FIG. 2.—Plasma 17-hydroxycorticosteroid values in normal subjects, patients with Cushing's syndrome, patients with probable Cushing's syndrome and patients referred as having, but not found to have, Cushing's syndrome.

and headaches with failing vision and the retinal changes of malignant hypertension were the presenting symptoms in 4 patients. Mental changes, particularly depression, occurred in three-quarters of the patients. Glycosuria was not common but a diabetic glucose tolerance curve was obtained in 12 out of 18 patients. In all, the serum electrolyte levels were normal nor was a low eosinophil count in the peripheral blood of diagnostic value.

The plasma 17-hydrocorticosteroid levels are shown in Fig. 2. In most instances the value was above the upper limit of normal, 18 μg. per 100 ml., but often not strikingly so. In 5 patients the level was within the normal range, but the infusion of ACTH caused a greater adrenal response than occurs in normal subjects (Fig. 3). The urinary excretion of 17-ketosteroids (Fig. 4) was raised in some patients but abnormal values were not found as often as increased plasma 17-hydroxycorticosteroid levels. Although high 17-ketosteroid values may confirm the existence of adrenal disease, normal values in no way exclude Cushing's syndrome.

One patient had a pituitary chromophobe adenoma compressing the optic chiasma and ballooning the sella turcica; the state of his adrenal glands is not known. 3 patients had an adrenal adenoma. 11 had bilateral hyperplasia and in 4 the adrenal glands appeared normal at operation and on histological examination. This anatomical normality of the adrenals

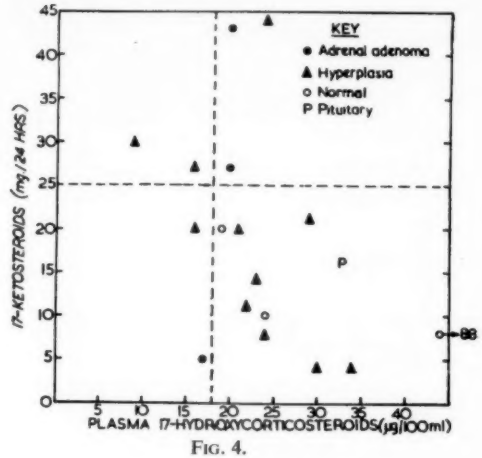

FIG. 4.

FIG. 3.—The adrenocortical response, as measured by the increment in plasma 17-hydroxycorticosteroids, to a six-hour infusion of ACTH (2 units per hour) in patients with Addison's disease, in normal subjects, and in patients with Cushing's syndrome who had a normal control value of plasma steroids.

FIG. 4.—Comparison of urinary 17-ketosteroid excretion per twenty-four hours and plasma 17-hydroxycorticosteroids in patients with Cushing's syndrome. The symbols (*see* key) indicate the adrenal pathology. Dotted lines show upper limits of normal steroid values.

in some cases of Cushing's syndrome has been observed by Cushing (1932) and more recently by Sprague (1953).

Three women, aged 41, 42 and 53, presented difficult diagnostic problems. They had amenorrhœa, moon facies, truncal obesity and facial hirsutism, but no striæ, skin atrophy or osteoporosis. 2 had diabetic glucose tolerance curves, and 2 were severely hypertensive. The plasma 17-hydroxycorticosteroid and urinary 17-ketosteroid values were normal. In 2 the response to a six-hour infusion of ACTH was greater than normal. In the third this was not measured and the patient had a subtotal adrenalectomy. Hypertension of 230/130 has persisted, but headaches and retinal changes have subsided; her "Cushingoid" appearance has regressed, and she is no longer diabetic on maintenance therapy with 12·5 mg. cortisone twice daily. The other 2 patients are still under observation.

In 14 patients clinical and biochemical evidence failed to establish a diagnosis of Cushing's syndrome. In 5, obesity was confined to the trunk but was more generalized in the others who had fat pads on the backs of their fingers. Without hormone assays it was particularly difficult to assess post-menopausal hypertensive women with round, plethoric faces who had gained weight and had an abnormal glucose tolerance curve.

Hormone assays.—Chemical methods for calculating adrenocortical hormones are difficult because of the large number formed and because in both urine and plasma they are present in conjugated and unconjugated forms (Bongiovanni and Eberlein, 1955). The method of Norymberski *et al.* (1953) is recommended for measuring the urinary excretion of glucocorticoids and their metabolites. The technique of Nelson and Samuels (1952) for estimating unconjugated plasma 17-hydroxycorticosteroids is useful but unsuitable for routine use. In most cases of Cushing's syndrome increased amounts of glucocorticoids can be demonstrated in urine and plasma by these methods. Sometimes the plasma level may be more informative than the urinary excretion, and Jailer and his colleagues found in 2 patients that repeated urinary assays were normal whereas on four out of five occasions the plasma levels were abnormally high (Wallace *et al.*, 1955).

How are the normal urinary or plasma corticosteroid levels found in some patients with undoubted Cushing's syndrome to be explained? Sometimes perhaps a steroid is secreted

which is not estimated by the method used (for example corticosterone is not measured by the Nelson and Samuels' technique). In other patients marked day-to-day fluctuations in adrenocortical activity may necessitate repeated estimations being made (Birke *et al.*, 1956). Another difficulty may be that adrenocortical activity is only slightly greater than normal. Normally adrenal activity varies throughout the day, secretion being lowest during the night and reaching a maximum at about 6 a.m. (Bayliss, 1955). Failure of this nocturnal reduction in hormone secretion might be sufficient to induce hyperadrenalism, and many but not all cases of Cushing's syndrome lose this diurnal variation (Laidlaw *et al.*, 1955; Lindsay *et al.*, 1956). Equivocal hormone findings occur most often in patients with adrenal hyperplasia, and it is in these cases that the response to ACTH stimulation (2 units per hour infused intravenously for six hours) is so helpful (Fig. 3).

Differentiation of adrenopathies.—The distinction between adrenal hyperplasia, adenoma or carcinoma may be made by palpating an adrenal tumour, which usually indicates a carcinoma is present; by finding enlargement of the sella turcica, which suggests a pituitary adenoma and adrenal hyperplasia; or by presacral air insufflation. Often hormone assays make the differentiation.

The excretion of 17-ketosteroids is usually high in adrenal carcinoma, low in adenomas and intermediate in hyperplasia, but the overlap between the three is so great that in individual cases reliance cannot be placed on this differentiation (Forbes and Albright, 1951; Sprague, 1953).

In adrenal hyperplasia the response to ACTH, as measured by glucocorticoid secretion, is greater than normal but minimal or absent in patients with an adenoma or carcinoma. Suppression of the pituitary will reduce the excretion of 17-ketosteroids and glucocorticoids in cases of hyperplasia but not when there is a tumour. Although cortisone or hydrocortisone in high dosage suppresses the pituitary (Jailer *et al.*, 1954), they contribute substantially to the urinary glucocorticoid and 17-ketosteroid excretion; 9 α-fluorohydrocortisone (Cope, 1956) and $\triangle_1$-9 α-fluorohydrocortisone, which suppress the pituitary in a daily dose of 5–10 mg. and 4–6 mg. respectively, are preferred because they do not add significantly to the amount of steroid excreted in the urine.

Dr. Richard Asher: *Psychiatric Aspects of Cushing's Syndrome*

Mental changes in Cushing's syndrome are very common and a rough estimate from published cases suggests that two-thirds of the patients show some degree of psychiatric disturbance and one-fifth of all cases become psychotic. The commonest change is depression of the mood but severe psychotic changes may occur, with melancholia, retardation and delusions of persecution.

There are three possible causes for the psychiatric symptoms:

(*a*) That Cushing's syndrome is caused by psychic trauma and that the same emotional insult that initiates the endocrine change is also responsible for the psychiatric disturbance. This is an unlikely theory but hard to disprove. There is no good evidence that either Cushing's syndrome or psychoses are caused by psychic trauma; they seem to come "out of the blue".

(*b*) That the mental changes are reactions to the physical stigmata of Cushing's syndrome. As other disfiguring diseases do not show nearly so high a proportion of psychiatric disturbance it seems reasonable to dismiss this theory as improbable.

(*c*) That the mental changes are due directly to the endocrine disturbance. This is the most probable explanation and we have this evidence in its favour:

(i) As it is known that other endocrine diseases produce mental symptoms it seems reasonable to expect that this one might do so.

(ii) Cortisone administration can produce psychiatric changes, so excessive cortisone secretion might be expected to do likewise.

(iii) When the endocrine dysfunction is remedied by treatment the mental changes usually clear up at the same time.

The identification of the hormone responsible for the mental symptoms and the mechanism of their production remain unknown. Attempts to correlate the degree of psychiatric disturbance with steroid levels, electrolyte figures or changes in the cerebrospinal fluid have all proved unfruitful. It is strange that cortisone is noted for producing euphoria whereas hypercorticalism usually produces gloom and despondency, but now cortisone is readily available and less highly thought of, euphoria from its use seems less common.

How do the mental changes respond to bilateral adrenalectomy (which seems the only treatment for Cushing's syndrome)? The number of cases effectively treated and adequately followed up is small, but enough to suggest that the results are good.

Hertz *et al.* (1955) record a young soldier with Cushing's syndrome who ran amok in the guard room with maniacal behaviour followed by an attempt at suicide. Prolonged mental hospital treatment and 26 E.C.T.s had no effect on his apparently schizophrenic psychosis, but when the endocrine component was recognized a dramatic recovery immediately followed bilateral adrenalectomy. Hamm (1955) had 2 cases, both confined to mental institutions with severe symptoms, who made an excellent recovery after operation. Of the 4 severely psychotic cases recorded by Trethowan and Cobb (1952), 3 recovered completely and 1 improved. Other cases with less severe mental symptoms recovered as physical improvement took place. It seems probable that both major and minor psychiatric symptoms clear up completely when Cushing's syndrome is effectively treated.

As an illustration I will describe one of my own cases.

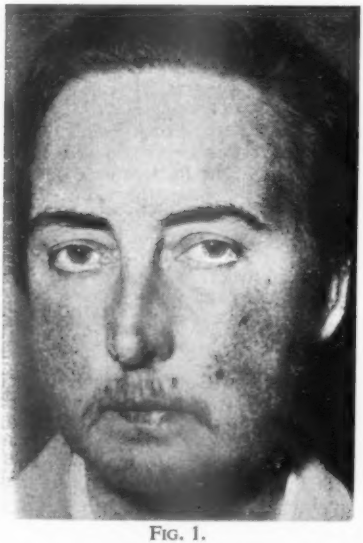

FIG. 1.

FIG. 2.

Mrs. M., aged 40, was admitted to a mental hospital in October 1954 with six months' severe depression. She did not improve with E.C.T., and after one month she was transferred to the Central Middlesex hospital for investigation of a coincidental sciatic nerve palsy. She was mentally too ill to give much history—she was mute and negativistic and usually had to be forcibly fed. Her husband gave a history of her two years' amenorrhœa, rounding of the face, increasing hairiness of the cheeks and chin, 4-st. gain in weight and spontaneous bruising of the legs. These changes were fully confirmed by inspection of the family photograph album. Her face showed the classical changes of Cushing's syndrome (Fig. 1), her urine contained sugar, her legs showed multiple spontaneou

bruises and her blood pressure was 210/140 mm.Hg. Her mental state was even more pathological; most of the time she stayed motionless in deep dejection, mute, miserable and beyond the reach of any kindly or comforting word. Occasionally she would whisper her desire to die; otherwise she was silent and inaccessible.

Total bilateral adrenalectomy was carried out by Mr. Peter Gummer on December 22, 1954. Mental and physical improvement began a fortnight later and continued steadily. Six weeks after operation she was well enough to be allowed home. Two months later she was mentally normal and the change in her appearance was so striking that nurses who had cared for her at the time of operation were unable to recognize her (Fig. 2). Two years after the operation her mental and physical recovery are wholly maintained. Her menses have returned, the hypertension has gone and she is a vigorous, alert and intelligent woman enjoying a happy family life with her husband and children. She takes cortisone 12½ mg. daily.

Dr. A. Stuart Mason: *Treatment of Cushing's Syndrome by Adrenalectomy*

In April 1953 Dr. Sprague presented to this Section the experience of the Mayo Clinic in the treatment of Cushing's syndrome. He noted the poor prognosis of the disease and the ineffectiveness of earlier treatments. He then reviewed the excellent results obtained by radical subtotal adrenalectomy. This operation is now accepted as the treatment of choice for Cushing's syndrome associated with bilateral adrenal hyperplasia.

Radical resection, or total removal of both adrenal glands has been a feasible operation only since the recent introduction of cortisone and hydrocortisone; experience of the procedure comes slowly because of the rarity of Cushing's syndrome. For these reasons I have attempted a review of the present status of adrenalectomy in Cushing's syndrome by adding my own experience to that of several colleagues.[1]

A valid assessment of adrenalectomy depends on a series of cases which is homogeneous from the clinical aspect, confined to the years when essential hormonal therapy has been available, and with an adequate period of post-operative observation. Therefore, every case included in the series fulfilled the following criteria:

(1) An unequivocal diagnosis of Cushing's syndrome in the absence of an adrenal tumour.

(2) Treatment by adrenalectomy; the first operation being performed between January 1, 1950, and December 31, 1955.

(3) A minimum follow-up period of nine months.

The series comprises 52 cases, the sex and age of the patients being given in Table I. The sex ratio shows a preponderance of females compared to that in other published series (Bishop, 1954) with a relatively large number in middle age. The final clinical assessment is recorded in Table II. The total mortality rate is 25%, but for those patients who survived three months after operation the mortality rate was 9·3% during the period of observation. The results of adrenalectomy are excellent in terms of recovery from Cushing's syndrome and it is unnecessary to dwell on the dramatic clinical change that follows the operation. Only 2 survivors had persistent but non-progressive adrenal hyperfunction and both refused further treatment. However, it is important to realize how many patients have been left with permanent adrenal hypofunction, either from deliberate total adrenalectomy or from atrophy of the adrenal remnant.

The amount of adrenal tissue removed at operation has varied considerably, as shown in Table III. There has been a trend towards more radical removal; 10 of the 11 total adrenalectomies were performed after June 1952 and in 20 of the 26 subtotal adrenalectomies performed since that date less than 16% of adrenal tissue remained; in only 4 of 15 subtotal operations performed before that date was such a small adrenal remnant left.

Some of these operations were performed in two stages; it is advisable to perform the full operation in one stage whenever the patient's condition at operation will allow. Total removal of one adrenal and subtotal resection of the other is preferable to subtotal resection of both adrenals. One patient relapsed some time after resection of both adrenals and it was impossible to know which adrenal should be approached for further operation.

The reason for a radical approach to adrenalectomy is apparent from Table IV. Removal of 50% or less of adrenal tissue failed to control Cushing's syndrome, except in the instance of 2 cases aged over 45 years who also had post-operative deep X-ray therapy to the pituitary. Removal of 90% to 95% of adrenal tissue gave the best results in terms of curing Cushing's

[1]The following contributed material: Dr. R. Asher, Dr. R. I. S. Bayliss, Dr. P. M. F. Bishop, Dr. A. C. Crooke, Dr. R. Fraser, Dr. R. Green, Dr. J. D. N. Nabarro, Professor F. T. G. Prunty, Dr. S. L. Simpson and Dr. A. W. Spence. I am deeply grateful to them and the many other surgeons and physicians who were responsible for the clinical care of these patients.

Total 13 (25% Mortality Rate)

Post-operative

(1) Immediate 5
(2) Within three months 4
} 9 { 5 of 39 subtotal adrenalectomies; 4 of 11 total adrenalectomies

Long-term: 4 deaths. Time after operation: 1 year in 3 cases; 5 years in 1 case

syndrome, but there was a significant proportion of cases left with permanent adrenal hypofunction.

6 patients were cured of their original disease by removal of 75% or more of adrenal tissue but relapsed subsequently. The eldest was 37 years of age but the other 5 patients were all under 25. Indeed, 5 of 13 patients of that age group who survived subtotal adrenalectomy relapsed within the period of observation. The average interval between initial operation and relapse was two years. In that time the adrenal remnant had enlarged by four to eight times its original size. This tendency to further adrenal hypertrophy with a concomitant relapse to Cushing's syndrome appears to be confined to the youngest age group.

Of the 12 patients who were not cured of Cushing's syndrome or who subsequently relapsed, 2 died with non-progressive adrenal hyperfunction and 2 survived in a similar state. 8 cases were submitted to further operation, the adrenal remnant being removed in 4 instances and radically resected in the other 4 cases. 2 of the latter patients were cured of Cushing's syndrome but developed adrenal hypofunction, 1 relapsed again and the adrenal remnant was removed, and 1 continued to have a mild degree of adrenal hyperfunction which disappeared spontaneously two years after the second operation.

The 13 deaths occurring in the series are analysed in Table V. There is no mention of post-operative complications which did not prove fatal, but this does not imply that the operation is not fraught with difficulties of management. The appropriate medical care and the problems encountered are very different from those associated with the removal of normal adrenal glands. Cardiovascular disorders were predominant as the cause of death at all times. Death in the immediate post-operative period was due to pulmonary embolus (2

cases), heart failure (2 cases), or cerebral hæmorrhage (1 case). Hypertension played a part in these deaths and in all those which occurred subsequently, with the exception of 1 patient who was mistakenly deprived of his maintenance therapy some weeks after total adrenalectomy. The state of the vascular system is determined by age as well as endocrine factors. The mortality rate in this series was 15% (4 deaths in 26 cases) for those under 35 years old, 22% (3 deaths in 14 cases) for those aged 35–44 years and 50% (6 deaths in 12 cases) for those over 44 years old.

Hypertension may persist after operation and be independent of any abnormal adrenal stimulus. This occurred in 6 patients whose adrenal function became normal after operation. It was also seen in one patient after total adrenalectomy. Continuing hypertension was observed mainly in the more elderly patients with a relatively long history of Cushing's syndrome.

It is difficult to assess the effect of the severity of Cushing's syndrome on the final prognosis, as no case was submitted to adrenalectomy unless the disease could be termed at least moderately severe. The age of the patient and perhaps the duration of the disease appear to be the most important factors in final assessment. The influence of deep X-ray therapy as an adjuvant to adrenalectomy was not ascertained fully as only 6 patients were given this treatment after operation. 2 elderly patients with conservative subtotal adrenalectomy may well have been helped by such therapy. 3 of the other patients developed adrenal hypofunction and 1 had a relapse of Cushing's syndrome.

This series confirms the general experience that Cushing's syndrome is cured by removal of at least 75% of adrenal tissue.

These cases also show that:

(1) There is a very narrow margin between removing enough adrenal tissue to prevent relapse and the amount which causes adrenal hypofunction. There is virtually no margin in patients under 25 years of age. In consequence, the grave decision to undertake a total adrenalectomy is advisable in this group, because of, rather than despite their age.

(2) Patients aged over 45 years are more liable than the younger ones to die after operation, particularly after total adrenalectomy. They are also likely to have suffered irreversible damage to the vascular system. Earlier diagnosis is obviously of importance, but, failing this, subtotal adrenalectomy removing 75% of the tissue or even unilateral total adrenalectomy is preferable to more radical operation. Post-operative deep X-ray therapy to the pituitary should be employed.

(3) Patients aged between 25–45 years should be treated by subtotal adrenalectomy, removing 85—90% of adrenal tissue.

(4) At all times the success of adrenalectomy in curing Cushing's syndrome should be measured against the hazards of operation and the dangers of permanent adrenal hypofunction.

BISHOP, P. M. F. (1954) Recent Advances in Endocrinology. London.
SPRAGUE, R. G. (1953) *Proc. R. Soc. Med.*, **46**, 1070.

Dr. J. D. N. Nabarro favoured total adrenalectomy for the treatment of florid cases. Subtotal adrenalectomy, as well as carrying a risk of relapse, might be deceptive: although the patient had sufficient adrenal cortical tissue for ordinary activities there might be no reserve for additional stress.

He mentioned a young patient with bronchial carcinoma complicating Cushing's syndrome due to adrenal cortical hyperplasia. The patient underwent total adrenalectomy and was reasonably well one year later; the carcinoma was progressing but at a much reduced rate.

Dr. C. L. Cope said that many people had now encountered cases showing well-developed clinical Cushing's syndrome, in which laboratory tests for adrenal function were normal, or almost so. The first ten cases he had studied all had urinary hydrocortisone excretions above the upper limit of normal, but the hydrocortisone output of the eleventh was normal. The situation now was that adrenal function tests were of confirmatory value in Cushing's syndrome if raised well above normal, but of little or no value when within normal limits.

Adrenal inhibition tests were of no value in establishing the presence of adrenal hypofunction, since both normal and hyperplastic glands could be inhibited. But if, in an ambiguous case, adrenal inhibition could not be clearly produced by a potent steroid like 9 α-fluorohydrocortisone, then there would be greater suspicion of adrenal tumour and the indication for early surgical exploration of the adrenals would be stronger.

Dr. A. W. Spence said that normal adrenal glands were occasionally found in undoubted cases of Cushing's syndrome. The histological appearance of an endocrine gland was no

necessarily an index of the amount of hormone it was secreting. This was certainly true for the thyroid gland and it seemed to be true in the case of the adrenal cortex.

In patients with Cushing's syndrome due to adrenocortical hyperplasia the treatment indicated depended on the severity of the disease. In the incomplete or milder cases the removal of one gland might produce a satisfactory result, although admittedly a relapse sometimes occurred. The effect of irradiation of the pituitary gland had on the whole been disappointing, although in one patient with the complete syndrome, removal of one gland—followed some months later by irradiation of the pituitary—produced a most satisfactory response. In the severer cases the choice of treatment rested between subtotal and total adrenalectomy. Now that cortisone was available he favoured total adrenalectomy for these patients, because with the subtotal operation a relapse might occur. In one of his patients on whom subtotal adrenalectomy was performed, the subsequent relapse was as severe as the original disease and necessitated a further operation to remove the hyperplastic remnant.

This patient became pigmented after the first operation and deeply pigmented after the second. Pigmentation of this type was at first thought to be due to corticotrophin, but later it was shown to be produced by the melanocyte-stimulating or melanophore-expanding hormone. He understood that this hormone was secreted by the pars intermedia. Did this mean that in Addison's disease and in some cases of Cushing's syndrome there was increased activity of the pars intermedia or was the pigment hormone also produced by the anterior lobe?

Dr. A. C. Crooke and his colleagues had been disappointed with subtotal adrenalectomy for Cushing's syndrome because it was difficult to determine how much gland to remove and recurrence of the initial symptoms or the development of adrenocortical insufficiency was common. They had therefore performed total adrenalectomy recently but were anxious about what complications might arise from this procedure.

Four of their patients who had had total adrenalectomy for Cushing's syndrome or for malignant hypertension, and who had been treated with cortisone only in a dosage of from 37·5 to 50 mg. daily, had developed pain in the spine with persistent slight hypercalcæmia of 11 to 13 mg. per 100 ml. plasma. One, a woman aged 37 years, who had severe Cushing's syndrome complicated by malignant hypertension, had her operation on 29.9.55. She was readmitted for study of her calcium balance and was found to excrete a total of 625 mg. of calcium, including 230 mg. in her urine, on a diet containing 100 mg. calcium daily. They suspected that the bone pains and hypercalcæmia of these patients were associated with progressive loss of calcium and osteoporosis as a result of a specific adrenocortical deficiency.

Mr. R. B. Welbourn said that 13 cases of Cushing's syndrome (12 with hyperplastic or hyperfunctioning adrenal glands and one with an adrenal adenoma) had been investigated and treated by Dr. D. A. D. Montgomery and the speaker in the past three and a half years.

In only one, who came to autopsy, was there certain evidence of a basophil adenoma. The ages ranged from 15 to 53 years, and there were 11 women and 2 men in the series. Special methods of investigation included measuring the excretion of: reducing corticoids (Broadbent *et al.*, 1953), which were raised in all of 5 cases; 17-hydroxycorticoids after two days' stimulation with corticotrophin (Reddy *et al.*, 1952), which were raised in 6 out of 9 cases; and 17-ketosteroids, which were raised in 6 out of 11 cases. Pre-sacral insufflation with oxygen, combined with intravenous pyelography and tomography, was used routinely, but gave false positive and false negative results. It was probably of most value in localizing large tumours.

Treatment consisted of irradiation of the pituitary in 2 cases, subtotal removal of a gland containing an adenoma in 1, and sub-total (95%) removal of one gland plus total removal of the other (in 2 stages) in 12 (Welbourn, 1957). Pituitary irradiation produced no benefit and the patients subsequently underwent adrenalectomy. The results of adrenalectomy were as follows:

No. of patients	13
Immediate post-operative deaths	1
Later deaths	2
Complete remission at 1 to 3½ years after op.	10
No. requiring permanent cortisone replacement ...	3

The patient who died post-operatively developed acute peripheral circulatory failure and coma. The circulation responded temporarily to nor-adrenaline and hydrocortisone intravenously, but the coma did not. No cause of death was found *post mortem*.

The non-adenomatous adrenal glands varied in weight from 2·5 to 15 grams and were normal histologically.

The clinical remissions had been striking (Beck *et al.*, 1954) and all the patients now looked normal. The blood pressure had fallen significantly in all but had returned to normal in only 4, namely the 3 youngest and the oldest. 2 patients had generalized Addisonian pigmentation and 2 others had had their adrenalectomy scars pigmented temporarily.

Dr. Leonard Simpson stated that although the classical clinical picture of Cushing's syndrome was well defined, it was not surprising that there were various deviations, particularly as the hyperplastic adrenal gland could secrete glucocorticoids and androgens in varying proportions. Although a motley of ill-defined clinical material should be excluded, there still remained a number of atypical or incomplete forms of Cushing's syndrome which merited consideration from the point of view of radical therapy, including subtotal adrenalectomy.

As to treatment, subtotal adrenalectomy was effective in a sufficiently high percentage of cases to be regarded as the method of choice, with a mortality near zero. A portion of the adrenal gland could be kept at low temperature for long periods, for auto-transplantation if and when severe chronic adrenal insufficiency resulted (technique of tissue preservation of Rob and Eastcott, 1955). The vicissitudes and vulnerabilities of patients with severe Addison's disease, or with total adrenalectomy, even in the modern cortisone era, led him to the view that total bilateral adrenalectomy was rarely, if ever, justified for non-malignant conditions.

Finally, one of the most severe cases of Cushing's syndrome under his care at St. Mary's Hospital had adrenal glands of normal size and appearance, and of normal weight, and normal histology; and yet the patient made the most dramatic return to normality after bilateral subtotal adrenalectomy by Professor C. G. Rob, and has remained in normal health for some years.

ROB, C. G. and EASTCOTT, H. H. G. (1955) *Brit. med. Bull.*, **11**, 217.

Dr. O. Garrod drew attention to data which showed how careful one had to be before assuming that the severe electrolyte disturbances sometimes found in Cushing's syndrome were due to increased aldosterone secretion.

Dr. T. M. Chalmers, Dr. and Mrs. J. F. Tait and the speaker had recently studied the steroid excretions in two cases of Cushing's syndrome due to proven adrenal carcinoma. Both patients had severe hypokalæmia (plasma potassiums of 2·7 mEq./l.) and a very low total exchangeable body potassium, 22·3 and 24·3 mEq./kg. respectively (normal range 35–48 mEq./kg.). The daily urinary steroid excretions in the first case were as follows: aldosterone 4 μg., cortisol 1,200 μg. In the second case, before removal of the adrenal tumour, they were: aldosterone 5·8 μg., cortisol 370 μg., corticosterone 34 μg. After removal of the tumour, the plasma potassium having risen to 4 mEq./l. and the exchangeable body potassium to 35·6 mEq./kg., the steroid excretions were: aldosterone 15 μg., cortisol 5·3 μg., corticosterone 4 μg. The normal ranges of steroid excretion for the method used (Ayres *et al.*, 1957) were as follows: aldosterone 5–22 μg., cortisol 13–86 μg., corticosterone 2·2–9 μg.

It would seem, therefore, that the severe electrolyte disturbances in these cases were due not to excessive aldosterone secretion, the output of this "mineralocorticoid" hormone being at the lower limit of normal, but to excessive secretion of one or both of the so-called "glucocorticoids", cortisol and corticosterone, both of which might have powerful "mineralocorticoid" actions in large doses, comparable with the amounts sometimes secreted in Cushing's syndrome. Unfortunately, because the corticosterone excretion was not measured in the first case, it was not possible from this data to assess the relative role of corticosterone in producing these changes.

Parapsoriasis

By J. T. Ingram, M.D.

Parapsoriasis is relatively uncommon and the natural history of the disease, often extending to forty or fifty years, is such that no dermatologist has sufficient experience to talk with authority and it is important to pool our knowledge. The fact that parapsoriasis is almost without symptoms and is unresponsive to treatment increases the difficulty in keeping patients under review.

I shall not discuss parapsoriasis en gouttes, also described as pityriasis lichenoides, for we are now agreed that this is a different entity, self-limited, recovering spontaneously and giving rise to no disturbing sequelæ. I intend to mention briefly poikilodermie of Jacobi and the malignant reticuloses or lymphomas. I shall confine my attention in the main to parapsoriasis en plaques and parapsoriasis lichenoide which is the same as parakeratosis or lichen variegata.

Toward the end of last century and the beginning of this, experienced dermatologists in many countries independently described affections which Brocq (1902) believed to be related and which, without prejudice, he gathered into one group on clinical and morphological grounds alone. Because of some resemblance to psoriasis and the lichens he used the term parapsoriasis and we have since added little to our knowledge of these affections. His terminology and classification are universally employed to-day.

His first group was parapsoriasis en gouttes which was clearly identical in his mind with the pityriasis lichenoides chronica of Juliusberg (1899) later enlarged to include an acute and varioliform variant by Habermann (1925) and Mucha and now generally excluded from the field we have under consideration.

His second group, parapsoriasis en plaques, remains distinctive and well established. Generally, however, the eruption, starting on the legs or arms, presents defined, bizarre, macular lesions of a fawn colour with the semblance of scaling. They are fixed and never disappear though they may wax and wane, they may enlarge or more lesions may appear. Parapsoriasis is either symptomless or sensitive to changes or extremes of temperature, giving a sensation of pricking, burning or soreness but not of itching and no desire to rub or scratch. It may improve and temporarily clear with warmth and sunshine or following the application of thorium X. Otherwise the disease is entirely resistant to treatment but the patients are in good health.

Radcliffe Crocker (1905) used the term xantho-erythroderma perstans which is beautifully descriptive.

A variant which Brocq likened to a "leopard skin" shows profuse symmetrical, nummular or oval lesions mostly on the trunk. A small almost guttate form of this type of parapsoriasis may be difficult to differentiate from pityriasis lichenoides and may require prolonged observation before a decision is reached.

There may be less persistent papular lesions with parapsoriasis en plaques. They have been discussed in detail by Civatte (1936, 1951) and they may confuse the issue but they are different from and less lichenoid than the papules of pityriasis lichenoides and do not run the regular cyclical course of the papules of that disease.

Brocq's parapsoriasis lichenoide, described by Unna as parakeratosis variegata and by English authors as lichen variegata, shows a papular, lichenoid and plaque eruption, reticular in a fine or coarse-meshed fashion, scaly and dusky in hue by reason of congestion and pigmentation. Brocq stressed its resemblance to lichen planus; it is not unlike the lichenoid drug eruptions we have seen in recent years from mepacrine. It is more widespread in distribution than parapsoriasis en plaques but equally persistent and fixed and resistant to treatment. It is symptomless or associated with slight discomfort but no itching. It is much less common than parapsoriasis en plaques.

Civatte (1936, 1951) used the term parapsoriasis lichenoide for a type with the more delicate network and atrophy or pseudo-atrophy and the term parakeratosis variegata for the coarser, thicker, more scaling type. These may be confused with poikilodermie of Jacobi which is a finer, macular affection of flaming telangiectatic networks often with atrophy, pigmentation, papules and ulceration closely resembling X-radiation damage and not at all suggestive of lichen planus. Similar changes in the skin are caused by sunlight, X-radiation, heat and cold, drugs, syphilis, infections and cancer where the target organ would seem to be vascular rather than epidermal.

With these two distinctive types of eruption there is little difficulty for the experienced dermatologist but great difficulty arises from the fact that a number of patients present eruptions that are intermediate between these two types, a fact which Brocq himself noted fifty years ago. In addition, the pattern may change slowly over the years so that at one stage the picture presented is typical of one form of parapsoriasis and at others of poikilodermie. In these intermediate cases difficulties arise over the presence of papular elements, the epidermal thickness of lesions, the degree of scaling and the vascularity. In the same patient, some lesions or even parts of lesions may be persistently pale and others bright red, or there may be a follicular stippling of erythema giving an appearance resembling a fading cattle ringworm lesion. These variations are difficult to understand and are not elucidated by histological examination.

Furthermore the leukæmias and malignant reticuloses (the lymphomas) at any stage may produce xerodermatous or erythrodermic states or bizarre erythematous eruptions indistinguishable from intermediate types of parapsoriasis. A retrospective diagnosis of parapsoriasis in a patient now suffering from a malignant reticulosis may very well be correct but is uncertain.

I have recently reviewed the patients I have seen in private practice with parapsoriasis, a total of 30 in a series of 25,000 patients. I believe that these patients would all be accepted by a gathering of dermatologists such as this and I have omitted all cases in which I had any doubts.

I have seen fifty times as many cases of psoriasis and fifteen times as many of lichen planus.

In the 25,000 patients I have also seen 15 with pityriasis lichenoides and 8 with poikilodermie of Jacobi.

Of the 30 patients under review 19 were male and 11 female and the average age of onset was 39 in males and 36 in females. However, while the age of onset varied from 5 years to 80 years the disease rarely started before 30 years of age or after 45.

The average duration in the patients who have come under my care to date is eighteen years but the range has been from one to fifty years. 4 of the 30 patients have not been traced since the war and 3 others have died, 1 from mycosis fungoides and 2 from unrelated natural causes. The remaining 23 patients have been reviewed this year.

Of the 30 patients 5 presented the pattern of parapsoriasis lichenoide (parakeratosis variegata) and the remainder were essentially examples of parapsoriasis en plaques. One of these, in whom the eruption has persisted now for twenty years, is of Brocq's "leopard skin" pattern and a number of the others show intermediate types of lesions.

A point of some interest is that the son of one of my patients with parapsoriasis has also developed the affection. The father, who died from intestinal obstruction at the age of 65 years, had a coronary infarction a few years before his death. He had had parapsoriasis en plaques for forty-five years. The son, now aged 43 and a patient of my colleague Dr. S. T. Anning, has exactly similar parapsoriasis en plaques which has been present twenty-three years. He also had a coronary infarction two years ago.

In 2 of my patients with parapsoriasis en plaques the eruption cleared, in 1, a boy, after eight years and in the other, a female, after nine years. The affection had started in the one at the age of 5 and in the other at the age of 20.

In 4 patients tumours have developed. In 2 the clinical picture was that of mycosis

fungoides, arising twelve and thirty years after the onset of parapsoriasis. One of these patients has died from the disease. In one patient, a man of 81, parapsoriasis has been present for twenty-one years and during the past ten years the patient has produced tumours clinically resembling mycosis fungoides, which have ulcerated and healed spontaneously in the course of one to six months. The fourth patient, a female aged 76, has had parapsoriasis en plaques for forty years. Ten years ago she developed a single large tumour on the forehead which was excised and histologically showed the infiltration of a malignant lymphoma. She has had no further tumours. I have seen this tendency to tumour formation, single or multiple, in other patients without discomfort or other suggestions of grave malignancy and regard it as an indication for conservative treatment.

In my hospital records there are five examples of malignant reticuloses arising in the course of parapsoriasis at intervals of six to thirty years after the onset of the disease. 4 have died from the disease. In my experience such a transition has been more common in the parapsoriasis lichenoide pattern and in intermediate cases approaching this pattern rather than in the pure parapsoriasis en plaques of the xantho-erythroderma perstans type. This is in accord with the view of Lapière (1949, 1956) and others who suggest that the presence of reticulation and telangiectasia forebodes a lymphomatous development. I do not find the incidence of such change as high as Lapière would put it and I think what I have called the simple pattern of parapsoriasis en plaques can be expected usually to run a benign course.

The last observation I would make on my series is on the coincidental association of parapsoriasis with other dermatoses. 4 patients had xeroderma, familial, from birth. 5 others suffered dry eczematous eruptions from various causes which ran courses quite independently of the parapsoriasis. None had psoriasis.

I cannot get figures of the incidence of parapsoriasis in warmer climates but most patients improve in summer weather. One of my patients says that he clears while in South Africa to relapse on his return to this country. Serri (1951) found few cases reported in Italy.

The differential diagnosis is commonly difficult and not readily resolved. The mimicry of parapsoriasis seen in eczema and psoriasis and with some drug eruptions; the fixity of the eruption reminiscent of drug rashes and the similarity of its behaviour to that of xeroderma and other essentially epidermal reactions as pityriasis rubra pilaris are noteworthy.

Are we dealing then with a single disease entity sometimes presenting as a benign dermatological affection, sometimes as a systemic affection? We are familiar with the conception in vascular disease, in lupus erythematosus, sclerosis, tuberculosis, sarcoidosis and the reticuloses. Or are we dealing with a symptom complex that can be provoked by a variety of stimuli but demands a certain predisposition? There is evidence to support both ideas but the latter would seem the more probable.

Parapsoriasis Lichenoides en plaque, with Necrotic Nodules, showing Features of Poikiloderma.
—L. FORMAN, M.D., F.R.C.P.

D. B., female, aged 55.

History of skin eruption for thirty years and has been under observation for over twenty-five years. It commenced with a generalized irritable erythema which cleared after a few weeks to be followed by a chronic eruption which was widely distributed over the trunk and limbs.

This has shown the following morphology: (1) On the breasts and trunk a network of brownish-yellow papules—"parapsoriasis lichenoides". (2) Brown, non-pruritic slightly

chapped plaques some becoming confluent—"parapsoriasis en plaques" (Fig. 1). (3) Necrotic nodules healing with scarring. (4) Darker brown, scaling, lightly infiltrated plaques on the buttocks and abdomen, with periods of oozing, healing with pigmentation, dilated capillaries, and slight atrophy recalling the changes of "poikiloderma" (Fig. 2).

FIG. 1.—Parapsoriasis en plaques.

FIG. 2.—Plaque scaling, lightly infiltrated, pigmented with dilated capillaries, of "poikiloderma". Network of linear papules, parapsoriasis lichenoides.

Sections of scaling plaque on thigh (1932): Acanthosis and parakeratosis intra-epidermal vesicles, infiltration of upper dermis with lymphocytes.

Section of nodule: Dense infiltrate of papillary and subpapillary layer of cutis with an infiltrate of plasma cells, lymphocytes, endothelial cells with hæmorrhage.

Treatment and progress.—During 1938, thorium X 500 e.s.u. in spirit was painted on different areas, amounts used 1 c.c. to 4 c.c. at each treatment, 8 treatments in all being given with considerable improvement.

April 25, 1957, lichenoid papules are to be seen on the breast with slight pigmentation. Superficial plaque, brown, non-infiltrated on the right chest (*cf.* parapsoriasis en plaques). A scaling patch on the right thigh darker in colour and slightly infiltrated.

Comment.—There are several questions which remain to be answered. Thus, do parapsoriasis lichenoides, parapsoriasis en plaques, and retiform parapsoriasis exist as entities, morphologically pure, unchanged and innocent? This cannot be certain in view of the very long prodromals of mycosis fungoides. However, in this case with a duration of thirty years, and in another similar case with a duration of twenty-six years, the course appears to be relatively benign. Both cases have responded favourably to thorium X in that a considerable resolution of affected skin has been maintained. The changes of poikiloderma, with erythrodermia, atrophy and skin hæmorrhages may also be long standing but may terminate with malignant tumours. One case of mine developed after twelve years a reticulosarcoma with a histology resembling that of Hodgkin's disease (*Proceedings of the* 10*th Int. derm. Congr.*, London, 1952, p. 535).

Another case was reported by Dr. G. B. Dowling and Dr. E. Waddington (*Proceedings of the* 10*th Int. derm. Congr.*, London, 1952, p. 487) of poikiloderma atrophicans vasculare with a duration of twenty-five years before the onset of mycosis fungoides.

Again, does the skin reaction lead to continued stimulation of the reticulum elements causing eventually an uncontrolled metaplasia? It can be argued, however, that the reticulum changes are primary, the skin reaction being an expression of a response, beneficent in nature, eventually breaking down and allowing the reticulum to become malignant.

Lastly, should our attack on parapsoriasis and poikiloderma be more active, without awaiting the tumour stage, using all the methods available, including thorium X, beta rays, Grenz rays, &c.?

Liver Surgery in Relation to Diseases of the Colon and Rectum

PRESIDENT'S ADDRESS

By RONALD W. RAVEN, O.B.E., T.D., F.R.C.S.

THE relationship of the liver to diseases of the colon and rectum is a subject of academic and practical interest to surgeons. In a number of these diseases there are serious changes in the liver and the assessment of its condition is essential. Our knowledge of the behaviour of the liver under various circumstances has been enriched by the latest methods of biophysical and biochemical investigation.

STRUCTURE AND FUNCTION

Since the detailed account by Bradley (1908) of the morphology and development of the liver an extensive literature on this subject has been built up. Electron microscope studies demonstrate the details of this lobulated compound tubular gland and unveil the structure of its polyhedral cells. It shows the protoplasm with its mitochondria, ergastoplasm and inclusions of glycogen, fat and protein witnessing to the intensive metabolic activity within the cells. Other features include the large-sized nuclei, the quantity of nucleoprotein contained within the distensible nuclear membrane and the fine network of chromatin granules (Figs. 1, 2, 3).

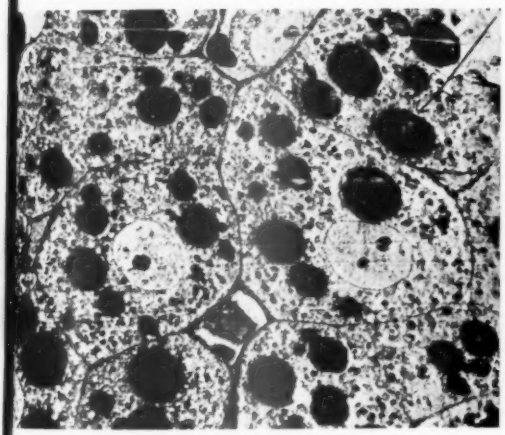

FIG. 1.

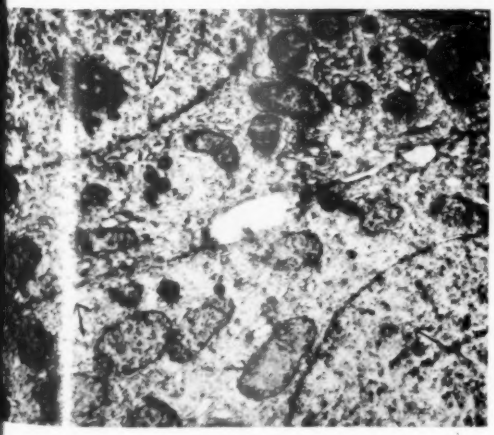

FIG. 2.

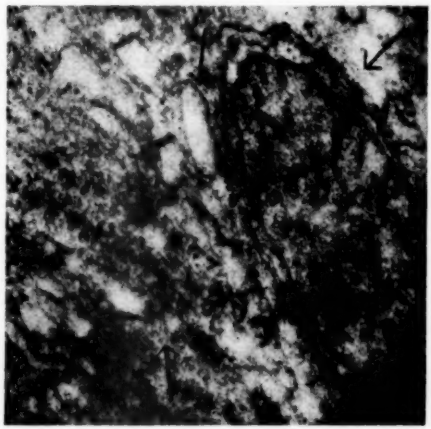

FIG. 3.

FIG. 1.—Electron microscope study of rat's liver showing the general arrangement of the cells and a large number of lipid granules in the cytoplasm (arrowed). ×1,250. (Courtesy of Dr. Mercer).

FIG. 2.—Electron microscope study of rat's liver showing only a part of two cells; the cell membranes are seen running obliquely down the centre and parts of the two nuclei in the corners (arrowed). Mitochondria with their characteristic internal structure are seen in the cytoplasm. ×6,250. (Courtesy of Dr. Mercer.)

FIG. 3.—Electron microscope study of rat's liver showing only a small area of the cytoplasm of a single cell; on the right there is part of a mitochondrion; a large number of nucleoprotein granules and cytoplasmic membranes are also seen (arrowed). ×37,500. (Courtesy of Dr. Mercer.)

Its functions are many and varied; they include the metabolism of pigments, carbohydrates, proteins and fats. It is an important excretory organ for bile constituents, toxins, drugs, and antibiotics; other functions are concerned with detoxication, storage, regulation of enzymes, water, salt, hormones and the blood volume.

Assessment of liver function.—This must be done before operation and is required in many colonic and rectal diseases in order to estimate liver damage and safeguard it from further harm. Important work was done by Maclagan (1956) on liver function tests. The tests required for each patient are chosen according to the clinical condition in the light of the clinician's experience.

Liver function tests.—In the interpretation of the results of these tests it must be remembered that a normal range can be found when severe liver damage is present because the parenchyma has a large functional reserve. Approximately one-tenth of the normal parenchyma is sufficient to maintain adequate function (Bollman and Mann, 1931) and this is demonstrated when large primary and metastatic tumours are present.

In the conservative treatment of ulcerative colitis a group of tests is done at intervals, and evidence of increasing liver damage influences the decision to carry out surgical treatment. In patients with liver metastases, extensive liver damage as shown by a group of tests may exclude the necessity for an exploratory laparotomy. This group includes a positive urinary urobilinogen, retention of bromsulphthalein and alkaline phosphatase raised above 13 units.

Liver biopsy has provided information about liver diseases, and corrected erroneous conceptions; it has influenced the treatment of certain conditions and helped with the prognosis. For example, Himsworth (1950) stated that in fibrotic conditions of the liver an exact diagnosis can be a decisive factor in lengthening a patient's life provided the appropriate treatment is given. Liver biopsy is performed at laparotomy, by needle aspiration and by peritoneoscopy. I prefer the first when the liver can be inspected and palpated and an adequate wedge of tissue selected and excised (Figs. 4, 5, 6 and 7). Experience is necessary to interpret the histological appearances for they differ from those seen in necropsy specimens. They can differ also in aspiration and surgical biopsies. The following are indications for biopsy:

(1) *To exclude liver disease when liver function tests are abnormal.*—One or more liver function tests can be abnormal when liver disease is absent and this may occur in chronic ulcerative colitis, as shown by this patient:

Male age 38 with severe ulcerative colitis of five years' duration preceded by amœbic dysentery ten years ago. Liver function tests: Serum bilirubin 0·2 mg.%, total serum protein 6·6 grams%, thymol turbidity 5, thymol flocculation 2+, serum colloidal gold 4+, zinc sulphate turbidity 8, ammonium sulphate turbidity 3. Liver biopsy: normal appearance. Operation: total colectomy and anterior resection of rectum with immediate ileo-rectal anastomosis. Post-operative liver function tests: Serum bilirubin 0·1 mg.%, thymol turbidity 3, thymol flocculation 0, zinc sulphate turbidity 6, serum colloidal gold 0.

(2) *To exclude liver disease when the liver is palpable.*—A normal liver is often palpable and an incorrect assumption may be made that it is diseased unless a biopsy is done.

(3) *To confirm liver disease.*—Some liver conditions remain obscure without a biopsy, as in ulcerative colitis, amœbic dysentery, chronic infections, benign and malignant tumours.

Results.—A liver biopsy was considered advisable in 30 of my patients who underwent major abdominal operations. In 12 (40%) the histological appearance of the liver was normal. The abnormalities discovered were generalized fibrosis in 7 (23%), local fibrosis in 3 (10%), fatty degeneration in 6 (20%) and carcinoma metastases in 2 (7%).

The Liver in Diseases of the Colon and Rectum

In view of the intimate vascular relationship between the liver, colon and rectum it is surprising that serious effects are not produced more often in the liver by rectal and colonic disease. Effective immunity against many liver infections may be provided by its rich blood supply.

Hepatic lesions in chronic ulcerative colitis.—These should be recognized so that they may be treated or to safeguard the liver from further adverse effects by surgical treatment of the colitis. In more than 500 patients studied at the Gordon Hospital serious liver lesions were uncommon. Liver function tests were done in about one-half, and approximately one-third of these showed minor deviations from normal, only a small number having severe changes.

The following hepatic lesions may occur: (i) Abscess, single or multiple; (ii) Inflammatory foci. (iii) Interlobular hepatitis. (iv) Hepatic fibrosis. (v) Intrahepatic thrombosis. (vi) Fatty degeneration. (vii) Cirrhosis. (viii) Amyloid degeneration.

(i) *Liver abscess.*—This is rare in contrast to its relative frequency in amœbic infection of the colon. Lansbury and Bargen (1933) reported one case; Elsom and Ferguson (1941)

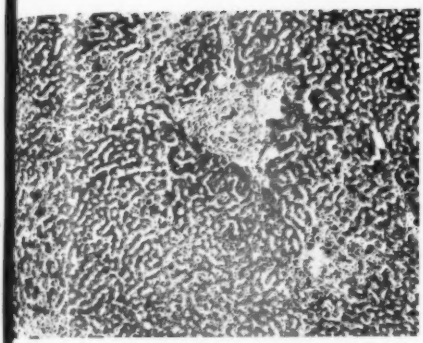

FIG. 4.—Liver biopsy showing normal parenchyma in a case of chronic cholecystitis. ×32.

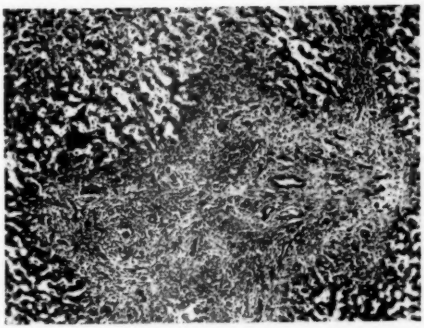

FIG. 6.—Liver biopsy showing the changes of moderately severe biliary cirrhosis—dilatation of biliary sinusoids, peri-lobular fibrosis, lymphocytic infiltration and proliferation of bile ducts. Case of empyema of the gall-bladder. ×32.

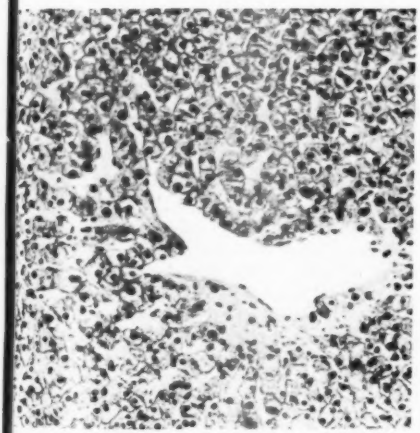

FIG. 5.—Liver biopsy showing a minimal degree of fatty infiltration in a case of chronic cholecystitis. ×125.

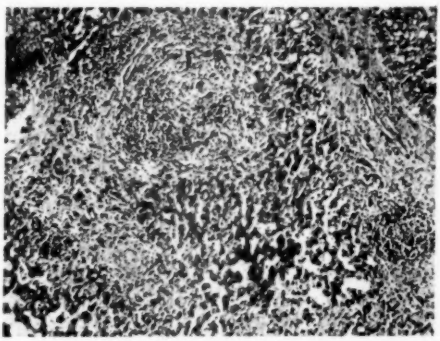

FIG. 7.—Liver biopsy showing the changes of multilobular cirrhosis—patchy fibrosis replacing liver cells with bile duct regeneration. Case of chronic cholecystitis. ×32.

reported a patient who developed it two years after an ileostomy and died; Treusch (1952) gave a detailed report of one patient with a history of four years before she died with abscesses in the upper half of the right lobe. Jones and his colleagues (1951) described one patient who developed pylephlebitis and liver abscesses.

(ii) *Inflammatory foci.*—These are scattered within a lobule, or in the periportal tissue. In the parenchyma they are associated with cell necrosis, but the inflammatory infiltration is predominant. The appearances resemble severe interlobular hepatitis where the lobule is also affected (Kimmelstiel *et al.*, 1952); a similar condition was described by Warren and Sommers (1949).

(iii) *Interlobular hepatitis.*—Inflammatory round-cell infiltration occurs into the interlobular connective tissue with frequent involvement of the adjacent parenchyma where necrosis develops. Later bile duct proliferation and pseudolobulation occur.

(iv) *Hepatic fibrosis.*—A large area of one lobe may be affected without nodular regeneration (Jones *et al.*, 1951).

(v) *Intrahepatic thrombosis.*—Thrombi are found in the hepatic blood vessels; congestion

and necrosis occur in adjacent tissues. Thrombosis of the hepatic and portal veins with massive ischæmic necrosis was described by Kleckner *et al.* (1952).

(vi) *Fatty degeneration.*—This is common and varies in severity; it is probably caused by malnutrition, toxæmia and debilitation (Fig. 8). It was found in 47 (52%) of 91 cases reported by Jones *et al.* (1951). Himsworth and Glynn (1944–5) considered a high fat content of the liver might protect it against necrosis and found that fatty infiltration must be of long duration before fibrosis develops. Kimmelstiel *et al.* (1952) failed to find fat necrosis in severe fatty degeneration. Pollard and Block (1948) stated that fatty changes might cause hepatic insufficiency and cirrhosis. It may be a reversible process.

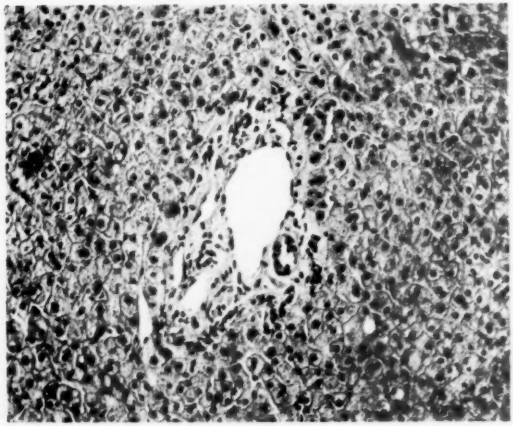

FIG. 8.—Section of liver showing a moderate degree of fatty degeneration and passive venous congestion. Case of chronic ulcerative colitis treated medically for nine years; died from congestive heart failure due to pulmonary embolus, no operation. ×125.

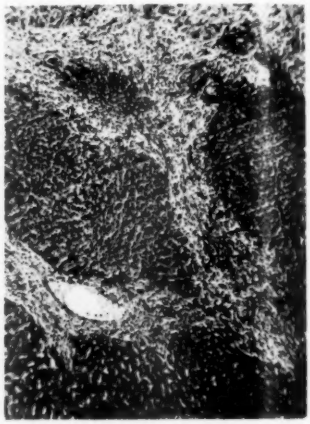

FIG. 9.—Liver biopsy showing multilobular cirrhosis with some regeneration of bile canaliculi. Case of severe ulcerative colitis. ×69.

(vii) *Cirrhosis.*—This is a rare complication. Kimmelstiel *et al.* (1952) found 11 cases in the literature; Jones *et al.* (1951) found 3 cases in 91 cases at necropsy; Tumen *et al.* (1947) reported 5 cases in a series of 151 cases. Kleckner *et al.* (1952) noted it occurred in young adults with colitis for one to sixteen years. Ross and Swarts (1948) considered that anæmia, marked weight loss and protein deficiency cause hepatic insufficiency which, if uncorrected, progresses to fatty degeneration, and serious, irreversible changes. The nutritional factor may be the most important; deficiencies arise from the defective food intake, faulty absorption and protein loss in the rectal discharge. The patients are also subject to a greater risk of serum hepatitis than the general population. Cirrhosis is usually indicated by jaundice, hepatomegaly alone or with splenomegaly, ascites, abnormal liver function tests and biopsy. In the Gordon Hospital series there is only one patient with typical cirrhosis who is under my care:

Female, aged 40, with a history of ulcerative colitis for two years treated conservatively, with tenderness over the pelvic colon and hepatomegaly. Investigations including rectal biopsy, confirmed ulcerative colitis. Patient was treated conservatively for several months and liver function tests were done at intervals with these results:

	Pre-operative			Post-operative	
	12.1.53	10.6.53	6.11.53	24.3.54	8.10.56
Serum bilirubin	0·3 mg.%	1·1 mg.%	0·8 mg.%	0·8 mg.%	0·5 mg.%
Serum alkaline phosphatase	72 units	58 units	56 units	50 units	27 units
Thymol turbidity	3	6	3	5	2
Thymol flocculation ..	0	2	1	2	0
Gold flocculation	0	3	2	1	1
Zinc sulphate turbidity ..	4	7	8	5	3
			Total protein	8·11 gram%	7·5 gram%

The patient's condition gradually deteriorated and on November 16, 1953, a total colectomy and anterior resection of the rectum with an immediate ileo-rectal anastomosis was performed. Liver biopsy showed multilobular fine cirrhosis with some regeneration of the bile canaliculi (Fig. 9). The patient has made a good recovery.

(viii) *Amyloid degeneration* secondary to ulcerative colitis is extremely rare.

Hepatic lesions in amœbiasis.—These have a frequency which is determined by the incidence and efficient control of the primary intestinal infection. A diminution has occurred because amœbiasis is now diagnosed earlier and treated more effectively. De Bakey and Ochsner (1951) reported an incidence of liver involvement in 7·6% to 84·4% (average 36·6%) in necropsy cases, and in clinical cases from under 1% to over 25% (average 8·1%). The abscess is often single (70%) and usually affects the right lobe (85%).

The symptomatology may be entirely hepatic without any symptoms of dysentery. Liver function tests, however, are normal. Radiological appearances include elevation of the diaphragm, consolidation of the right lung base and a pleural effusion. Treatment is with emetine hydrochloride or chloroquine diphosphate and if there is no response both drugs are given together. When an abscess forms, aspiration is required in addition to these drugs and antibiotics and open drainage may be necessary when the wall is very fibrotic. When this type of abscess is in the left lobe of the liver a left hepatectomy is preferable to open drainage.

Pyogenic abscess of the liver.—Gangrenous appendicitis was common before antibiotics were available, and then suppurative pylephlebitis was greatly feared. A liver pyogenic abscess is less frequent, however, than an amœbic abscess. Ochsner *et al.* (1938) reviewed 186 cases of liver abscess during 1928–37, of which 139 (74·7%) were amœbic and 47 (25·2%) pyogenic. At present, cholangitis following common bile duct obstruction is the most common cause and the second most frequent is septicæmia.

Other infections in the portal venous area caused hepatic abscesses in 10·2% of the collected cases and 8·4% of the personal cases in the report of Ochsner *et al.* (1938). These included inflammatory lesions in the terminal ileum, cæcum, colon and rectum. Kramer and Robinson (1926) reported a case of suppurative diverticulitis with pylephlebitis and liver suppuration; a similar case was reported by Whyte (1906). Other primary infective lesions are bacillary dysentery, infected carcinoma of the colon and rectum, regional enteritis, proctitis and infected hæmorrhoids. Taylor (1949) reported the association of regional enteritis and multiple liver abscesses. Alders (1944) reported a male patient who developed a liver abscess after the ligation of internal hæmorrhoids; the abscess burst into the right anterior subphrenic space which was drained with the recovery of the patient.

Metastatic Cancer in the Liver

Approximately one-half of patients who die with cancer have liver metastases. This vulnerability of the liver is due to its position in relation to the portal and systemic circulations, its large size and the composition of its cellular contents. It is affected by many varieties of malignancy including carcinoma, especially of the alimentary tract, pancreas, uterus, breast, bronchus, kidney and adrenals; sarcoma; malignant melanoma; argentaffinoma; neuroblastoma; malignant lymphoma and teratoma.

Portal vein dissemination is the main route of spread from the common sites of malignant tumours in the alimentary tract; those in other sites not connected with the portal system may gain entrance by invading viscera already connected, so that tumours in the ovary, uterus, prostate, bladder, kidneys and adrenals can metastasize to the liver.

Segregation of portal blood in the liver.—It has been suggested that blood from different abdominal organs does not mix in the portal vein and has a lobar distribution in that the left lobe receives a disproportionate amount from the superior mesenteric vein. Clinically one lobe of the liver is found sometimes to contain one or more metastases while the other appears free, this is important in relation to partial hepatectomy. We investigated this problem by injecting 0·1 ml. of ^{24}Na with an activity of 50 μc. into a small tributary of the portal vein and the subsequent passage of radioactivity through the right lobe of the liver was recorded by a collimated scintillation counter placed directly over the centre of this lobe. The counter was then moved over the centre of the left lobe and the injection was repeated into a vein adjacent to the previous one. Our studies have not shown any marked asymmetry in the distribution of portal blood between the right and left hepatic lobes. It cannot be postulated, therefore, that a patient with carcinoma in a certain part of the gastro-intestinal tract is more likely to develop metastasis in one lobe of the liver than the other.

Hepatic artery dissemination.—Metastases reach the liver from primary and secondary tumours in the lung.

Lymphatic dissemination is an uncommon route.

Spread by direct extension of a carcinoma of the hepatic and splenic flexures, transverse colon and other neighbouring sites is common. The primary tumour becomes adherent to Glisson's capsule, an inflammatory reaction develops and malignant infiltration occurs across this adherent area. Liver necrosis then takes place and severe hæmorrhage occurs into the peritoneal cavity, lumen of the stomach or colon and the patient presents as an emergency.

Spread within the liver.—The vascularity of the liver favours intrahepatic spread. Invasion of the right or left main branches of the portal vein causes metastases in the corresponding lobe; when a large radical is invaded a wide segment is affected; invasion of a small venule causes metastases in a localized area. One parent metastasis can therefore disseminate quickly throughout the liver.

Spread from the liver.—Metastases invade the efferent hepatic veins entering the inferior vena cava and are carried to the lungs. The inferior vena cava may be directly invaded (Willis, 1952). The liver acts as an intermediary for pulmonary metastases from primary tumours in the portal venous area. Willis (1952) found 86 of these tumours with hepatic metastases had also produced secondaries in the lungs in 27; in 88 tumours without hepatic metastases, lung metastases were present in only 8.

Incidence and operability of hepatic metastases from carcinoma of the stomach, colon and rectum.—An analysis was made of the relevant details in the case-records of 1,000 patients with primary carcinoma in these sites at the Royal Marsden and Gordon Hospitals; hepatic metastases were considered present in 65 cases on clinical assessment and 157 cases on visual assessment, a total of 222, or 22·2% (Table I).

TABLE I.—INCIDENCE OF HEPATIC METASTASES IN CARCINOMA OF STOMACH, COLON AND RECTUM

Site of primary carcinoma	Clinical assessment		Visual assessment—operation or necropsy	
	Total No. of cases	No. with hepatic metastases	Total No. of cases	No. with hepatic metastases
Stomach	84	27 (32·1%)	276	63 (22·8%)
Colon	37	12 (32·4%)	135	33 (24·4%)
Rectum	102	26 (25·5%)	366	61 (16·6%)
	223	65 (29·1%)	777	157 (20·2%)

The operability was assessed in 157 of the 222 cases with hepatic metastases; operation or necropsy was not done in the remaining 65 cases (Table II).

TABLE II.—ASSESSMENT OF OPERABILITY OF HEPATIC METASTASES IN CARCINOMA OF THE STOMACH, COLON AND RECTUM

Site of primary carcinoma	Total No. of cases	No. of possible cases for partial hepatectomy	No. of cases unsuitable for partial hepatectomy
Stomach	63	14 (22·2%)	49 (77·8%)
Colon	33	10 (30·3%)	23 (69·7%)
Rectum	61	17 (27·9%)	44 (72·1%)
	157	41 (26·1%)	116 (73·9%)

In the series of 157 cases assessed visually for hepatic metastases, 116 cases (73·9%) were considered unsuitable for partial hepatectomy due to extensive liver involvement or other inoperable metastases. This leaves 41 cases (26·1%) with hepatic metastases considered operable for further analysis (Table III).

TABLE III.—DETAILS OF HEPATIC METASTASES FOR WHICH PARTIAL HEPATECTOMY WAS POSSIBLE

Site of hepatic metastases	Total No. of cases 41
Left lobe. Partial hepatectomy performed	5 (12·2%)
Right lobe. Partial hepatectomy performed ..	1 (2·4%)
Solitary metastasis in right lobe	14 (34·1%)
Two metastases in right lobe	2 (4·9%)
Multiple metastases in right lobe	1 (2·4%)
Direct invasion of left lobe	4 (9·8%)
Solitary metastasis in left lobe..	3 (7·3%)
Solitary metastasis—site not stated	4 (9·8%)
Two metastases—site not stated	7 (17·1%)

Summary of statistics.—In a series of 1,000 cases of carcinoma of the stomach, colon and rectum, the incidence of hepatic metastases was 222 cases (22·2%). In the total series a partial hepatectomy was considered possible in 41 cases (4·1%). In the series of 222 cases with hepatic metastases, 41 cases (18·5%) are considered suitable in retrospect for a partial hepatectomy; the operation was carried out in 6 cases (2·7%).

Scheme of treatment of metastatic liver carcinoma.—The management of the following groups of patients is described.

(1) *Metastatic liver cancer from a silent primary tumour.*—The liver symptoms and signs dominate the clinical picture. An exploratory laparotomy and liver biopsy confirm the nature of the hepatomegaly.

(2) *Silent liver metastasis.*—This is a frequent finding when operating for a primary carcinoma of the colon or rectum.

(*a*) *The primary tumour is operable.* When there is diffuse liver involvement the abdomen is closed for the patient's life expectancy is short and palliative treatment is given. When considerable liver parenchyma remains and its function is satisfactory the organ containing the primary tumour is removed. This may retard the progress of the liver disease. When liver metastases are localized in one lobe a right or left hepatectomy is done four weeks after the primary disease is removed.

(*b*) *The primary tumour is inoperable.* Palliative treatment is given.

(3) *Delayed liver metastases after excision of the primary tumour.*—(*a*) *There is no local recurrence.* When clinical examination indicates that one lobe of the liver is affected it is confirmed by an exploratory laparotomy and if there are no other demonstrable metastases or recurrences a left or right hepatectomy is done.

(*b*) *Local recurrence is present.* Palliative treatment is given.

Results of hepatectomy operations for secondary cancer

Left hepatectomy.—A survey of the cases reported, including my own, revealed the following results. A left hepatectomy was performed in 16 patients; 7 patients were alive and well 4, 9, 11, 12, 13, 18 and 20 months later; 1 patient was alive with disease 5 months later; 5 patients died 12, 18, 24, 24 and 24 months later; 3 patients were lost sight of. A local excision of the metastasis was performed in 7 patients; 3 patients were alive and well 6, 8 and 48 months later; 1 was alive with disease 15 months later; 3 patients died 4, 7 and 8 months later.

Right hepatectomy.—A survey of the cases reported, including personal communications and my own, gave the following results. A right hepatectomy was performed in 11 patients; 4 patients were alive and well 12, 18, 18 and 18 months later; 1 patient was alive with disease 6 months later; 2 patients died 4 and 24 months later; 4 patients were lost sight of.

Swellings of the Liver which Simulate Malignant Tumours

Liver swellings occur which resemble malignant tumours and a wrong diagnosis may be made. Surgeons are familiar with "nodules" in the liver which may or may not be metastases. In these cases further investigation should be made. A biopsy of the "nodule" is performed, an operable primary tumour is excised and partial hepatectomy considered later. When a biopsy is not possible and the primary tumour is operable the operation designed to cure the primary disease is performed. The following swellings are considered in this connection.

Liver anomalies.—A good account of these was given by Cullen (1925). A hepatic lobe such as Riedel's may increase in size forming a tongue-like projection from the right lobe which reaches into the right iliac fossa. It is more frequent in females. It may cause intestinal occlusion, as in a case described by Cullen when the hepatic flexure of the colon became adherent to the liver and kinked. Numerous furrows may occur in the liver substance forming intervening lobules which are sometimes pedunculated. Multiple lobes, sessile or pedunculated, may be present in the postero-inferior aspect of the liver.

Liver cysts of various types occur; they include blood vessel cyst, ciliated epithelial cyst, lymphatic cyst and retention cyst.

Hydatid cyst.—According to Dew (1955), 75% of hydatid cysts occur in the liver; the right lobe is affected four times more often than the left. There are two varieties, the first is a unilocular cyst which slowly increases in size, the wall may become fibrosed or calcified and sometimes the cyst is infected and filled with pus. In the second the outer cyst wall is absent and the inner germinative and middle laminated layers invade the liver like a malignant tumour.

Polycystic disease.—A series of 24 proved cases were reported by Comfort *et al.* (1952) in 23 the liver was diffusely affected and in 1 the left lobe was involved. In about half the number of patients polycystic kidneys were present.

Certain chronic infective lesions can be mistaken for metastatic tumours:

Tuberculosis.—Randolph (1930) reported an autopsy on a patient who died after an operation for uterine carcinoma and found many discrete caseous nodules of inactive tuberculosis in the liver which were confirmed histologically. Miliary tubercles occur in the liver in acute miliary tuberculosis and in chronic tuberculosis of lung and bone. Wolf and Flory (1945) reported a case of ileo-cæcal tuberculosis with liver involvement. A tuberculoma is sometimes found forming a caseating swelling, the lesion may be multiple, secondary to pulmonary or abdominal tuberculosis. The swelling may become large and resembles a necrotic tumour or gumma.

Syphilis.—Gumma may be single or multiple in the liver, which is usually not enlarged unless chronic congestion or cirrhosis is associated. Liver nodules may press on the inferior vena cava and the openings of the hepatic veins into it causing ascites and enlarged collateral venous plexuses. Spontaneous healing is frequent leaving marked scarring and nodularity of the liver.

Actinomycosis of the liver is usually secondary to actinomycosis of another organ and the infection reaches it by direct extension from the stomach, duodenum or transverse colon, or through the portal vein from the appendix, cæcum, colon or ano-rectal region.

Benign tumours may be mistaken for metastatic carcinoma:

Hæmangiomata are found more often in the liver than in any other abdominal organ. They are usually small and found in the left lobe; when multiple they cause nodularity of the liver. They are red-purple, rarely protrude above the surface and are compressible unless calcified.

Adenoma is not rare; it may be asymptomatic and discovered at laparotomy, or it may cause an upper abdominal swelling which presses on, or displaces, neighbouring organs and structures. Its consistence varies from soft to hard and it may be single or multiple (Schrager, 1937).

Connective tissue tumours comprise fibroma, lipoma, leiomyoma and myxoma; they are usually small.

Malignant lymphoma often affects the liver; the extent and nature varying with the type of lymphoma. Sometimes discrete nodules are found which simulate metastatic carcinoma, especially in lymphadenoma and reticulum-cell sarcoma.

Nodules of regenerative hyperplasia of the liver were reviewed by Begg and Berry (1953) when they collected 29 cases from the literature and added 4 more. The nodules were pedunculated (19 cases) or clearly delineated from normal tissue (14 cases); the majority had a nodular surface. Histological examination revealed a pattern usually associated with post-necrotic cirrhosis or subacute hepatitis.

Focal hepatic cirrhosis occurs in both sexes at any age and the lesion is usually solitary, but multiple nodules occur which vary in size from a few millimetres to several centimetres. It is often asymptomatic and found at laparotomy when it must be distinguished from primary or metastatic liver cancer. Benz and Baggenstoss (1953) found 34 cases at necropsy comprising 40 nodular lesions. The nodules were usually subcapsular, hard and in the right lobe.

Biopsy of liver "nodule" is frequently necessary to determine its true nature. When the primary tumour is in the pelvic colon or rectum and the abdomen is opened through an infra-umbilical incision visualization of the liver is not possible. In these cases an aspiration-biopsy is done by the method of Pack and Brasfield (1955); the surgeon's right hand is introduced through the wound to identify the "nodule" in the liver so that an assistant can introduce an aspiration needle through the parietes which is then guided by the surgeon into the "nodule".

The Malignant Argentaffinoma Syndrome

Cassidy (1930) described an association of symptoms and signs in a young male patient with an abdominal tumour and liver metastases who experienced a peculiar flushing of the skin of his face and developed pulmonary stenosis. A description of the symptomatology of a malignant argentaffinoma of the small intestine with liver metastases was given by Thorson *et al.* (1954). An argentaffinoma can occur anywhere in the gastro-intestinal tract and up to 1950 approximately 60 cases had been reported in the rectum (Raven, 1950; Thorson *et al.*, 1954).

Clinical groups.—(1) In some patients the tumour is an incidental finding, as in the appendix.

(2) In other patients the symptoms are abdominal or rectal, depending on the site of the primary tumour.

(3) Metastases usually occur in the regional lymph nodes and liver and the general effects are seen of 5-hydroxytryptamine secreted by the hepatic metastases which passes into the blood without being converted by the liver into the inactive metabolite 5-hydroxyindole acetic acid. The release of large amounts in the body produces effects resembling those of histamine release including a fall in blood pressure, dyspnœa and flushing of the skin of the neck.

The following case record demonstrates the value of colonic and hepatic surgery in the treatment of this syndrome. A patient had a carcinoma of the cardia and lower œsophagus infiltrating the left lobe of the liver which I treated by surgical excision. In the portion of liver removed there was a metastatic nodule of argentaffinoma and at a subsequent operation two primary argentaffinomata, and a metastatic lymph node, and several liver metastases were excised by a partial enterectomy, right hemicolectomy and partial right hepatectomy (Fig. 10).

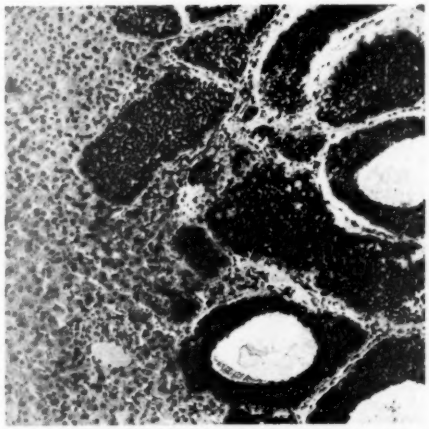

FIG. 10.—Section of liver showing a metastasis of argentaffinoma. ×56.

HEPATECTOMY

History.—The development of hepatectomy operations during the nineteenth and twentieth centuries is divided into two periods.

First period.—Segmental resections of the liver were performed with intrahepatic ligation of blood vessels, and considerable ingenuity can be discerned in the technique employed. The end-results of the *nineteenth century* were generally favourable for benign tumours, but much less satisfactory for malignant tumours. Local recurrence or generalized metastases occurred frequently several months after operation.

Second period.—Lobectomy operations were performed with extra-hepatic ligation of the main blood vessels and lobal duct (Raven, 1949). During the first forty years of the *twentieth century* partial hepatectomy with intrahepatic ligation of the blood vessels was performed with great frequency. The technique of left hepatectomy with extra-hepatic ligation of the main blood vessels and bile duct of the lobe was described independently by Pettinari (1947) and by Raven (1949). This technique was applied to right hepatectomy which was performed by Lortat-Jacob and Robert (1952).

DEFINITIONS OF PARTIAL HEPATECTOMY

Wedge resection.—A lesion at, or near, the anterior border of the liver is resected by two angular incisions. *Elliptical resection.*—A lesion superficial in the substance of the liver is resected by an encircling incision. *Transection.*—Part of a lobe is excised by an antero-posterior incision through its substance. *Left hepatectomy.*—A left subtotal or total lobectomy is performed; in the latter operation the caudate lobe is included. *Right hepatectomy.*—The right lobe is removed.

Combined operations.—(1) *In 1-stage:* hepato-gastrectomy; hepato-œsophago-gastrectomy; hepato-cholecystectomy; right hepato-hemicolectomy. (2) *In 2-stages:* right or left hepatectomy following a left hemicolectomy or an abdomino-perineal excision of the rectum.

Principles of Technique

Left hepatectomy (Raven, 1949).—The abdomen is opened through a transverse incision made half-way between the umbilicus and ensiform cartilage which commences 5 cm. to the right of the mid-line and ends at the left costal margin; a second incision is made at a right angle from this transverse incision upwards in the mid-line to the base of the ensiform cartilage. The left lobe of the liver is mobilized by dividing the left lateral, left coronary, longitudinal and round ligaments; the latter is ligated before division. The left lobe is now retracted to the right and the left branch of the portal vein, left hepatic duct and the left branch of the hepatic artery are ligated and divided.

There are usually three main hepatic veins from the posterior aspect of the liver which join the inferior vena cava in the posterior hepatic groove. One vein passes from the right lobe and another from the left lobe, which open obliquely into the inferior vena cava; the third vein is from the middle of the liver and spigelian lobe and it pursues a straight course to join the main vein. The left and middle veins are ligated and divided.

To remove the left lobe, an oblique antero-posterior incision is made with the diathermy knife from the attachment of the round ligament to end posteriorly immediately to the left of the right hepatic vein joining the inferior vena cava. The raw area of the right lobe is peritonealized by covering it with peritoneal folds derived from the divided liver ligaments. The peritoneum covering the hepatic artery, common hepatic duct and portal vein is sutured. The wound is closed and a soft rubber tube is placed in position to drain the region of the divided liver.

Right hepatectomy (Raven, 1947; Lortat-Jacob and Robert, 1952; Pack and Baker, 1953).—The same technical principles are applied to this operation. The abdomen is explored through a right paramedian incision which is then extended into the pleural cavity through the right eighth intercostal space. The right leaf of the diaphragm is divided radially towards the inferior vena cava. The right lobe of the liver is mobilized by ligating and dividing the round ligament, dividing the longitudinal and right coronary ligaments. The cystic duct is then ligated and divided; the right hepatic duct and the right branch of the hepatic artery are ligated and divided. The right branch of the portal vein is shorter and broader than the left branch and must be exposed anteriorly, the liver is then rotated to the left so that this vein can be exposed also posteriorly; it is then ligated and divided. The inferior vena cava is then exposed and the two hepatic veins from the right lobe and middle part of the liver and any smaller veins are identified, ligated and divided. The left hepatic vein is seen and preserved. The right lobe of the liver is then removed by dividing the liver with the diathermy knife antero-posteriorly immediately to the left where the main right hepatic vein joins the inferior vena cava.

Any bleeding vessels and small bile ducts in the divided left lobe are transfixed and the bare area is peritonealized using the divided hepatic ligaments. The peritoneum covering the hepatic artery, common hepatic duct and portal vein is sutured. The diaphragm is then sutured and the right pleural cavity is closed with underwater drainage; a soft rubber tube is placed in position to drain the region of the divided liver and the abdominal wound is closed.

Effects on the Liver of Operations

Experimental work has shown morphological and biochemical changes in hepatic cells. Cole and Leuchtenberger (1956) compared the histological appearances in dogs pre- and post-operatively. In the pre-operative liver the chromatin in the nuclei was finely granular and evenly distributed, but in the post-operative liver it was coarse, coalescent, distributed irregularly, and large rarefied areas were present. The nucleoli after operation became larger with irregular borders. The changes were most obvious three to six hours after operations and no appreciable differences were seen three or four days later, and the severity of the operation did not influence the effects. These workers also found an increase in the tyrosine content of the cytoplasm three hours following operation, but no change occurred in the desoxyribonucleic acid in the nucleus. The interpretation of these results is not yet clear; they may indicate increased protein synthesis by the liver or the presence there of the products of increased protein catabolism.

Clinical work also demonstrates certain changes. In 11 patients undergoing a major abdominal operation serial liver function tests were done before, at the end of the operation and three days later. In 9 patients the serum bilirubin rose as much as six times its pre-operative level; greater increases were found in those given blood transfusions. No changes occurred in the flocculation tests, and in 2 patients a mild fall occurred in the total serum

proteins. Tagnon *et al.* (1948) carried out liver function tests in 20 patients immediately after an extra-abdominal operation and found a significant increase in bromsulphthalein retention in 14. The effects of giving ether and Pentothal-sodium were not important. Geller and Tagnon (1950) investigated changes in the tests in 33 patients after major abdominal operations; in 17 of 22 there were abnormalities in the bromsulphthalein test; in 14 of 22 in the cephalin flocculation test, and 24 of 33 patients had abnormally high serum bilirubin for several days. There was an increased production of bilirubin and post-operative impairment of liver function with blood transfusion. Keeton *et al.* (1948) found the maximum excretion of urinary urobilinogen occurred on the third day after herniorrhaphy and cholecystectomy which returned to normal by the sixth day.

Causes of Liver Damage in Operations

These include trauma, shock, anæsthesia and inanition. Anoxia in anæsthesia or shock causes parenchymal damage. French *et al.* (1952) observed no difference between the effects of ether and cyclopropane; Geller and Tagnon (1950) found no changes in the liver function tests with nitrous-oxide gas, ether and oxygen, spinal anæsthesia alone and combined with Pentothal Sodium. Keeton *et al.* (1948) found that post-operative inanition affected liver function and a high caloric diet containing 2·6 grams protein per kg. resulted in a positive nitrogen balance.

The effects of liver abnormalities can be greatly increased by even minor operations and may cause death. For example hepatic coma may develop in twenty-four to forty-eight hours after a paracentesis. This procedure is usually necessary to relieve dyspnœa or severe abdominal distension, but it must be done with caution; when severe liver damage is present the operation is done in stages. Severe gastro-intestinal hæmorrhage is an important cause of hepatic coma; the retained blood may release ammonia. The hæmorrhage and shock are controlled and when practicable the blood is removed from the colon by an enema.

Other precautionary treatment with liver damage.—Bed-rest is essential when the liver is tender, jaundice is present and liver function tests very abnormal. Protein deficiencies are rectified as much as possible. Avoid acute infections, maintain the urinary output and do not overload with fluid when oliguria is present and not associated with dehydration. Caution is necessary in the use of ammonium salts as diuretics, of sedatives, analgesics and hypnotics. Morphine is contra-indicated for it is conjugated in the liver before excretion; pethidine can be given. Choose the barbiturates with the greatest renal excretion, namely barbital and phenobarbital, and carefully grade the dosage. Avoid paraldehyde and chloral hydrate; bromides can be given. Fluid intoxication and dehydration should be prevented and the electrolyte and water balances maintained. The diet should be rich in protein, such as meat and fish, and 150 grams are taken with 350 grams carbohydrate, and 70 grams of fat. Vitamins and liver extract are included but salt is excluded when ascites or œdema is present.

Liver Regeneration following Hepatectomy

The liver possesses good power of regeneration; Schroeder (1906) quoted Ponfick who removed three-quarters of the organ and found it regenerated to four-fifths of its normal weight, and in some cases it regained its full weight. Localio and Saltz (1950) described the regeneration of the liver in a patient after massive mechanical destruction. Pickrell and Clay (1944) stated that large areas of the liver can be destroyed by disease or removed surgically and regeneration occurs promptly and almost completely.

Acknowledgments

I wish to thank those who have helped me in various aspects of this work. *Pathology*—Prof. E. Boyland, Dr. G. Lumb, Dr. R. B. Prothero, Dr. J. W. Whittick. *Experimental*—Dr. E. H. Belcher, Mr. M. S. C. Birbeck, Mr. C. I. Cooling, Mr. G. M. Lunn, Dr. E. H. Mercer, Dr. R. B. Prothero. *Statistics*—Mr. C. I. Cooling, Dr. I. P. M. MacDougall, Mr. D. E. Pegg. *Literature*—Miss J. DISCUSSION ON THE ÆTIOLOGY OF PRE-ECLAMPSIA

Professor J. C. McClure Browne:

Placental Ischæmia is not an Ætiological Factor in Pre-eclamptic Toxæmia

No two speakers on the subject of pre-eclamptic toxæmia will present the same points of view, because there are as many theories on this subject as there are obstetricians.

My interest in pre-eclamptic toxæmia and its ætiology is, I think, clearly an inherited one, and obviously it must be due to some hitherto undescribed dominant gene. Then in 1946 I was fortunate enough to come under the influence, first at Hammersmith and later in Edinburgh, of Professor Robert Kellar, who in his own inimitable way goaded me into taking a more active interest in this particular problem. About that time, too, the work of Beker (1948) and of Bastiaanse and Mastboom (1949) revived attention on the placenta as the supposed starting-point of the chain of events which culminates in eclampsia. As far back as 1914, Professor James Young—my predecessor at Hammersmith Hospital—had postulated that the red infarct which could be, and still can be, demonstrated in cases of eclampsia was the site of origin of chemical substances which initiated the whole syndrome. Ernest Page (Ogden *et al.*, 1940), too, had shown that partial occlusion of the aorta in the pregnant bitch resulted in a rise in systemic pressure. From these observations, and others, arose the idea that placental ischæmia existed in pre-eclamptic toxæmia, and, as with so many matters in obstetrics, once it had been postulated, it became apparently accepted as a fact, and on this supposed fact new theories of the ætiology of pre-eclamptic toxæmia were put forward.

If one accepts that placental ischæmia will indeed cause a rise in systemic blood pressure, then it is logical to suppose that pre-eclamptic toxæmia will develop in conditions where the pregnant uterus is subject to over-distension; conditions such as hydramnios, twins and, in some cases, in the primigravida. Professor K. Franklin and Mr. Sophian have shown that distension of the pregnant rabbit uterus will cause a renal cortical ischæmia which could be held to account for the occurrence of albuminuria. Recently, however, McGaughey *et al.* (1956) in experiments on the dog have failed to show that a specific utero-renal reflex exists.

Up till 1948, though there was evidence to suggest that placental ischæmia might have an important role to play in the ætiology of pre-eclamptic toxaemia, nobody had shown that such a condition actually existed, and it seemed to me vital to prove or disprove this. To do this Veall and I considered that it was important that the placenta should be studied *in situ* before the fœtus was delivered, and indeed before the uterus was opened. The first problem was to find the placenta under these conditions, and for this reason we developed a method of locating it using tracer doses of radio-active sodium (Browne, 1951). The method (Browne and Veall, 1953), though established purely for this experimental purpose, has important clinical applications in the exclusion of placenta prævia as a possible cause of antepartum hæmorrhage, and is in general use to-day at Hammersmith for that purpose.

In cases where we found that the placenta was situated anteriorly it was possible to inject a tracer dose of ^{24}Na into the chorio-decidual space, and to record the time taken for it to be cleared by the maternal placental circulation In the normal case—that is to say the woman without pre-eclamptic toxæmia or hypertension—between 38 and 40 weeks the mean half-period for clearance was 21 seconds. In cases with pre-eclampsia the mean half-period was 65 seconds, more than three times as long, showing clearly that in pre-eclampsia a true placental ischæmia existed. However, in cases of essential hypertension, even mild cases, where the hypertension had antedated the pregnancy, the same degree of ischæmia was found. We concluded therefore that the placental ischæmia was the result and not the cause of the hypertension which is one of the cardinal features of pre-eclamptic toxæmia. We were astounded at the marked reduction in maternal placental blood-flow that occurred when hypertension was present, and at first refused to accept it as valid. However, careful review of our methods and results showed that we should indeed accept it. Subsequently, Morris *et al.* (1955) at University College Hospital adapted our method to study the clearance of radio-active sodium from uterine muscle, and showed that there, too, the same reduction in blood-flow as evidenced by prolongation of clearance time existed. Walker and Turnbull (1953), working on the other side of the placental membrane, found that in these conditions there was evidence of fœtal anoxia, in that the concentration of hæmoglobin

in the fœtal blood was raised. Neither Morris nor I found any diminution of tissue clearance in striated muscle.

The existence of this placental ischæmia in cases of hypertension, whether essential or pre-eclamptic in origin, explained many things. For example, it explained why the baby tends to be small in cases of essential hypertension and the serious significance of hypertension in association with post-maturity in which placental insufficiency is also a feature (Browne, 1954). It explained, too, many of these cases of intra-uterine death in the last few weeks of pregnancy, when only a mild hypertension was present.

This clear evidence, therefore, that hypertension causes placental ischæmia, suggests that the uterine tension theory for the origin of pre-eclampsia is wrong. We are told by the exponents of this theory that the tension of the primigravid uterus, or the presence of twins, or hydramnios, conditions frequently associated with pre-eclamptic toxæmia, produces a placental ischæmia and if the intra-uterine tension be reduced—for example, by rupturing the membranes—then the ischæmia is diminished and the toxæmia is immediately improved. But this certainly is not my experience in clinical obstetrics, and I am sure we would all agree that there are many instances of serious deterioration in cases of pre-eclamptic toxæmia after surgical induction has been performed, so that we are compelled on occasion to perform Caesarean section in this particular type of case because of imminent eclampsia.

Mr. Norman Morris:

The pioneer work of Professor McClure Browne stimulated Dr. Helen Payling Wright and myself to investigate the clearance rate of ^{24}Na from the myometrium. Initially we selected mothers at rest in hospital between 30 weeks and term. A point was chosen on the abdominal wall about 4 cm. below and lateral to the umbilicus. This was infiltrated with between 1 and 2 c.c. of 1% lignocaine. The injection needle was then introduced through this area into the myometrium and 0·3–0·4 ml. of ^{24}Na with an activity of between 5 and 10 μc. was injected (*see* Fig. 1). A Geiger counter was then arranged over this site and the rate of clearance of the ^{24}Na recorded. After correcting our results for the rising background they were then expressed in terms of the time taken for the counting rate to reach half value (Fig. 2). These figures clearly show a reduction in clearance rate and therefore presumably of myometrial blood flow in relation to pre-eclampsia.

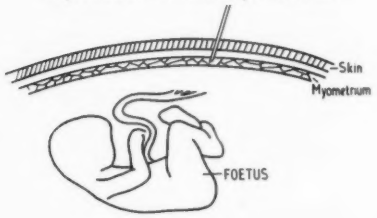

FIG. 1.

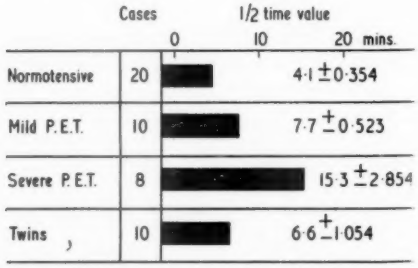

FIG. 2.—Uterine clearance rate of ^{24}Na in pregnanc

Our series was then extended to some 90 cases. In a few we measured the clearanc rate after lowering the blood pressure with protoveratrine and the results are shown i Fig. 3. Lowering the blood pressure appeared to improve the clearance rate.

We then investigated the effect of exercise upon the clearance rate of Na from bot the myometrium and the anterior belly of the quadriceps. For this we devised an Exercycl With the patient at rest an initial clearance reading from an injection into both th uterus and the quadriceps was obtained in a similar way to that already described. Sh

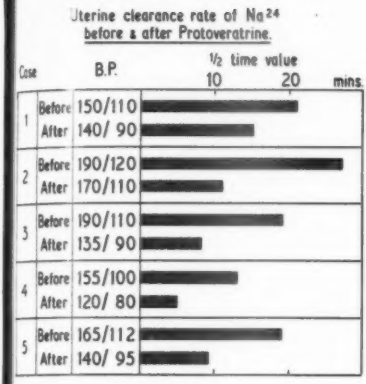

FIG. 3.

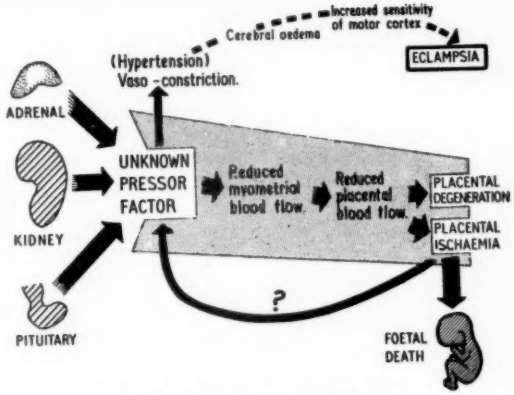

FIG. 4.—Pressor effect in P.E.T.

was then encouraged to use the apparatus; after she had achieved a steady pace for some 5 minutes, she stopped for a few moments just long enough for us to give an injection into the uterus and quadriceps. After this she resumed her cycling for a further 5 minutes. At this point she stopped and was encouraged to relax as much as possible. The results were as follows:

In both groups there was a significant rise in diastolic pressure during exercise. In the 5 minutes following the pressure fell rapidly towards the resting level.

	Resting	During exercise	After exercise
Normals ..	73·3 ± 1·75	85·5 ± 2·22	75·8 ± 2·31
Pre-eclamptics ..	93·3 ± 1·71	98·9 ± 2·53	91·4 ± 2·45

In both groups there was a statistically significant decrease in uterine clearance rate during exercise. This quickly returned to normal within 5 minutes when exercise was stopped.

Uterine clearance rate: Time to half value in minutes.

	Resting	During exercise	After exercise
Normals ..	4·07 ± 0·27	5·43 ± 0·42	3·07 ± 0·43
Pre-eclamptics ..	7·17 ± 0·22	8·75 ± 0·52	6·25 ± 0·53

These results therefore suggest that during exercise there is a reduction in blood flow to the uterus with a quick return after this is stopped. Furthermore it seems probable that this reduction in uterine blood flow is the result of a generalized splanchnic vaso-constriction since in the non-pregnant exercise also reduces the renal blood flow. The actual extent of reduction is possibly governed by many other considerations such as height, weight, skeletal development and the general state of bodily fitness.

It may be of value to consider the possible clinical significance of these findings. It is well established that rest usually helps to prevent deterioration in a case of pre-eclampsia; physical activity appears to have the reverse effect.

The origin of the pressor mechanism is unknown. Mr. Sophian thinks it largely originates from the kidney, others think it may come from the placenta while still others believe it may arise in the adrenal or pituitary. Whatever its origin, we would probably agree that its effect on the uterus and placenta is as indicated in Fig. 4. It can be seen that exercise by intensifying the vaso-constriction will also temporarily exacerbate these changes.

Since physical activity produces a subsequent hypertensive exacerbation of some duration it would appear that the increased splanchnic vaso-constriction provoked during exercise may also have the effect of stimulating or perpetuating the production of the pressor factor from whatever viscera this may arise.

In this way a vicious cycle is established. The blood pressure rises and eclampsia becomes more imminent. The uterine blood flow is progressively reduced. The changes occurring in the placenta are illustrated in Fig. 5. The placental blood flow is impaired and trophoblastic anoxæmia results. This, in turn, may result in irreversible trophoblastic degeneration and infarct formation. These changes may be associated with an intrinsic failure of placental development which sometimes seems to be a related factor in severe early pre-eclampsia.

As term is approached there is a natural reduction in placental function, sometimes referred to as "senility".

As a result of all these changes there is a progressive reduction in placental function and intra-uterine death of the foetus may occur. Rest can only partially reverse this sequence of events and, clearly, to be effective, it must be instituted at a very early stage.

Fig. 6 illustrates the ill-defined frontier between the normal patient and the one with

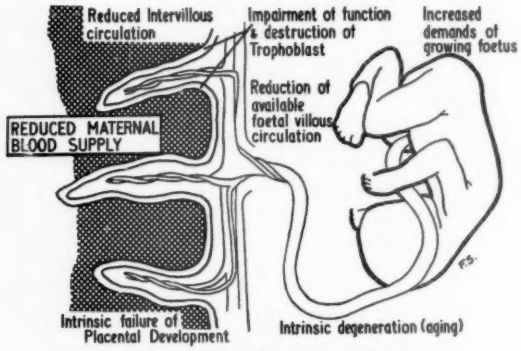

FIG. 5.—Placental changes in P.E.T.

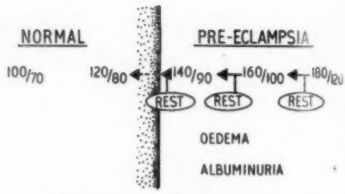

FIG. 6.—The effect of rest on the incidence and severity of P.E.T.

pre-eclampsia. Many of us do not agree regarding the upper limit of the normal blood pressure and we confine our attention to those patients who show indisputable evidence of pre-eclampsia, such as hypertension, œdema, and albuminuria. Our results are good, but many women do progress to moderate or even severe pre-eclampsia before we see them.

I believe that *all* primigravidæ and any other patient thought to be particularly susceptible to pre-eclampsia should be advised to rest as much as possible from 30 weeks onwards. In all probability this measure would completely alter the pattern of severity of pre-eclampsia. The mild cases would occur later, or never at all; the moderate would become mild, and the severe, moderate. In turn the perinatal mortality from this condition should be much reduced.

Mr. John Sophian: *The Cause of Pregnancy Toxæmia*

If patients with incipient or pre-existing hypertension are excluded toxæmia is *never* met with outside primigravidity, hydramnios, concealed accidental hæmorrhage, hydatidiform mole, or multiple pregnancy.

Since "essential" hypertension can possibly occur as a result of a renal mechanism [1], and since renal ischæmia can be held to explain the œdema, hypertension and albuminuria which characterize the toxæmic state [2]—signs entirely similar to those of acute glomerular nephritis, an undoubted renal disease [41]—it is reasonable to infer that a renal ischæmic change occurs in pre-eclampsia. This condition is associated with an increased resistance to stretch of the uterine muscle and such a resistance could be evoked by uterine over-distension; or even normal distension of the primigravid uterus. The utero-renal reflex demonstrated by Franklin and Sophian [3] has shown that by provoking resistance in the rabbit's uterus (by fluid distension) a stimulus is produced causing renal cortical ischæmia. Evidence has thus been produced to correlate these renal changes with toxæmia [4]; further, all grades of renal ischæmic change, and cortical necrosis have been produced by renal nerve stimulation [5], which suggests that anuria can result from a reflex response. Evidence of a utero-renal reflex is provided by the over-distension of the uterus in concealed accidental hæmorrhage causing anuria due to renal cortical ischæmia. It has been shown that removal of the distension-stimulus by rupture of the membranes and interruption of the suggested nervous reflex by splanchnic block [6 and 7] is sufficient to overcome incipient or early anuria. Correlation of the severe cortical ischæmia of anuria with the renal state underlying pre-eclampsia was shown when intravenous saline, mistakenly administered as a therapeutic measure to an anuric, precipitated œdema, hypertension and fits [8]. Albuminuria is always detectable in the earlier oliguric phase and when an excess of salt and water exists in the presence of renal ischæmia all signs of toxæmia are evoked. Pre-eclampsia and eclampsia may also be produced when this sequence is reversed, salt and water retention being preliminarily affected by giving D.O.C.A. and salt, followed by renin [9].

In the pre-eclamptic process there is a great deal of evidence to show that renal ischæmia

is continuing as pregnancy advances, evidence that is derived from the reduced glomerular filtration rate and renal plasma flow figures [10] and from renal biopsies [11]. The signs can also be construed as those resulting from renal ischæmia [12]. It is suggested therefore that the *continuing* ischæmia of the kidney is responsible for the signs of pre-eclampsia. *Sudden* renal shut-down, as evidenced by the development of anuria, has a possible counterpart in the suspension of renal function in the salmon when it changes its river habitat for the sea; and it can be shown that this is entirely due to the presence of salt in the new environment [13]. It should be noted also that the kidney is more prone to an "anuric" shut-down if the liver is damaged [14], and as a corollary, renal damage of an ischæmic type can result from compression of the porta hepatis [15]. The supervention of fits, coincident with severe exacerbation of hypertension, has been seen following prolonged clamping of the remaining renal pedicle, after unilateral nephrectomy; cerebral vascular spasm accompanies this manifestation. Further, these experimental animals, who have been kept on saline, can occasionally develop severe œdema, thus demonstrating the association of œdema, hypertension and fits with ischæmia of the kidney [16]. In the causation of fits, changes in the electrolyte concentration of the plasma have been shown to be responsible [17]. Sodium and chloride concentration of the plasma can therefore be responsible both for a renal shut-down, as in the salmon, and for the production of fits, while salt is necessary for the production of hypertension [18]. Renal ischæmia can cause the retention of salt and water [42] and a 1% reduction of the glomerular filtration rate (G.F.R.) can account for the retention of 10 grams sodium daily—a not inconsiderable amount when spread over the later months of a toxæmic pregnancy when G.F.R. is markedly reduced. Recent work in the experimental animal has demonstrated a reduction of one-third in the G.F.R. during the early periods of uterine distension [19]. Nephron dissections, which help to differentiate purely ischæmic lesions from those in which poisons have been active, clearly indicate that the tubular damage is due to ischæmia in the anuria following eclampsia [20]. All this evidence suggests the presence of renal ischæmia in pre-eclampsia which by producing salt and water retention can be responsible for hypertension, fits and even anuria. Alternatively, the principal effect of renal ischæmia may be directly upon the vascular system, enhancing hypertension and evoking encephalopathy. It has been shown in nephritis that reducing the renal blood flow increases the escape of protein through the glomerular filter by slowing the stream, suggesting that renal ischæmia produces the albuminuria as well [21]. It follows that every sign and complication of toxæmia can be explained by renal ischæmia. Corticoids [22], which are in the main responsible for the shifts of retained water and electrolytes in the body compartments are of secondary importance.

Evidence that the uterine stimulus originates in the resistance to stretch of the myometrium is both direct and indirect. Uterine tone has been shown to be raised in hydramnios [23], in toxæmic pregnancy [24], in concealed accidental hæmorrhage [25] and also in hydatidiform mole in which Acosta-Sison [26] has drawn attention to the association of the height of the uterus with the severity of the toxæmia, an implication of increased regression also present in primiparity indicating increased myometrial tension [37]. Apart from this direct evidence, puncture of the membranes in pre-eclampsia [27] and oliguria [28] is associated with clinical improvement before labour commences, while introduction of a hydrostatic bag for purposes of induction in toxæmia has been observed at least on one occasion to precipitate anuria. It should be added that interrupting the arc of the utero-renal reflex by caudal analgesia has great therapeutic value [29], as has destruction of the nervous pathways [38]. It has been shown, that increased tension of the uterine wall causes a reduced circulation through the myometrium [30] while a noticeably reduced myometrial circulation has been found constantly and continuously in pre-eclampsia [31]. This circulation can also be diminished by exercise [12]. On one occasion in toxæmic pregnancy considerable augmentation of the blood flow through the uterine wall and amelioration of the pre-eclamptic signs were apparent on the death of the fœtus [32]. Presumably this was due to its crumpling, resulting in a reduction of the stretch factor with corresponding diminution of the utero-renal reflex. Prolonged contraction of the uterus during labour has on one occasion been found to coincide with the onset of toxæmia [33]. The adenosine content of the blood in toxæmia, indirect evidence of a heightened uterine tone, has been found to be much higher than in normal pregnancy [34].

Toxins originating from the fœtus or the placenta cannot be responsible for the ætiology, since amelioration of toxæmia results on the intra-uterine death of the fœtus, although it is still retained *in utero*. Such toxæmia can recrudesce at labour when the death of the fœtus and placenta exclude the renewed manufacture of such hypothetical substances [4]. Nephron dissections of the kidney of patients with eclamptic anuria do not show any toxic effect on the tubules [20]. Neither is it reasonable to assume that toxin production is exclusive to first pregnancies alone; indeed no toxin has yet been found.

Examination of the hypothesis that hormones are responsible for pre-eclamptic signs suggests that such substances play no primary part in production [35]. An antigen reaction can be excluded, as its incidence should become more pronounced in later pregnancies, whereas toxæmia is a disease of the primigravid. Dietetic theories fail to appreciate the effect of salt which aggravates the condition.

Certain criticisms have been levelled against the thesis put forward here viz.:

(1) It cannot explain postpartum eclampsia. But Franklin has found renal ischæmia particularly marked during labour and coinciding with the postpartum contractions of the uterus.

(2) It has failed to produce toxæmia experimentally. This work was carried out with rabbits and the rabbit's uterus cannot resist stretch for a period long enough to allow pre-eclampsia to develop; neither has the animal suitable suprarenals, a fact indicated by the D.O.C.A. priming necessary to provoke eclampsia [9].

(3) A denial of the existence of the "dual" [Trueta, 39] circulation in the kidney on which the thesis is based. This criticism originated because current biochemical interpretations of renal hæmodynamics were only valid for a single renal circulation. However, Pappenheimer [36] claims that a dual circulation must be postulated to explain the filtration fraction and the less than 100% extraction ratio that prevails.

It is again postulated that the ætiology of toxæmia is to be found in the resistance of the myometrium to stretch provoking renal ischæmia. This, if pre-existent in essential hypertension or brought about by the utero-renal reflex or exercise [40] explains the reduced uterine blood flow it effects.

DISCUSSION ON PREVENTION OF ECLAMPSIA

Professor G. Gordon Lennon:

Induction of Labour in Pre-Eclampsia and Eclampsia

I. *Indications:*

(1) To cure eclampsia after control of fits

(2) To cure toxæmic accidental hæmorrhage

(3) To cure pre-eclampsia (To prevent eclampsia and/or accidental hæmorrhage).

A. Acute case. (*a*) Rising blood pressure despite treatment. (*b*) Increasing albuminuria.

B. Acute on chronic case. (*a*) Rising blood pressure. (*b*) Accidental hæmorrhage.

C. Chronic case. (*a*) Maintenance of blood pressure at toxæmic level (140/90 or above) under treatment and gestation at least of 36 weeks' duration. (*b*) Continuing slight or recurrent slight albuminuria. Slight albuminuria not exceeding 14 days' duration.

(4) To avoid placental insufficiency. Cured pre-eclampsia however mild or recurrent; gestation at least of 36 weeks duration.

Before considering relevant points I should like to emphasize that from 1951 to 1956 I have taken 130/80 as the *upper* limit of normal blood pressure, a level indicated for many years by Professor F. J. Browne. Any woman who has started pregnancy with a blood pressure of this level, or below, and who rises to a level of 140/90 I have regarded as toxæmic. In 1951 the severity of toxæmia in my wards was high. An attempt, therefore, had to be made to impress general practitioners with the importance of the condition in its early stages by admitting to hospital those patients with a blood pressure of 140/90 and no other signs of toxæmia. In addition, visiting lecturers helped the crusade including Dr. Hamlin and Professor Bruce Mayes from Sydney who have done so much to teach us the intensity of pre-natal care required in the management of toxæmia. In this connexion I would like to mention another from Sydney, Mr. T. Dixon Hughes lately deceased, who was the prime instigator of the wonderful results achieved at Crown Street Hospital. He showed before anyone else that in practice, albeit his private practice, eclampsia need not occur, and I wish to record this small tribute to him. Latterly in Bristol, patients with early evidence of toxæmia have not been admitted to hospital, but have been put to bed at home with daily supervision by midwives and general practitioners. Since I believe that fulminating eclampsia represents inadequate pre-natal care, general practitioners have been asked to see that patients with a blood pressure which does not settle within forty-eight hours after rest in bed at home must be sent into hospital, or should be assessed on the advice of a consultant. Thus, I can show that whereas there were 13 cases of eclampsia in 1951, 1952 and 1953 there has only been one case since 1954, and that in a non-booked case. In fact since 1951 there has only been one case of eclampsia in a booked case (postpartum, one fit). The average total deliveries each year in the Professorial Unit is 1,300, 80% of which are booked.

When the results after the use of hypotensive agents such as sodium amytal, Apresoline, phenobarbitone, Serpasil are assessed the fœtal death-rate is independent of effective lowering of the blood pressure. The relationship between the severity of the condition of toxæmia—particularly in the presence of albuminuria—and fœtal mortality is a close one. No less intimate is the association between the maturity and fœtal risk. In my opinion the results we have obtained do nothing to alter the view that placental damage once sustained is irreversible, and fœtal survival depends on the amount of residual functional placental tissue and the fœtal maturity.

Knowing then that even a mild toxæmic episode can lead to some degree of placental ischæmia (Browne and Veale, 1953) and appreciating the possibility of placental insufficiency in the post-mature (Walker, 1954), recently confirmed by MacKay (1957), even a cured mild pre-eclamptic should have labour induced at 38–39 weeks, or, should the toxæmia recur, at any rate after the 36th week. Indeed, MacKay has this to say: "the infant who is in a very dangerous situation is one whose mother has been suffering from a long-continued mild toxæmia and who is allowed to become post-mature. The cord oxygen levels in these cases may be truly desperately low." There should be no combination of post-maturity and even mild pre-eclampsia.

Changes of Method of Induction

I. *Methods:*

(1) *Medical induction:* Oxytocic drip.

(2) *Surgical induction:* (*a*) Rupture of forewaters. (*b*) Cæsarean section.

(3) *Combined medical and surgical induction:* (*a*) Rupture of forewaters followed by oxytocic drip. (*b*) Oxytocic drip followed by rupture of forewaters. (*c*) Cæsarean section after *a* or *b*.

(*a*) *Rupture of the Forewaters*

Since 1953 the Drew Smythe catheter has not been used. All surgical inductions, therefore, are now by rupture of the forewaters. This change was precipitated by a maternal death from sepsis (the only death from sepsis) after a Drew Smythe induction of labour for toxæmia. Three days after induction the patient died in the second stage of labour, and at post-mortem there was found a pool of pus between the membranes and the uterine wall, at the site of the puncture. Obviously, the cardinal principle of "where there is pus let it out" had not been obeyed. Since then, in 1954 and 1955 a series of 987 surgical inductions by rupture of the forewaters has been carried out. 51% of these inductions were for pre-eclamptic toxæmia and essential hypertension. Only 13 cases developed genital tract infection giving rise to notifiable pyrexia, and in this connexion I would lay stress upon adequate vaginal toilet as well as vulval toilet before vaginal examination prior to induction. In this series of inductions there were no maternal deaths, stillbirth rate (corrected for abnormalities) was 1·1% and the neonatal deaths (corrected) was 0·5%. The Cæsarean section rate was 1·94%. There were only two cases of prolapsed cord. From experience then I believe that rupture of the forewaters is the more reliable method of induction of labour, and it does not matter whether the head or breach is free or engaged. 78% of this series were delivered within forty-eight hours of induction, and only 3 cases had a prolonged first stage of labour following rupture of the membranes. 81% were delivered following a first stage of twelve hours or less. A comparable series with not such good results when using a Drew Smythe catheter has recently been published by Manly (1956).

(*b*) *Oxytocic Drip*

All cases of induction for toxæmia should have a vaginal examination to determine the state of the cervix. If the cervix permits rupture of the forewaters then this should be carried out. If the cervix does not admit penetration by the finger and the case is the more chronic variety of pre-eclampsia, then an oxytocic drip (Syntocinon) is set up in an attempt to open up the cervix. This drip, similar in every way to the one employed twenty-four hours *after* rupture of the forewaters, is started with 1 unit of Syntocinon in a bottle of 5% glucose solution (540 ml.). It is regulated at a rate of 12 drops per minute rising at half-hourly intervals to a total of 60 drops per minute. 5 units of Syntocinon are put in the second bottle, again starting at a rate of 12 drops per minute. When uterine contractions occur the drip is maintained at *that* same number of drops and is continued until labour has been completed. Formerly, the drip was not set up until forty-eight hours after rupture of the forewaters, but this has been advanced to twenty-four hours after rupture because of urgency in many cases of pre-eclampsia. If the drip is being used to open up the cervix it will take at least forty-eight hours, and maybe even slightly longer before the cervix is sufficiently dilated to permit forewater rupture. If the membranes have been ruptured for forty-eight hours and labour not completed chloramphenicol is given. This was the preparation decided in consultation with the pædiatricians and which we have used now for some four years. Recently, Smith *et al.* (1956) advocated streptomycin and oxytetracyline in such cases but we believe that adequate cover for baby and mother is provided by chloramphenicol without risk of blood disease and without painful injections.

Theobald *et al.* (1956) reviewed a large number of cases which had had oxytocic drips and they advocate a dilution of 1 in 10,000 and 1 in 5,000 with the drip maintained at a rate of 40 drops per minute. This drip is set up with supervision by the house surgeon only for the first half hour when fœtal distress may occur and the drip may have to be taken down. I tried Theobald's procedure but with less success than my own method as far as the onset of labour was concerned.

Since June, 1954, oxytocic drips have been used at Southmead Hospital in an average of 10% of cases. It is noticeable that if the drip percentage falls the Cæsarean section rate rises. Out of 81 oxytocic drips used in cases of toxæmia at Southmead Hospital there was only one fœtal death (32 weeks, blood pressure 210/130, albumin +++).

Pethidine is used as indicated during drip therapy.

(*c*) *Cæsarean Section*

I find that other indications for Cæsarean section occur in an average of 25% of toxæmic cases. Where toxæmia is the only consideration I would say that Cæsarean section has to be employed (1) for the acute, very premature case of pre-eclampsia and (2) in the more chronic case where the pre-eclamptic state is deteriorating and labour has still not ensued after surgical and (or) drip induction and (3) in a very few cases of eclampsia. In failed drip cases, and these are very few, it is wise to ponder that the activity of the female uterus is not always readily stimulated even after rupture of the membranes in cases of post-maturity, and Baird (1955) has shown the influence of age in this connexion. Whereas Cæsarean section was used more frequently in cases of toxæmia some years ago, it is only seldom used now when toxæmia is the only indication, and in this series for the past three years has been used in slightly over 3% of cases each year.

Cæsarean section in toxæmic accidental hæmorrhage is seldom indicated. The combination of anoxia and prematurity is highly dangerous for the fœtus, and the results obtained do not justify the use of Cæsarean section at any rate until near maturity.

Results

(1) The fœtal salvage rate in toxæmic cases from 36 weeks onwards in my series was (and should be) almost 100%. Before 36 weeks, including early cases, the fœtal salvage rate is just over 50%. (Stillbirths and neonatal deaths almost equal in number.)

(2) Comparing 1951 and 1956 figures of induced toxæmic cases there has been an overall improvement in fœtal salvage of 5%. This does not illustrate the whole picture, however, because now the improved results are obtained with greater ease and avoidance of worry by rupture of forewaters (61% of cases), oxytocic drip before or after rupture (10% of cases), and Cæsarean section is only just over 3%.

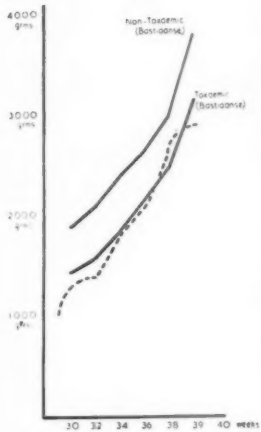

FIG. 1.

There remains a hard core of stillbirths and neonatal deaths in 6·5% of non-induced cases, almost the same figure for both years 1951 and 1956. They include intra-uterine deaths, not only in emergency cases, and it would appear that they result from a reluctance to induce labour in some cases, particularly when the degree of prematurity is great. A bolder approach in future may salvage some of these.

(3) Fig. 1 illustrates the mean size of baby at different stages of gestation in normal pregnancy and in toxæmic cases. The graph was compiled with the use of Bastiaanse's figures (1956), and also the mean weights of the stillbirths and neonatal deaths (presumably the more serious cases) in my series. Babies from toxæmic mothers weigh less on the average than do babies from normal mothers. At 32 weeks in the toxæmic case one can expect a baby of 3 lb., at 34 weeks one of 4 lb., at 37 weeks one of 5½ lb., and at term a baby of 6½ lb.

I have great pleasure in recording my thanks to Dr. T. E. Oppé, Dr. G. Herdan, Mr. S. R. Hewitt, Mr. E. M. Edwards, and Mrs. Doreen Hillier who helped prepare this review.

Mr. C. Keith Vartan:

Plea for Standard Normal Blood Pressure

The recording of the blood pressure in the pregnant woman is so important a feature in hospital practice to-day that it seems hardly credible that as recently as twenty-five years ago, it was not a routine procedure at all. In 1940 the ante-natal case papers supplied to the midwives of a well-known County Council contained no column in which this observation could be noted. This is just one illustration of the state of affairs then pertaining. The blood pressure received attention when the presence of albumin in the urine was noted. The obstetrician, in short, has not been interested in hypertension for very long, which is probably the explanation that we are still not agreed among ourselves as to what we will accept as the upper limit of normal blood pressure, and why we have no common language when we come to discuss the vitally important subject of the hypertensive manifestations in pregnancy, a Gilbertian situation, in the words of Jack Point "What is all right for B would quite scandalize C (for C is so very particular)". Figures varying from 130/70, to 150/100 are held to be normal. The standing Maternity and Midwifery Advisory Committee of the General Health Services Council of the Ministry of Health suggests a diastolic pressure of over 90.

Bastiaanse (1956) has written "There is no consensus of opinion as to the maximum value above which the blood pressure must have risen to be defined as hypertension", and goes on to state "it would be very desirable to reach a unanimous opinion with regard to this

matter". Gibson in his papers of 1954 and 1956 on the "Prognosis of Toxæmia of Late Pregnancy" states that "there is no measure of agreement as to what level of blood pressure should be considered as evidence of chronic hypertension" and later "Comparison with the experience of others is of doubtful value because so much depends upon the level of blood pressure which is accepted as evidence of hypertension".

This independence of thought constitutes a great stumbling block when it is applied to the treatment of pregnant women, and we should by now be ready to accept one standard throughout the country. The general physician has of course been interested in the blood pressure for far longer than has the obstetrician, and reference to their standard works show that with remarkable unanimity, they postulate that 120/80 is the normal blood pressure. Yet how much more important is the dramatic and fitful progress of the blood pressure in pregnancy than the measured tread of this disorder in the non-pregnant state. We might well ask, "by what right does the individual obstetrician chose his own individual standards".

In 1933 F. J. Browne writing of the early signs of pre-eclampsia enunciated his view that we should all accept the 130/70 standard (since changed to 120/80). This pronouncement was kindly received but the general consensus of opinion was that this figure was impossibly low, that far too many normal women would thereby be classed as abnormal. This adverse reaction could not have been based on the experience of those who were criticising Browne; they had not till then thought in terms of 130/70, neither was it supported by the opinion of the general physicians. Browne's dictum has not been refuted subsequently by workers in hypertension. Many obstetricians still hold the view that 130/70 is unrealistic and some have gone further and have said that Browne has done a disservice to obstetrics by this pronouncement. One can only hope that this rejection is not based on the fear of having too many patients *needing treatment* on their hands.

Leo Hahn (1952) in an extensive study of adolescent schoolboys found a mean reading of 117/67 at the age of 15 and he quotes other workers who show what one might expect in examining a large number of young men. In a study of the blood pressure of 6,000 prisoners Alvarez and Stanley (1930) found as high an incidence of hypertension at the age of 15 as at the age of 40. Hines (1937) using the "cold test" as a means for detecting hypertensive cases among 400 school children, found 18% of hypertension. Robinson and Brucer (1939), reporting on 11,000 persons' blood pressure readings, stated that the normal range of systolic blood pressure for men and women is from 90 to 120 mm. of mercury and that the normal range of diastolic blood pressure for men and women is from 60 to 80 mm. of mercury. They stressed that a normal person reaches his mature blood pressure at about adolescence and keeps that range throughout life. In the light of these observations, we should expect to find from 15% to 20% of our patients to be hypertensive, but no more, even on the 130/70 standard.

I believe that the high incidence of eclampsia is very largely due to the regarding of figures well above 130/70, as being still within the normal range.

The prime purpose of this paper is to put on record the results recorded during the last eight years at a hospital where rightly or wrongly the 130/70 standard is adhered to, so that the extent of the problem, that is the number of patients who, in fact, must be regarded as abnormal, and who have to be admitted for ante-natal supervision, can be shown. Secondly, I shall compare the behaviour of patients commencing pregnancy with a normal pressure, with those who are hypertensive on booking, a study which has not previously been made. Throughout the paper the term pre-eclampsia will be used only for those patients whose blood pressure was below 130/70 on first booking (if in the first twenty weeks), and in whom the blood pressure subsequently rises, and the term hypertension for those who are already above this figure (either figure above, but neither below) on first booking.

The women booked at this hospital are primiparæ; multiparæ who have had some abnormality during the previous pregnancy, labour, or puerperium; women who have a general medical disease; and inevitably a number of women whose home conditions make hospital confinement desirable. The borough in which the hospital is situated has its prosperous parts but it also has its slums. There is, however, no economic selection. The hospital has 63 maternity beds and bookings are made on the basis of 20 patients per bed per annum. There are no beds designated for ante-natal care alone.

Hypertension

During the last eight years 10,682 women have been confined and of these 1,077 had a blood pressure of above 130/70 on booking. Thus 10% of all women primiparæ and multiparæ, young or old, who book are hypertensive, but what is surely more striking is that 90% are, in fact, below the Browne 130/70 standard.

The criterion for admission to hospital is the coincidence of albuminuria or of œdema or of excessive weight gain. All of which are associated with a further rise in B.P. 18·1% of these 1,077 developed albuminuria and 36·9% developed œdema. Thus about 40–50% of these hypertensives deteriorated and were admitted. This seems a high admission ra

for any hospital and particularly for one with no designated ante-natal beds but it must be related to the stage of pregnancy at which these women are admitted. In 1955 it appeared that of the 113 patients admitted, 25 were within two weeks of term and 52 were at or beyond term. In practice these 77 patients would be considered for induction either at once or after a few days' rest, because the pregnancy aggravates the hypertension. They therefore present no problem of prolonged ante-natal bed occupation.

If we deduct the patients at 38 weeks or over from the list of 113 we are left with only 32 who would require a period of bed rest of over a week. 14 others (36 and 37 weeks) might or might not have to wait, according to the size of the baby.

The most important treatment which they have is rest; possibly a low sodium diet if they are very œdematous, usually a mild sedative; hypotensive drugs have been tried but without much apparent success. Most patients respond to rest fairly quickly. Their blood pressure falls and the albuminuria does not increase. If there is no albumin in the urine a patient may be allowed to go home after a short period of bed rest. If, however, she is within a week or two of term, induction by rupture of the membranes is preferred. This is the logical treatment; it is the pregnancy which is exacerbating the hypertension; therefore, we terminate the pregnancy.

Unfortunately the figures for 1948 are incomplete, but in the following six years 245 patients or 28·7% of this group were induced on this account.

The antagonism to the practice of rupturing the membranes is probably weakening but that is not to say that it can be lightly undertaken. The operation must be performed with proper surgical skill if it to be successful.

Cæsarean section was performed on 18 occasions. There has been no maternal death in these 1,077 hypertensives. There were 23 stillbirths and 11 neonatal deaths in the eight years. All cases are included, there has been no "correction". The percentages are 2·13% and 1·2% respectively. No woman developed eclampsia.

Pre-eclampsia

The women whose blood pressures were below and stayed below 130/70 till the second half of pregnancy and then rose number 1,631, an average of 204 per annum. The stage of pregnancy at which they are admitted, and again about half of these require admission and for the same reasons, œdema, albuminuria and excessive weight gain, is given for the same year (1955) as in the hypertensions. The total admitted was 119.

In this group 36·7% develop albuminuria and 60·9% develop œdema. It should be noted that in the pre-eclamptic group 97 out of 119, or about 4/5 of the total may be induced forthwith and that 22/119 or 1/5 must have a period of rest in bed first, whereas in the hypertensive group who come under observation earlier, the number suitable for induction at once is smaller.

The treatment in hospital is basically the same but differs in this important criterion: no patient is allowed out undelivered. 652 women were induced in the eight years or 80% of all the pre-eclamptics admitted. There were also 24 Cæsarean sections performed.

The stillbirths numbered 53 (3·12%) and the neo-natal deaths 17 (1·04%). There was one maternal death from anuria in a women who developed post-partum eclampsia. There were altogether 4 women in this group who developed eclampsia; 4 in 10,682 or 1 in 2,670.

We are now in a position to compare the two groups (Table I).

TABLE I

	Hypertension	Pre-eclampsia
Incidence	10%	15·2%
Developing albuminuria	18·1%	36·7%
Developing œdema	36·9%	60·9%
Maternal death	0	1
Stillbirth	2·1%	3·12%
Neonatal death	1·2%	1·04%
Perinatal mortality	3·3%	4·16%
Subsequent developing eclampsia	0	4
Induced	28·7%	80%

(The total fœtal and neonatal loss is 3·73%)

This comparison has not been made before but I believe it shows one thing of great clinical importance, namely, that, in general, a hypertensive subject can take whatever this thing is that happens to her in pregnancy, better than the woman who was normo-tensive in the first half of her pregnancy, but who later deteriorates, although of course the very severe hypertensive (such as is not often seen in pregnancy) may be more likely to come to harm than a mild pre-eclamptic.

From these figures, too, it seems that her chance of developing eclampsia is less, but with only 4 cases in eight years it was necessary for me to turn further afield. I wrote to and received replies from Belfast Maternity, Bromley, Dartford, National Maternity Dublin,

Elsie Inglis, Glasgow Southern General, Guy's, Leeds, Liverpool, Manchester, Melbourne, Oxford, Newcastle-upon-Tyne, Queen Charlotte's, the Rotunda, St. Thomas', Southend, University College and Woking, and was thus able to collect information concerning 160 cases of eclampsia in booked patients. I asked just one question: what was the commencing blood pressure of the patients who developed eclampsia? Non-booked admissions are not included as this information was not available.

Summarizing the information received regarding the 160 cases of eclampsia it is found that 118 started their pregnancies with figures of or below 130/70 whereas only 42 started as hypertensives by this standard. Translating this into percentages we see that 73·4% of eclamptics start with a normal blood pressure and only 26·2% as hypertensives. Only 5% started pregnancy with a diastolic pressure of over 90. This is the second important point which emerges, and is of the greatest importance when it comes to treatment: one may take chances with a hypertensive but never with a pre-eclamptic.

Samuel Bard in his Compendium of Midwifery (Collins and Perkins, New York, 1808), stated that "if early attention would be paid to the signs and symptoms described they might not only be relieved, but the more dangerous state of convulsions which they threaten, would probably be prevented".

Hamlin states that eclampsia is a preventable disease. I agree, but one needs a little luck as well, for a woman may pass all the criteria of normality at her last attendance and delay for a day or two before seeking advice for her swollen hands and headache. The vital importance of "self-observation" must also be stressed to the patient, but all our watchfulness is jeopardized if we set a standard higher than the 130/70 originally advocated by Browne, and start our watching too late.

If further emphasis is necessary the published incidence of eclampsia at different centres in Britain should be compared with the 1 in 2,670 of the present eight-years series, and which should surely be attainable everywhere.

TABLE II.—INCIDENCE OF ECLAMPSIA AT DIFFERENT CENTRES IN BRITAIN

Hospital	5 years	Cases	Incidence
A	1946–1950	17 in 7,071	1 : 416
B	,,	19 in 8,743	1 : 460
C	,,	8 in 5,127	1 : 641
D	,,	21 in 13,501	1 : 643
E	,,	9 in 6,220	1 : 692
F	1949–1953	13 in 9,003	1 : 692
G	1946–1950	12 in 11,072	1 : 922
H	,,	4 in 3,937	1 : 984
I	,,	5 in 5,798	1 :1,159
Control	1948–1955	4 in 10,682	1 :2,670

These are the only hospitals from which consecutive maternity reports have been received: four are London teaching hospitals, three provincial teaching hospitals and two non-teaching hospitals. The standard B.P. at these hospitals is, in general, a diastolic of 90.

I think I have shown that eclampsia is most prevalent in those hospitals and schools where the information obtained by those who have studied the normal blood pressure has been so lightly set aside.

The occurrence of eclampsia is, of course, much higher than I have shown, for most of the eclamptic cases occur in the home and are admitted as emergencies, but we must remember that all practitioners and all midwives are, in the first instance, taught what they now regard as normal and abnormal.

The Minister of Health has shown that "the principal cause of avoidable maternal death in this country is toxæmia of pregnancy".

I believe the responsibility rests fairly and squarely on the shoulders of all who resist Browne's teaching. I believe we must radically change our complacent outlook and start teaching that 130/70 is the normal pressure for a pregnant woman.

CONCLUSIONS.—(1) Eclampsia is virtually a preventable disease. (2) It is not in the patients' best interest that obstetricians should disregard the advice of the physician that 120/80 is the normal blood pressure. (3) Comparisons of methods and results of treatment are impossible when variable standards are used. (4) Women who are hypertensive at the beginning of their pregnancy are a better risk than normal women who later develop pre-eclampsia. (5) A hospital which accepts the 130/70 standard must be prepared to admit 18·5% of its patients before they go into labour spontaneously, but of these over half are so near to term that they may be safely induced forthwith.

The Brain as a Machine

By W. GREY WALTER, M.A., Sc.D.
Burden Neurological Institute, Stapleton, Bristol

THE title of this paper needs some explanation. Physiologists are accustomed to speaking of organs of the body with a definite article, assuming that all such organs are essentially similar, at least in a given species. Human brains may be an exception to this convenient rule, since, however we may choose to describe cerebral mechanisms, we must accept the evidence for personal variations, and these variations may be the main diagnostic character of highly evolved central nervous systems. In fact, psychiatrists and psychologists seem to imply something of this nature when they consider stereotypy as a sign of mental pathology. This is not to say that we cannot envisage *any* features common to all human brains but we should realize that whatever general picture we may form of the mechanics of brain function should include a high potentiality for individual idiosyncrasies.

The term "machine" also is liable to misinterpretation. We still tend to think of machines as though they were simple devices to amplify or conserve human muscles but a much wider definition is permissible and indeed essential if we are to consider more than the simplest aspects of mental behaviour.

The problems facing brain physiologists to-day are novel from the standpoint of classical biology, but they are not very unlike those familiar in other sciences. It is perhaps in meteorology that we find the closest resemblance to human neurophysiology, for in charting and predicting weather conditions a meteorologist must take into account the operation of a large number of interacting mechanisms, most of which are mysterious in their origin, though all are capable of exerting a major influence. There are serious and well-known risks incurred when prediction is based on empiricism, as anyone may quickly learn who plans a picnic in England in August, but many of these risks are due to the difficulty of distinguishing between large-scale and small-scale phenomena. Fine weather does not exclude the possibility of a local thunderstorm and, in fact, may even promote it. Similarly, in the physiology of the brain a high-grade normal level of function does not exclude the possibility of epileptic seizures; I have suggested elsewhere that the very refinement of normal discrimination in human brains may actually increase the possibility of convulsive breakdown (Walter, 1953).

The science of brain mechanics is at an awkward age of its development, relying still on classical terms but attempting to explore the frontier of evolution. We are in the pre-Newtonian age as it were, in which we can still argue amiably in terms of Cartesian vortices, though we may feel that at any moment a theory of Gravitation may destroy and simplify our web of fancy. If we find the associations of the word "machine" too instrumental, we should perhaps recall that the etymological meaning implies simply *a way of doing something;* we should be encouraged therefore to study behaviour rather than static structure even though we may still lack the tactical equipment for detailed analysis of complex systems.

The first question we should ask presumably is "What does the brain do?" A specific answer is not so easy to frame. One can say plausibly that the brain does everything we can think of, but this is of no great help in the design of an experiment nor presumably in the examination of a patient. If the question is differently phrased, the answer may be more explicit. Knowing from prior information that much bodily behaviour is implemented by interacting reflex circuits, we may legitimately enquire how complex a behaviour pattern can be formed by such a system of reflexive action. This enquiry yields immediate gain for we find ourselves transported into the new kingdom of cybernetics; the physiological reflex is an older and, I think, clearer term for what engineers call "servo" or "feedback systems".

The cybernetic approach to this domain is both practical and powerful. There is now a great mass of information on the nature and action of reflex systems in flesh and metal. The early notions of neurophysiologists are unconsciously embodied in many of them, but are extended in some to a degree which is hard to emulate in a physiological laboratory. Many of these intricate analyses can be demonstrated by the operation of working models, as has been shown by Ashby (1952), MacKay (1956), Shannon (1952), Uttley (1956), Wiener (1950) and myself. It can easily be seen, for example, that a system with only two reflexes can display an astonishing variety of apparently "purposeful" behaviour patterns.

Such a model can easily find its way around quite a complex world. It can avoid starvation or self-destruction, it can attain its sources of nourishment and refreshment, it displays a commendable moderation in its quest for gratification and avoidance of pain, it can solve without difficulty the dilemma of Buridan's ass, it behaves as if it could recognize itself as in a category different from all other structures and others of its own kind in a related category as well. We may conclude therefore that mere complexity of behaviour does not inevitably require more than an assembly of reflexive circuits—a spinal cord.

Careful observation of the antics of such models reveals that elaborate though the behaviour patterns may be—and they may be so bizarre as to deceive even a trained observer of animals—they display no modification by experience, and such modification we must put in a different class from mere complexity. Here again, study of model behaviour suggests that there is one class of adaptation still outside or below the domain of brain function; this is the type of improvement in performance by repetition which may be, and often is, achieved by a process no more sophisticated than the running in of a motor or the wearing out of a garment. Modification of this type is sometimes referred to as practice. The really interesting part of brain mechanics would seem to reside in the fine structure of that behaviour which we usually describe as thinking and learning. We may then consider specifically, how may human brains perform these functions? Again, study of working models of learning can assist us, for in their design the first article of the specification requires that they exert a power of selection over the information they receive. Like an ordinary radio set, a learning instrument is useless if its reception is too wide. It must be capable of tuning itself, as it were, to selected stations. The significance of a signal is not necessarily increased by multiplication of sources. We must therefore investigate the mechanism whereby a human brain can be tuned—or can tune itself—to those sources of information which it can identify as "wanted". As a first step in such a study, can we decide what the information is wanted for? We must suppose at least that, in general, it is wanted for the survival of both the individual and the species, but in either case the aim is essentially statistical or probabilistic. That is, the justification of an aim is not necessarily logical, though a logical goal may often be considered as a special case or part of a statistical situation.

This general notion, that the mechanics of brain function may be based on processes of statistical selection and reflexion, seems to me one of the most powerful of recent developments. It receives some support from the now familiar fact that logical reasoning, in the sense of syllogistic inference, is more easily and rapidly performed by standard computing machines than by human beings.

From the experimental standpoint, therefore, we are led to search for any part of the reflexive machinery likely to be connected with the powers of statistical selection and coordination which are suggested as essential in this hypothesis.

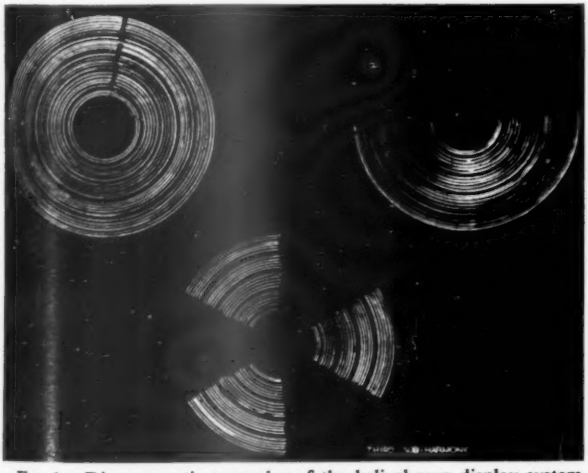
In many laboratories experiments are now in progress to study the details of learning in human beings with the modern aids of electro-encephalography and similar techniques. Although many claims have been made it still seems too early for evaluation of the results as a whole. There is some hope, however, of identifying certain features of a learning mechanism by specifications derived from theoretical analysis. Such considerations suggest that one of the most important aspects of such a mechanism would be a process analogous to that developed for automatic factories, whereby the flow of information and materials is coordinated in time so that the course of production is smooth and optimally related to the availability of components and the desirability of the finished article.

In a special sense, therefore, in the brain as in an automatic factory, time is of the essence. This does not mean merely that speed is of particular value, but rather that the sequence of events must somehow be preserved and classified. As a simple example, it is important for any creature to distinguish in some way between cause and effect, even in arbitrary terms. We must be able to decide for ourselves whether lightning causes thunder, or thunder lightning or whether both have a common cause. Even this simple problem is not as easy to solve as it might seem, bearing in mind the widely different rates of transmission of light and sound in the outside world and the even more intricately variable rates of propagation of nerve impulses arising from the eyes and the ears in the nervous system. Zeus and Electricity are names not explanations. We should recall also that in the elementary working models of reflexive behaviour, the provision of an autonomous scanning mechanism offered an immediate solution for many elementary paradoxes of choice and symmetry. One part of our experimental work has accordingly been directed to the detailed analysis of these brain activities which seem to maintain a regular though adaptable rhythm, in the expectation that these may be found to be related to the mechanism of process control required for the systematic evolution of adequate statistical behaviour.

Until recently the methods of analysis were inadequate to provide confirmation or refutation of these hypotheses but we now have available a method for displaying a

measuring with a new order of accuracy the time and space relations of electrical events in the brain. The methods used heretofore have depended in the main upon some form of integration, averaging or summation to achieve the necessary degree of resolution. For example, in the Wave Analyser introduced many years ago (Walter, 1943) the various frequencies present in an EEG record are separated out and the abundance of each component is then added up over a period of ten seconds so as to provide a spectrum of the brain activity over this relatively long period. Similarly in the Toposcopic Display System first described in 1951 (Walter and Shipton, 1951), the rhythmic variations in voltage were transformed into changes of brilliance of a scanning vector on a cluster of 22 cathode ray tubes which were photographed in such a way as to permit summation of regular components by superimposition on the photographic emulsion. More recently (Shipton, 1957) the toposcopic method has been extended and modified so as to provide a high degree of resolution with respect to time in each of the 22 channels. This has been accomplished by introducing a spiral scanning time-base upon which are projected the variations in brilliance corresponding to brain activity. The speed of this time-base can be very accurately controlled and adjusted, and since the scale is coiled helically on the tubes the length of the exposure can be considerably prolonged. This provides what is termed "line-to-line correlation".

In effect, the display consists of 23 concentric circles, each representing one complete rotation of the cathode ray spot, of which the brilliance is modulated by the incoming signal. If the rotation rate is, for example, one revolution per second, then the complete tube would be scanned in 23 seconds. At the other extreme, if the scanning rate is 23 r/s, then the time to complete the picture would be one second. The presentation is illustrated diagrammatically in Fig. 1.



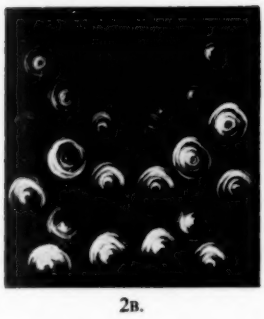


FIG. 1.—Diagrammatic examples of the helical-scan display system showing the 23 concentric circles. The gaps between the circles are to indicate time intervals during the exposure.

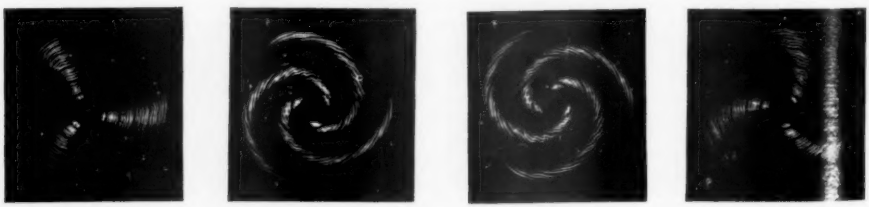
2A.

2B.

FIG. 2.—A, Alpha rhythms in normal subject at rest with eyes closed. The frequency varies from 8·3–9·6 c/s during the exposure but the phase relations in the various regions are consistent. B, Alpha rhythms in another normal subject with alpha frequency at 11·6 c/s again showing consistent phase relations which are similar to those in Fig. 2A although the frequency and distribution are different.

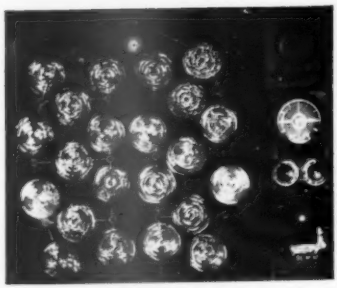


In this way records can be made either over a relatively long period with sacrifice of time resolution, or over a short period with a high degree of accuracy. For example, if it is desired to investigate the time relations of an alpha rhythm at 9 c/s the scanning rate can be set to nine revolutions per second and a device is available to lock the speed precisely to the frequency and phase of the incoming signal in one channel, which is then regarded as fiducial. Records obtained in this way are shown in Fig. 2, taken from two normal adult subjects. Here it is seen that the oscillatory waveforms of the alpha rhythms are represented as a group of black and white striped discs in the occipital region of the brain occupied by alpha activity; each line forming the disc is one "wave", and its length and brilliance indicate the wave

duration and amplitude respectively; in Fig. 2A the scanning frequency varied during exposure from 8·3 to 9·6 r/s. This was the range of variation in frequency of the alpha rhythm in the fiducial channel during this exposure, which lasted just under 2½ seconds. In each channel therefore there is a record of 23 waves and the time of occurrence of each wave in all channels can be seen at a glance, or, if desired, carefully measured. In this way can be obtained something approximating to an auto-correlation index for each channel and a cross-correlation index between channels. In this particular subject during this time it can be appreciated that this alpha rhythm is extremely regular in frequency and phase in each channel but the phase relations of the rhythm between channels are peculiar and intricate.

Fig. 2B shows a similar record taken from another subject whose principal alpha component was considerably higher in frequency—11·6 c/s. Here again there is a striking consistency in the time relations between channels. Furthermore, in spite of the difference in frequency and distribution of the alpha activity in the two subjects, there are marked resemblances in the phase relations between channels in both records. These records are two of a great many which exhibit unequivocal evidence that alpha rhythms do not occur precisely synchronously in all regions of the brain where they appear, but the time relations of their arrival may none the less be consistent over a period of several seconds, provided the mentality of the subject is undisturbed. These records were taken during rest, the subjects' eyes were closed and they had been asked to relax mentally as much as possible.

The next point to be established is that during the exercise of the mental faculties the consistent and coherent pattern of alpha distribution and time relations is elaborately but characteristically disturbed; this effect is exemplified in the next figure.



In order to follow the changes in alpha pattern associated with mental activity and stimulation, it has been found desirable to record at a scanning rate which is a sub-multiple of the rhythm to be investigated. This means that the exposure duration can be longer, while the estimation of time relations is correspondingly less accurate. When the scanning rate is exactly one-third of the frequency of the incoming rhythm, the records show patterns with three arms or petals which are perfectly straight, and, if the rhythm is entirely regular, with completely smooth edges. A test record of this type is shown in Fig. 3A. If, however, the frequency of the incoming signal is slightly greater than three times that of the scanning rate the three petals curl in a counter-clockwise direction (Fig. 3B). Contrariwise, if the signal is slightly less than three times the frequency of the scanning rate, the petals curl clockwise (Fig. 3C). The degree of curl—which can be seen at a glance—may be measured quite easily and indicates the precise frequency of the signal. In such an exposure the frequency of an alpha rhythm can be measured to an accuracy of 0·02 c/s (Fig. 3D). If measurements are made of each line, then it is possible to estimate the interval between individual waves as well as the over-all frequency. A record such as this displays just over seventy waves altogether, and if the activity is apparent in all channels, the total number of waves displayed in a single photograph is slightly over 1,500. The amount of information thus displayed is therefore very great and is certainly large enough to permit trustworthy computations of the significance of any changes that may be observed.

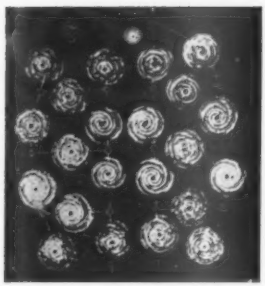
FIG. 3.—Test records showing the resolution of the display system run at one-third signal frequency. A, Signal at exactly three times scanning rate—9 c/s. B, Signal at 9·2 c/s. C, Signal at 8·8 c/s. D, Signal at 9·03 c/s.



Using this method it has been possible to demonstrate clear changes in alpha frequency and distribution during moderate mental effort, and a series of such photographs is shown in Fig. 4. The first exposure (A), shows the alpha distribution and frequency at rest and corresponds with the high speed record in Fig. 2A. During the next exposure the subject was asked to perform a simple mental calculation; the immediate effect of the instructions was to suppress the alpha activity in all but two channels in the right hemisphere which were connected antero-posteriorly between the central, temporal and parietal electrodes. Even

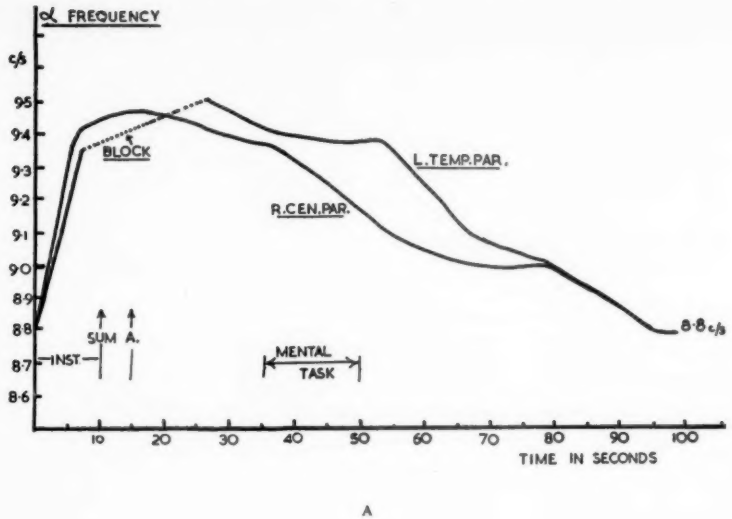

FIG. 4.—The effect of mental activity on alpha frequency and distribution in normal subject of Fig. 2A. The duration of each exposure was 8 seconds.

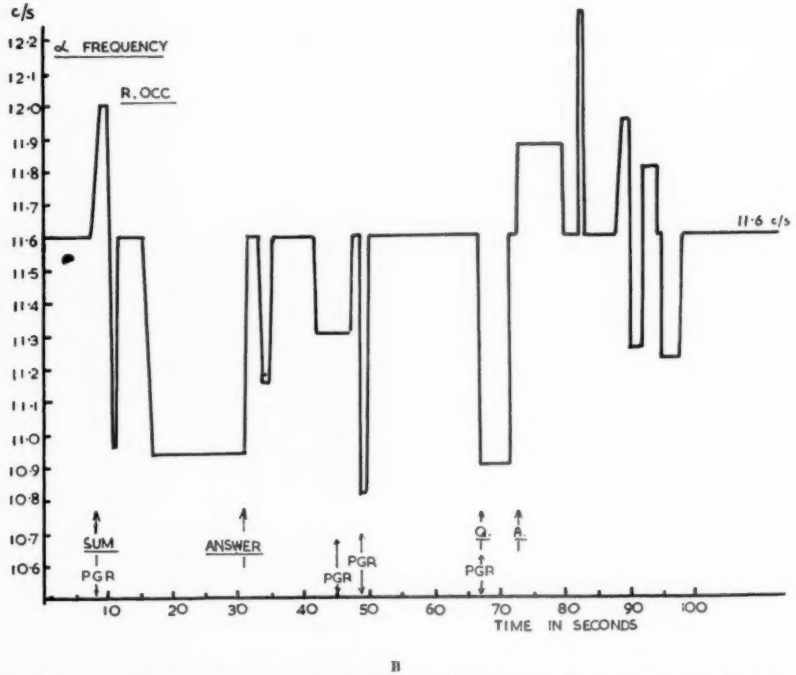
in these channels the rhythm was disturbed, as is shown by the curl of the three petals; the frequency in fact rose rapidly from 8·8 to 9·4 c/s.



The other exposures in this series show a gradual return to the resting state. These are consecutive exposures, the whole set corresponding to a period of nearly two minutes. The solution to the first simple problem was given just before the third exposure, but the effect of the mental activity long outlasted the solution itself. The effect of the second task was much smaller and limited to the left side.

It can be seen that alpha activity gradually returned to the right hemisphere though at higher frequency than before, while the left hemisphere remained affected until nearly the end of the period of observation and on this side, even when activity returned, it was still of considerably higher frequency than on the right side.

In the last exposure but one, the right hemisphere has returned to its original frequency and distribution, but the petals in the left hemisphere are still curling, indicating a slight but significant discrepancy in frequency between the two sides. In the last exposure the original pattern is restored to an extraordinary degree of concordance.

FIG. 5.—A, Graph of changes in the alpha frequency derived from Fig. 4. Note sustained rise i frequency of about 0·5 c/s and final return to original frequency. B, Alpha frequency changes i normal subject of Fig. 2B and Fig. 6. Note abrupt frequency shifts and return to original frequency C, Alpha frequency changes in same subject as in A under the action of Meratran. The steady frequenc has risen by 0·4 c/s and the rate of change during attention is abrupt and discontinuous, but again th frequency returns to precisely its original value.

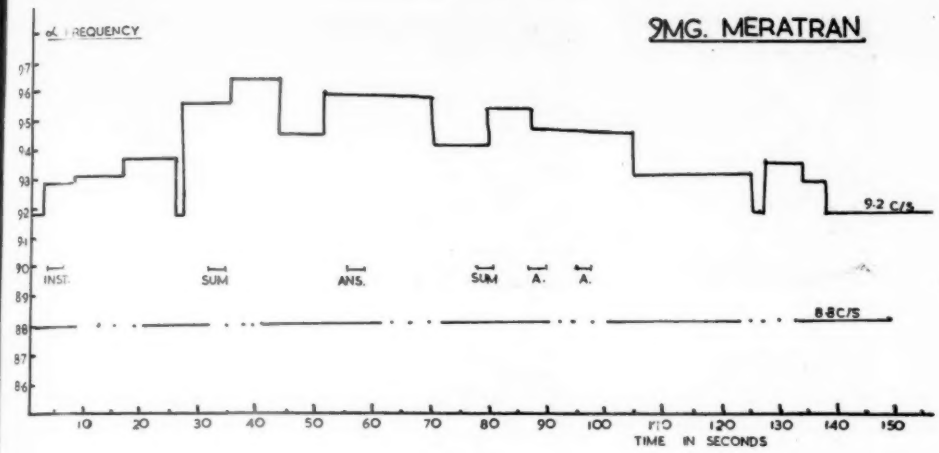

FIG. 5C.

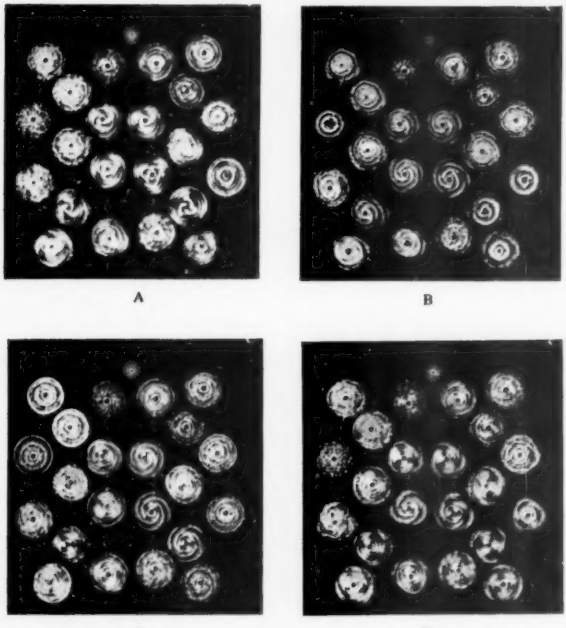
In order to exhibit these changes in alpha frequency in a more conventional manner, a graph has been plotted (Fig. 5A) showing the rise and fall in frequency of the alpha component in the right centro-parietal channel during this very modest mental exertion and this is compared with the frequency change on the left side where, as already remarked, there was initially total suppression of rhythmic activity.



The most striking general inference is, that in spite of the pronounced and sustained alteration in frequency, the mechanism returned ultimately to precisely the same rate of discharge as before the experiment, even to an accuracy of one part in 100. It should perhaps be said again that a change of this order would be quite inappreciable in a primary record. It is just detectable with a wave analyser, but the interpretation of such variations in spectral distribution is inevitably ambiguous.

This set of records demonstrates that, as for example in the third exposure, a single quite restricted region of the brain can remain rhythmically active when all the rest is desynchronized. As a corollary, the two hemispheres, and even adjacent regions, may display complete autonomy of frequency and responsiveness.

There can therefore be no question of a supreme central pacemaker as has been suggested from time to time to account for the approximate synchrony and symmetry of spontaneous brain rhythms; nevertheless the degree of coherence and inter-channel correlation during rest suggests there is at times an appreciable tendency for some degree of synchrony. This tendency has been found to be a highly personal character and it may well be more important in relation to mentality than measurement of average or gross frequencies, since the way in which local rhythms fall into and out of step seems to be strictly related to the dynamic aspects of mental effort.

From the standpoint of mentality, consideration of these subtle changes in alpha pattern permits detailed study of the duration and extent of various types of attention and arousal. In the subject of the foregoing illustrations simple arithmetic problems provoked an effect lasting nearly two minutes, far longer than the time taken for the solving of the problem or the appearance of any overt action.

In the other subject, a normal adult woman, similar studies yielded quite different results. This subject has resting alpha rhythms with a mean frequency of 11·6 c/s in the occipital regions as shown in Fig. 2B. Fig. 6 shows the effect of mental activity in this subject. There is first a clear *slowing* of the activity in nearly all regions, then a return to the original frequency on the left side, then a further deceleration only in the left central region. Here again the pattern of response is absolutely typical of this subject in such conditions. A curve of the alpha changes in the right occipital region is shown in Fig. 5B. The whole character of the curve is clearly different from that of the first subject; there are abrupt shifts of frequency in both directions, mainly downward during periods of mental concentration. Most of these latter changes were associated with reduction of palmar skin resistance—psycho-galvanic reflexes. These records show particularly clearly the separation of the various alpha components in terms of both frequency and distribution. In other experiments, when this subject was threatened with punishment for failure to solve problems, the alpha frequency

FIG. 6.—The effect of mental activity on alpha frequency and distribution in normal subject of Fig. 2B. A, shows the conditions during rest. B, Immediate slowing in all regions during the period of instruction. C, Desynchronization of the two hemispheres particularly in the parietal region. D, Desynchronization of the anterior and posterior regions in both hemispheres.

often *rose*, suggesting that the direction of alpha response may be a function of incentive quality.

For what it is worth—which may be little—these two subjects are very different in character. The first, who showed a sustained rise in alpha frequency, is original, speculative and persevering; the second, who displayed abrupt drops in frequency, is more receptive, conventional and erratic in her way of thinking.

As well as minute fluctuations in alpha frequency, other changes can be seen in these records. For example, in the subject of Fig. 4 an entirely new feature arose towards the end of the period of mental activity. The right frontal channel shows a component at about 3 c/s in the form of a single slow curl to the right in Fig. 4C and E; later, this component accelerated slightly (Fig. 4F) and then settled down to exactly 3 c/s (Fig. 4G). This was seen only during a period of mental activity and seemed to be associated with the return of the alpha rhythms to their resting state. It is tempting to consider this feature as an example of a restorative mechanism operating to maintain mental homeostasis.

The question naturally arises whether the fine structure of alpha responsiveness as illustrated in these cases is a permanent, unalterable feature of the electrical personality. In normal circumstances this seems to be the case. Even the most trivial details of the alpha patterns displayed by this means remain constant over a very narrow range in the same subject. None the less, by the action of certain drugs these characteristic features may be transformed or contorted. For example, the male subject of Fig. 4 was unobtrusively given a dose of 9 mg. of the drug *Meratran*, well known as an activating agent. The effect of this is shown in the graph in Fig. 5C where the changes in the alpha frequency in the right occipital region are plotted on the same scale as in Fig. 5A. These observations were made an hour after the unconscious ingestion of the drug; neither the subject nor his close associates were ever aware that he had taken it, possibly because he was very tired at the time. The effect on the alpha rhythms is clear and unequivocal as shown in the graph. There was a fairly rapid and sustained rise in mean frequency from 8·8 to just under 9·2 c/s and furthermore when requests were made to perform mental tasks as in the previous examination, the frequency changed abruptly and returned from time to time to its new resting level. The peak frequency was not greatly above that recorded during the normal period, 9·65 as compared with 9·45, but the general pattern of responsiveness was more irregular with sharp steps superimposed upon a sustained rise. It should be remarked that an alteration of this type would be only just perceptible as a long-term effect with a wave analyser, and the abrupt fluctuations in frequency would be quite undetectable even with this aid.

As another example of the action of drugs, the subject of Fig. 6 volunteered to take 100 micrograms of the hallucinatory drug LSD 25. During the action of the drug she reported vivid visual hallucinations for about four hours, but her personality remained unclouded and unperturbed, with only a minor persistent depression. In this case the effect of the drug, as reported by others, was again to raise the average frequency of alpha rhythms from a mea

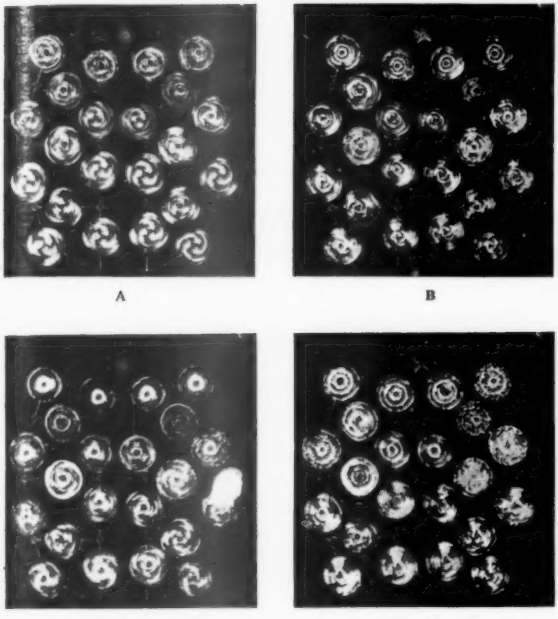

FIG. 7.—The effect on alpha frequency distribution of 100 gamma of LSD 25 in the normal subject of Fig. 6. A, Normal conditions before ingestion of drug. B, Comparison of normal alpha rhythms and flicker response. C, Acceleration of alpha frequency from 11·6–12·7 c/s and desynchronization of adjacent regions in the left hemisphere. D, Flicker responses evoked during action of drug.

of 11·6 to 12·7, which is considerably higher than the top frequency reached momentarily during mental activity in the normal state. Apart from this clear change in average frequency, there is a very marked alteration in the distribution and concordance of the various activities. In the normal state illustrated in Fig. 7A, the 11·6 c/s rhythm is everywhere synchronous and, in fact, the details of the various patterns are remarkably similar, even as far as the anterior frontal regions. Under the action of the LSD, however, the precise frequencies are quite different even in adjacent regions (Fig. 7C). For example, in the left occipital derivations, the parieto-occipital channel shows a clockwise curl indicating that the frequency is about 12·5 c/s whereas the near-by temporo-occipital channel shows a counter-clockwise curl indicating a frequency of about 12·8 c/s. This effect was observed during the greater part of the period of drug action and seemed to coincide with the phase of maximum hallucination. It does not seem unreasonable to suppose that this degree of disintegration in a subject whose alpha rhythms are normally closely synchronized may reflect a state of mind in which exogenous and endogenous stimuli are unusually dissociated. In Fig. 7B and D are examples of the effect of LSD 25 on the responses evoked by pattern flicker in the same subject.

These brief sketches from a physiologist's notebook are not intended to suggest that we are approaching anything like comprehension of the mechanics of mentality—they are merely illustrations of the evidence already to hand that there exist in the brain mechanisms which have that degree of order and consistency which we habitually associate with machines.

Earlier on, I pointed out the importance of "timing" in a mechanism such as we postulate in the brain. The extreme regularity and stability of the alpha processes in the subjects we have studied—and their subtle variations during thinking—suggest that there is here available a mechanism for preserving and comparing the sequence of events in time. Our present work is directed to investigating how these mechanisms operate during the course of learning and forgetting in human subjects. Such a study is unavoidably lengthy and elaborate, but there is already reason to hope that within a few years we shall be able to formulate a more detailed specification of brains as machines.

The observations reported here are the outcome of technical research and development by my colleagues, Mr. Harold Shipton and Dr. Raymond Cooper. It is a pleasure to acknowledge my gratitude to them and also to my friends who have acted as very patient subjects in these experiments.

Dr. W. Ross Ashby: Until a few years ago we all thought we knew what we meant by a "machine"; our experiences with the alarm-clock and the typewriter seemed to provide an adequate basis for considering what a machine could or could not do. As a result, we tended to expect that no machine could do the complex and subtle things that the brain does. Whenever some mechanism was produced that did something brain-like we were surprised.

Those days are gone. To-day it is known that if any action or form of behaviour can be unambiguously specified, then there is undoubtedly a mechanism that can do it. For to-day there exists a well-defined routine by which the specification of the behaviour can be re-coded into the specification of a machine that will produce it.

To illustrate this fact, and to make the statement a little more convincing, I have here (Dr. Ashby demonstrated the machine to the meeting) a simple machine that can be so used to provide any demanded behaviour, provided that the behaviour is objectively defined and that it does not exceed the machine's capacity in size. I have chosen three forms of behaviour for demonstration. The machine is controlled by switches, which form its "input", and displays its behaviour on a row of lamps, which light and go out.

The first behaviour is simply the pupillary reflex. When a switch is closed (to represent "light shining into the eye"), the lamps light in succession from left to right, representing the movement of one edge of the iris towards the centre. When the switch is opened, the lamps unlight in reverse order. In this example the "contraction" is sustained as long as the switch is closed.

A second demonstration (after change of some linkages) shows the same reflex when the contraction is not sustained. Closure of the switch results in the lamps lighting across from left to right as before, but the lighting is not sustained, and one by one the lamps go back, from right to left, into the unlit state even though the switch is kept closed. Keeping the switch closed gives no further action. If, however, the switch is opened (representing "light no longer shining into the eye") and then re-closed, the "reflex" will appear again, but again fail to be sustained.

A third demonstration showed a behaviour with "memory". Before the switch is closed, nothing happens on the lamps. When the switch is closed, again nothing happens. The switch can then be opened again (i.e. the "stimulus" removed) and still nothing happens; but later, after a definite period of delay, the lamps light and show a characteristic (arbitrary) piece of behaviour.

These demonstrations *prove* nothing, but they illustrate the fact that the modern logic of mechanism (Ashby, 1956) is able to handle questions of the relation between structure and function with a completeness impossible ten years ago.

Dr. D. M. MacKay: I should like to make a general remark on the limited usefulness of conventional quantitative mathematics in the theory of the nervous system, for I feel that Dr. Grey Walter may have been unduly apologetic in disclaiming an understanding of it. There are of course quantitative questions, concerning the information-capacity of a synaptic link or of a receptor organ, for example, to which one seeks numerical as well as qualitative answers. But I believe that the bulk of questions of psychiatric interest are organizational ones, demanding precise expression not in numerical terms but in the qualitative language of information-system theory.

The importance of this language lies, I think, in its ability to serve as a link between psychological concepts on the one hand and physiological concepts on the other. Hypotheses framed in terms of information-flow can, in principle, have implications—and so be tested—at both the psychological and the physiological level. With the development of even a skeleton "information-flow-map" of the nervous system, data expressed in the one language could begin to suggest hypotheses in the other (MacKay, 1954), so increasing the efficiency of diagnostic tests, and by the same token refining progressively the flow-map itself. What I am suggesting is quite different from the construction of a working model; for to those who understand a theoretical map a model shows little, while to those who do not, it often seems to show more than it should.

My point is that for the understanding of the general principles of such "maps" no high-powered mathematical training is required. The concepts involved (information-flow, control, selection, suppression, and the like) are more akin to those of administrative organization than to those of algebra. Inevitably, the "higher reaches" of this discipline, like any other, have their sophisticated techniques, and there is no royal road to their mastery. But I think it important to disclaim, as a theorist, any suggestion that psychiatrists lacking conventional mathematical training must find the theory of brain organization inscrutable, and must look to demonstrations by electronic "black boxes" as a less inscrutable substitute for understanding.

MACKAY, D. M. (1954) *Advanc. Sci., Lond.*, **10**, 402.

Dr. F. H. George: The importance of the models which have been discussed lies largely in their value as research tools. They are more useful to some than to others; I myself think there is a great deal to be said for the use of mathematical models. Certainly they would easily include the sort of models so far built in hardware. I emphasize this only to try and avoid any false impression at a time when mathematical biology is rapidly coming of age.

I would also like to emphasize that I believe that discussions on whether or not machines can be made to think are liable to prove fruitless.

Section of General Practice

President—JOHN H. HUNT, M.A., D.M.

[*March* 20, 1957]

DISCUSSION ON COMMON CONGENITAL ABNORMALITIES AND THEIR MANAGEMENT IN GENERAL PRACTICE

Dr. Lindsey W. Batten: It is unlikely, but not inconceivable, that in England, even in London, and in 1957, a family doctor might conduct a confinement. Imagine yourself present at such an event.

Suppose the young mother has disdained anything stronger than pethidine, has endured the first stage, played her full part in the second and is now expelling her baby.

Out comes the head; the babe screws and unscrews its face, opens its mouth, utters its birth-cry and turns pink. Shoulders and body follow; the crying and the pinkness continue and four limbs move vigorously. What may now happen is this: our doctor clamps, ties and cuts the cord, glances at the genitalia, picks up the child and holds the little thing—vernix, caput and all—before its mother's delighted eye. "There, madam," he says, "you've got a fine boy."

The triumphant mother's womb contracts and expels the placenta. No post-partum hæmorrhage for her. Something provocative of lactation may happen in her breasts. In any case she "remembereth no more the anguish" but goes to sleep happy, confident and ready to repeat her admirable performance at some not too distant date.

Every instinct in me applauds the doctor's action—simple, direct, unevasive, humane and in tune with the physiological conception of childbirth and with our growing understanding of the psyche-soma partnership. And yet, in its implications, how careless of truth and how supremely imprudent! "Here, madam," the prudent and truthful doctor would say, "is the principal product of your conception. His genitalia are those of a boy; his heart and lungs are efficient enough to oxygenate his blood and to supply air-pressure for crying and his neuromuscular system is good enough for making faces, shouting and moving limbs. He does not look like a cretin, mongol or microcephalic but I cannot, at present, tell you whether he will ever see, hear, or display normal intelligence, whether his cardiac septum is complete, his aorta of normal calibre, and his ductus arteriosus closed or closing; whether his many tubes or ducts are pervious and properly connected; whether the femoral heads are in their cups or even, now I come to think of it, whether he has webbed toes or a gap in his palate. In fact he carries no guarantee of sound materials or good workmanship. Whatever his defects, they are no fault of mine so, if you are prepared to accept delivery on these terms, will you be good enough to sign this form of disclaimer?"

But there are limits, I think, to prudence and veracity no less than to light-hearted shutting of eyes. Like good Englishmen we shall compromise. "Here is your baby, madam, very much alive and looking fine, but I haven't examined him yet in detail and there may be imperfections. Have some tea and go to sleep. I'll tell you all about him when you wake up."

A mother who is worthy to be shown her just-delivered offspring should accept this easily enough and we must then turn to a purposive and well-directed examination to discover or exclude whatever abnormalities can be discovered or excluded at this stage.

Should he find any congenital defects how is he as a General Practitioner to manage these? Management presumably includes whatever prophylactic measures may be open to us.

I would suggest that there are three ætiological classes: the Bad Seed, the Damaged Embryo and the Pressure Group, with radioactive particles as a possible *causa causans* in classes one and two. In a free community and with our limited knowledge we cannot as a rule do much about bad seed, though it does fall to us as family doctors to stand between our younger patients and needless exposure to X-rays. At a recent post-graduate lecture

there was mention of a young woman who at 28 had had 23 X-ray investigations, chiefly, I think, abdominal, Such a patient's family doctor is surely the man to protect her, thinking, if no one else does, of the children she may hope to bear. Apart from this, we should be aware of the broad facts concerning familial disease and inherited defects and should be ready to advise.

Much more can be done to protect the embryo threatened by two malign influences—X-rays and rubella. A beautifully illustrated article in a clinical journal lists 13 "indications for inviting radiological examination" in pregnancy. They include verification of pregnancy at the 10th or 12th week, estimation of the placental site, and of fœtal maturity and, of course, pelvimetry so that, simply in order to "make sure", a healthy mother and her embryo and fœtus might be subjected to several considerable doses of X-ray in a single normal pregnancy. Strangest of all, a history of previous abnormal fœtuses is held to invite radiological examination. The writer mentions and discounts any risk of inducing cancer or leukæmia in the fœtus but makes no mention of the mother's future children or grandchildren or of the development of the embryo. If such investigations were proposed for a patient of mine without very weighty cause I should fall badly short if I failed to mention risks and counsel caution.

Rubella, to quote Alexander Joe, is an illness "with but little morbidity and no mortality" said to confer a solid and lasting immunity—in fact an innocent disease of childhood; yet a deadly foe of the developing embryo, responsible for some of the most horrible congenital defects—involving cochlea, labyrinth, eye, heart and brain—and almost certain to leave its mark if contracted by the mother in the first two months of pregnancy. "Many children," to quote Joe again, "escape the disease which is commonly contracted in adult life from the second to the fourth decade".

Knowing all this, how can we look on with equanimity while parents and at least some schools, impose quarantine for rubella on young children? Must we not put it diligently about that every female child should be set in the way of rubella at every opportunity until she gets it? A campaign by the public health authorities to this effect seems to be overdue, and the family doctor should raise his voice. Research might then provide us with the means to give rubella to every small girl in our practices, or to provide an anti-rubella vaccine or female children.

If a wife of child-bearing age, not immune to rubella, is exposed to it I think we must warn her of the risks of conceiving, giving her all the contraceptive help she may need, and if there seems the slightest risk of actual pregnancy, administer the necessary dose of gamma globulin. If she is not pregnant we should invite her to acquire the immunity while she has the chance.

Confronted by actual rubella in early pregnancy we cannot remain silent. We must declare the risks, perhaps first to the husband but probably best to husband and wife together. We should be ready with our facts. Broadly, the truth seems to be that in the first two months the danger to the baby, both qualitative and quantitative, is very great. The cochlea may still be injured in the third month. So great is the reported risk in at least the first two months that the question of terminating the pregnancy must inevitably arise. Carruthers, quoted by Banks in Garrod *et al.* (1953) states that "after the third month the probability of congenital malformations becomes remote" and we must not forget to say so. Perhaps we should not be too certain that the rubella virus is the only one that can play this fiendish trick. We should at least not erect barriers between the young child and mumps.

Some prophylaxis, then, is possible for the "Bad Seeds" and "Damaged Embryos"; can anything comparable be done for the "Pressure Group"?

Of the existence of this group there is no question. The general idea is not new. You may remember than when Mirabell, in "The Way of the World", puts up counter-conditions to those under which Millament is prepared to "dwindle into a wife" he says: "*Item*, when you shall be breeding—which may be presumed with a blessing on our endeavour—I denounce against all strait lacing, squeezing for a shape, till you would mould my boy's head like a sugar-loaf; and instead of a man-child, make me father to a crooked-billet." We need no Mirabell now. External pressure, if it ever was a factor, is gone long ago but the group is with us still. Eden (1906) said "moving freely in his bath of liquor amnii the fœtus thus takes exercise". What goes wrong in these cases? Clearly some disproportion between bath and occupant, but "oligohydramnios" is an unsatisfying explanation. Is the volume of the bath determined by the tone of its walls or by the volume or pressure of the water? Is there a natural device for adapting the bath's capacity to its occupant's size? Or is the little thing a sluggard, who lies there just growing until he finds himself woebound? Are the answers known? Must we remain quite impotent? Are physiotherapy, maternal diet, fœtal manipulation or stimulation or perhaps injection of hypertonic saline into the bath all quite useless? Here, surely, is at least a field for research, and possibly one for ante-natal measures in the home.

Our duty is to detect and identify the abnormalities as early and as precisely as we can and then take the right action which, when they are "palpable and visible", will generally be to know the right man for the job, consult with him and guide patient and parents in the right way.

Our responsibility—and, with it, our anxiety—will be greater with the invisible, impalpable defects, of which deafness and mental defect are outstanding examples. Blindness and "congenital heart" fall into the same category.

Except, perhaps, for mental defect, such vast advances in treatment, direct or compensatory, have been made in recent years that it has become correspondingly more important to find the defects early, to declare them when found and—what is peculiarly the family doctor's job—to make sure that everyone concerned does the utmost possible for the afflicted child.

Congenital deafness is a striking example of a condition in which mother and family doctor should work out the diagnosis together, in which, if they do this early, they can take the first vital steps in treatment and in the management of which they should continue in partnership for years. Expert help, if obtainable, will be of very great value but much can be accomplished without it. Special diagnostic apparatus is not essential and there is no place for surgery or medicaments.

We have two vital tasks: to detect the deafness early—in babyhood rather than infancy, and to enlist the mother's all-important aid. No neo-natal examination can reveal congenital deafness. There are no physical signs, and whereas the appearance and movements of a baby's eyes give news of their functional ability long before he can say "I see", his ears give nothing away.

Everyone watches the eyes for evidences of sight; it is useless to watch the ears for evidences of hearing; this is, therefore, apt to be taken for granted. We should not forget it, or mistake response to sight, vibration or movement of air for response to sound. Often enough deafness is not even suspected until the infant fails to speak, perhaps not even then. "Backwardness" is apt to be thought of first.

The sign that a baby *sees*—in the full sense of the word—is that he looks at and shows recognition or appreciation of the target of his looking; the sign of *hearing* is that he turns towards and reacts to a significant sound whose source he cannot see. Testing-sounds should be soft—a quiet, familiar voice, a food-preparing sound—the tap of a spoon against cup or feeding bottle—and in our general examination of a four or six months baby we should test the hearing in this way, as we test the sight with a toy, torch, handkerchief or familiar face. A single, unmistakable response is proof of hearing but if there is none we must be patient and test further with bell, drum, rattle, pitch-pipe, mouth organ or whatever we have, not forgetting that a sensible babe will see no point in vain repetitions but will get bored and disregard our pranks. We must have patience and continue when he feels fresh again, until we can form a reasonable estimate of his hearing. If he is indeed deaf then it is our special province to persuade his parents to accept whatever is proven fact—but no more. All is not lost, neither has this babe sinned nor his parents—it is no one's fault, and we can tell them with confidence that almost certainly some hearing is present, because it almost always *is*, though none may be immediately detectable. They must have faith and act on it, not by collecting a dozen "independent opinions" or by looking for surgical, medicinal, electrical or manipulative *cures* but by seeking and obtaining expert auditory training as soon as it can be had and above all by talking to the babe. They must talk distinctly, repetitively and often, casting the bread of words and phrases on the waters to find it in the child's speech after many days. There is, I understand, no substitute for the mother's voice, speaking into the ear at the acceptable time, which ends at 3 years old.

Wonders are done in cultivating and expanding the islands of hearing many of these children possess. In modern auditory training centres the deaf are taught to *hear*.

I have dwelt on deafness not from any special knowledge but because it illustrates so well the tasks that fall to the family doctor when any congenital defect, especially one not medically or surgically curable, falls from the sky into a family under his care. It is a taxing but rewarding task and it is our own.

Eden, T. W. (1906) Manual of Midwifery. 1st Ed. London.

Garrod, A. E., Batten, F. E., and Thursfield, H. (1953) Diseases of Children. 5th Ed. London.

Dr. G. B. Mitchell-Heggs: It is difficult to know where "common" ends and "uncommon" begins when discussing abnormalities. "Uncommon" in general practice may mean fairly common in certain hospital skin departments, although rare in others. I noted a considerable difference in the incidence of certain disorders when working at the Royal

Berkshire Hospital, Reading, typical of a county town and country practice, as compared with St. Mary's and St. John's Hospitals, in London. Ringworm of the scalp and body, for instance, was more common at the former. Indeed, as far as the skin is concerned, there are no common congenital abnormalities apart from the nævus or, more strictly speaking, birth-mark group, with maybe ichthyosis thrown in for good measure.

Congenital disorders of the skin thus include the following: All types of nævi, that is to say, those which are abnormalities of the blood supply, which include nævus araneus, port-wine stain and the strawberry nævus; nævi in which the pigment cells are involved, that is, pigmented moles and melanomata and also junction nævi; those in which the epidermis is involved, or a combination of epidermis and dermis, in the verrucose or linear nævus. Urticaria pigmentosa may be described as nævus with mast cells in the corium and pigment cells in the basal layer of the epithelium.

Next are abnormalities of the epidermis; these are to be found essentially in babies in whom the sweat or sebaceous glands are not working adequately; it is rare to find a newborn child whose skin is working to excess with over-production of sweat or grease. On the other hand, an abnormal degree of dryness of the skin is not uncommon. In extreme cases, this can result in the condition known as ichthyosis fœtalis gravior.

In this group, therefore, there are all degrees from simple dryness or xeroderma to a marked scaling and bran-like appearance or ichthyosis (Fig. 1). Over-activity of the epithelium

FIG. 1.—Ichthyosis.

FIG. 2.—Vascular nævus.

round the hair follicles may lead to keratosis pilaris, and finally excessive production of horny tissue in the palms and soles results in keratosis palmaris et plantaris or congenital tylosis. A severe exfoliative disorder which occasionally occurs in nursing children is erythroderma desquamativum. It may be accompanied by constitutional symptoms and is generally fatal.

The next group of congenital abnormalities includes those in which there is a late or abnormal development of hair or nails, for which there is usually little one can do. Examples of these fortunately uncommon disorders include: monilethrix where the hair is sparse and brittle, with associated poor nail development, pachyonychia congenita, and congenital ectodermal defect.

Acquired infections that are of any significance are minimal, but it is important to mention congenital syphilis. As far as my department and private practice are concerned syphilitic babies have, practically speaking, disappeared, thanks no doubt to the excellent work done in general practice or in the Welfare, Maternity and other clinics.

So far as vascular nævi are concerned, there is considerable proof that the ordinary strawberry nævus tends to disappear with age, as we see so very few in children over the age of 5 or 6. On the other hand, those we do see give rise to considerable alarm among parents and relatives. Reassurance by the general practitioner or dermatologist is often not so convincing to them as a story that some baby had a nævus which started to bleed, and that no one could stop the bleeding.

In addition, babies are often brought because these vascular nævi are growing very rapidly. The mother has noticed that that particular part of the baby's body is unusually hot, and when the doctor sees it, he notices that a further growth of the lesion may cause other trouble. In other words, one round the mouth may interfere with suckling (Fig. 2), near the anus or vulva with defæcation or micturition, or near the eye, with vision.

In all such cases, if there is any doubt at all, it is important for the child to be seen by a specialist as soon as possible, and he is likely to recommend one of the following courses: (1) Further observation and no action. (2) Reference to a surgeon, for excision. (3) Reference to a radiotherapist. (4) The use of certain well-established procedures: (*a*) Injection

of sclerosing agents is often effective and fairly safe. (*b*) The carbon-dioxide snow stick, though first introduced over fifty years ago, can still produce satisfactory results.

It is important, however, that before these procedures are used, the surgeon or radiotherapist should be consulted, lest he feels that such preliminary treatment diminishes the ultimate chance of 100% success for his treatment.

So far as small fibro-cellular or pigmented moles are concerned, usually no action is required, unless they are more than a millimetre in diameter, or in a conspicuous situation likely to affect the child's beauty, or in a site where they are likely to be injured and possibly undergo malignant change. The removal of small moles is a normal procedure for most dermatologists or general surgeons, although large moles of this kind should usually be treated by a plastic surgeon.

Port-wine stains are often widespread, and such cases form one of the most disappointing groups of patients attending our out-patient departments. Over the years, I have tried reference to a plastic surgeon, used carbon-dioxide snow, combination of carbon dioxide with acetone, thorium X, soft X-rays, and so on, but the proportion of successes has been very small. It is just possible that with the passage of years, dermabrasion may prove helpful in a number of cases. So far, all treatments tend to lead to scarring, which may be worse than the original blemish. A very large proportion of the patients have half of the forehead, nose, cheek and chin involved, and some an upper limb (two patients of mine have involvement of half the body surface), thus very little treatment is practicable and safe for such cases.

Spider nævi do not usually disappear, but respond very well to treatment with electrolysis or actual cautery. Occasionally even carbolic acid applied on the pointed end of a matchstick produces quite satisfactory results, although I would not recommend this approach for lesions on the face or neck.

A considerable proportion of babies with ichthyosis tend to develop endogenous eczema and, in adult life, contact dermatitis. The general practitioner can do a great deal for the baby suffering from this disorder as, with proper care and prophylaxis, he may never become a patient suffering from eczema and dermatitis. When the skin is not active, as in the winter in cold climates, bathing with water must be limited to sponging the armpits, groin and feet, and the rest of the body massaged gently with an inert preparation such as arachis oil, olive oil, or a mixture of these with glycerin, anhydrous lanoline or vanishing cream base, &c. There is great value in adequate but not prolonged or excessive doses of vitamins A, B, C, and D for keeping the skin healthy.

Bath water can be softened by the use of bran with 3% emulsifying wax in water. In the summer these precautions are less necessary. Unless the skin is cracked and raw, do not discourage paddling or bathing when the age and opportunity arrive.

If the child with such a skin becomes fractious, rubbing his hands on legs or face, it is very important to ensure adequate sleep and sedation. If it is obvious that an eczematous reaction is starting, relieve irritation by the use of weak anti-pruritic sedative lotions, or tar and lead lotions. Various hydrocortisone preparations have proved to be a boon in many cases. Here it is a matter of experimenting with different types of bases and solutions. Dermatologists are constantly giving clinical trials to new mixtures. In certain cases, general ultraviolet light therapy, extra vitamin D, and so on, are certainly beneficial, and in others, addition of the vitamin B group to this seems to help. Always remember the danger of too frequent change of medicament, or too strong an anti-pruritic. Again, discourage vigorous cleansing of the skin with oil to remove ointment or picking of adherent crusts, as such over-enthusiastic treatment may prolong the disorder.

Assessment of the value of these procedures is extremely difficult because, as the child grows older, the endocrine glands take on their separate roles, the mind is more occupied by schooling or the influence of other children and sometimes the skin improves without any treatment, as one can see from comparatively neglected children seen in out-patient departments.

The rarity of certain disorders tends to make us less "aware" and alters the threshold level of diagnosis so it is wise to record at once "unusual" even though not diagnosable. Such clinical honesty often pays a dividend.

It is well to be suspicious of a child who appeared perfectly healthy at birth and who develops a measly rash, fractiousness and runny nose in association with loss of weight, as further investigation may reveal that the child is suffering from congenital syphilis. The nasal discharge may be hæmorrhagic, or again, the child's skin may be shrivelled and greyish with bullæ on palms and soles. At a later stage, the picture follows that of syphilis in adult life, with the gradual development of infiltrated lesions on the palms and soles, coppery rash and so on.

It has been pointed out to me by one of my clinical assistants that frequently we have to decide if patients with a skin disease can be inoculated or vaccinated and with what risk.

The majority of such patients can be vaccinated, but make an exception of those where an active eczematous eruption is present. There is no doubt that vaccination has acted as a trigger factor in the development of eczematous eruptions in certain patients. If an active eruption has subsided it is a question of where they are going to live, and whether quick vaccination can be procured if cases of smallpox occur in their district. They cannot postpone vaccination if they are proposing to proceed to Africa or other countries where smallpox is very common.

Mr. D. N. Matthews: The surgical management of many congenital malformations is the responsibility of the plastic surgeon, and it is essential that there should be close liaison between him and the general practitioner. The arrival of a malformed child in a family creates at once psychological and emotional problems for the parents and the other children. Similar problems confront the affected child as it grows older.

In the parents there is often a sense of guilt and shame, which can be dispelled by simple, patient explanation of what can be done, the right age at which to do it, the time it will take, and the scope and limitations of treatment. The sooner the parents receive this help the less will be their distress. The plastic surgeon should, therefore, see the child as soon as possible, and formulate as complete a plan of treatment as is practicable. He must also consult with the general practitioner, who will inevitably be asked many questions by the parents, no matter how carefully the specialist explains matters. Older children will benefit greatly if they are treated in the same way; their confidence and co-operation are gained at once. In formulating the plan, the plastic surgeon must take into account the harm done to the child by prolonged separation from its parents, and the increased difficulty such separation may cause the parents and the other children in accepting the deformed infant back into the home if normality cannot be fully restored. He must also pay attention to the added handicap the child will suffer if education is seriously interrupted, and should bear in mind the aid which other departments can offer. The Child Guidance Clinic, the Almoner, the special educational facilities at the disposal of the local health authority and the Probation Officer may all have important parts to play in adjusting the child through adolescence to adult society. But above all others, the general practitioner has the greatest influence in bringing the child and the rest of the family safely and happily through these difficulties.

The problems commonly confronting the plastic surgeon include clefts of lip and palate, birth-marks, moles, deformed ears and hands, ptosis and genital deformities. Each can only be touched on briefly in a general résumé of the subject.

Cleft lip and palate.—Clefts of the lip are repaired at about the age of 3 months, and necessitate ten days of hospital care. If the palate is cleft as well, the anterior part and the nostril floor are repaired at the same time. The rest of the palate, or the whole palate if the lip is intact, is usually repaired at the age of 15 months and necessitates between two and three weeks in hospital. In most cases, the primary repair of the lip is permanently acceptable, but in some cases revision of the scar, perfection of the cupid's bow or adjustment of the nose tip or alar cartilage are needed (Fig. 1A, B). These soft tissue corrections

A B

FIG. 1.—Secondary correction of hare-lip deformity: elevation of the nose tip.

can be made at the age of 3½ years, thus giving ample time for scar lines to fade before school age. The corrections rarely need more than one operation in all, and necessitate hospitalization for two weeks. In complete bilateral clefts, fullness may have to be added to a tight upper lip and is provided by the over-full lower. This can be done any time over

the age of 4 and takes about a month to do. If the bony framework of the nose is deformed, there are advantages to be gained by leaving this until the nose is fairly fully grown to avoid subsequent retardation. 12 to 14 years of age, depending on the size of the child, is satisfactory, and the procedure, which is similar to a corrective cosmetic rhinoplasty, takes two weeks.

If speech is not developing satisfactorily by the age of 8, improvement can be made in suitable cases by an operation on the pharynx (pharyngoplasty). This necessitates about two weeks of hospitalization. It is after such operations that the speech therapist is of the greatest help. Finally the orthodontist has a most important part to play in all clefts of the palate by assisting the expansion of the maxilla with spring-loaded appliances between the ages of 7 and 14.

Birth-marks.—These are red marks in the skin. They occur more commonly on the head and neck than elsewhere, and are of several different clinical types. The flat pink capillary lesion is the most likely to fade spontaneously and can be safely watched unless it is growing out of proportion to the overall growth of the child. The first sign of fading is usually the appearance of scattered white areas in it. These gradually extend and coalesce. If such a lesion fails to fade, it can be made to do so in most instances by surface applications of beta rays exhibited either as isotopes or as a radium plaque, or by carbon-dioxide snow. Raised cavernous lesions, which can be squashed flat by pressure, are more serious since they can grow with great rapidity and become formidable operative problems; if therefore they are progressing or fail to begin to regress after being stationary for a few months, they should be treated as emergencies. Shrinkage can frequently be induced by the injection of sclerosing agents such as saturated saline or by interstitial diathermy or a combination of the two. Great care must be exercised when using saline or a slough can easily be caused. Sclerosis may avoid the necessity for any operation, and will always reduce its magnitude. Treatment of these lesions can be begun safely in very young infants, and delay on account of age is wrong. It is nearly always possible to formulate a complete plan of treatment as soon as it is decided that action needs to be taken. Pulsating arterial lesions always need surgical excision.

Moles.—Pigmented lesions can only be satisfactorily treated surgically. Their removal is requested on cosmetic grounds or for fear of malignancy. Whilst it is true to say that malignancy in childhood is excessively rare, it is impossible to deny the possibility of malignant change in adult life. A request for removal on this ground is nearly always founded on a known tragedy in an adult, and it is unwise to refuse it. The technical requirement will be decided by the site and size of the lesion, and will vary from simple excision and suture to elaborate plastic repair. There is no evidence to support the fear that interference may promote malignancy.

Deformed ears.—The simplest deformity is an accessory auricle. It can be removed under brief anæsthesia in early infancy, and necessitates at most one night in hospital. There is nearly always a small cartilaginous element beneath the skin nodule, which must be taken away as well to prevent its subsequent growth.

Bat ears are the commonest of the deformities of the auricle, and are satisfactorily treated at 4 years or any age after this. The operation is done from behind the ear and necessitates ten days in hospital (Fig. 2A and B). Attempts at correction by positioning the infant in

A B

FIG. 2.—Bat ears. Correction by modelling the cartilages through a post-auricular incision.

the pram or by wearing a close-fitting cap are useless. The deformity often has a profound psychological effect on a school child, particularly a boy, and is well worth correcting.

Absence of the pinna presents a complicated problem of reconstruction, and no matter what is done, the result will fall short of perfection. It is well worth doing, however, particularly in a boy. It necessitates four or five operations. The interval between the first and the second should be two months as a minimum. The second, third and fourth stages are done consecutively and take nine weeks in all. The fifth takes two weeks and can be done a month after the fourth. In bilateral cases, it may be desirable to fenestrate one side to assist hearing. In girls a smaller procedure to provide the lower half of the pinna can be done in two stages.

Deformities of the hand.—These are of an infinite variety, and a plan has to be worked out for each. There are many for which little can be done. The primary concern must always be to improve function. Improvements in appearance are secondary to this. Appearance can often be helped by fitting a prosthesis worn as a dress hand on special occasions, but this should not be done until the child becomes self-conscious and asks for some disguise. In early childhood, it is imperative that the parents overcome their natural inclination to hide the deformity and encourage the child to use the hand as fully as possible. It is remarkable how little limitation quite a serious deformity ultimately imposes on the child if the problem is approached in this way. Little can be done surgically until the child is at least 3, and treatment may have to be postponed longer still to allow bony growth to occur.

Simple deformities, such as syndactyly, are readily amenable to surgery and are best tackled when the child is about 4. One or two operations may be needed, each necessitating a fortnight in hospital.

Ptosis.—Congenital ptosis may be unilateral or bilateral, partial or complete. Most cases show some improvement up to the age of 2 years. All show temporary deterioration through childhood during illness, fatigue or emotional stress. It is best to wait before repairing the deformity until the child is 2 years old. Operation is successful at any age after this. In bilateral complete cases, the child is virtually blinded by the lids, and interference is necessary when the child starts sitting up, but in this event a further secondary procedure is often required at 2 years. The results of surgery are excellent. The operation is performed from inside the upper lids and in bilateral cases is best done in two stages. Each stage necessitates ten days' hospitalization and the two can be done at one admission, totalling three weeks. The epicanthic fold, which often accompanies ptosis, is repaired at the same operation.

Genital deformities.—Hypospadias is the commonest and is not accompanied by incontinence, no matter how far back the opening is placed. It is best, therefore, to wait for normal continence to develop before operating. The repair is made in two stages, each taking about a fortnight with a minimum interval of three months between them. Treatment is usually undertaken when the child is between 2 and 3 years old.

Epispadias is more serious since in many cases it is accompanied by lack of sphincter control. When the deformity extends upwards from the urethra to the abdomen, the condition of ectopia vesicæ results. Epispadias is a lesser degree of the same malformation. In some a reasonable amount of control can be achieved, but in the larger and longer clefts, as in ectopia vesicæ, it is often impossible. Much work has been done and some progress made towards solving the technical problems which this deformity presents, but in many cases ureteric transplantation into the colon is still the best procedure.

The ectopic opening of the anus into the posterior vaginal wall, which is a commoner malformation than might be supposed, can be corrected with good sphincteric control in most cases.

[*April* 30, 1957]

DISCUSSION ON AORTIC STENOSIS

Dr. Raymond Daley:

Little advance has been made in the basic understanding of naturally acquired valvular disease since the classical observations of Corrigan in 1832, who described the dynamics of regurgitation, and of Hope in 1835, who noted "the small, weak arterial pulse of aortic stenosis while the heart is giving a violent impulse".

The ætiology of aortic stenosis is often not clear either on clinical or histological grounds. It is a pity that some writings in the past have been so dogmatic in stating that juvenile rheumatism is the cause of the lesion in almost every patient. Congenital aortic stenosis is an important disease with considerable possibilities of surgical improvement. I believe that a number of patients suffer from arteriosclerotic stenosis and there are, of course, a few rare causes such as fibro-elastosis. The historical evidence of rheumatism or chorea in 50 of our patients is less than 50% but a history of rheumatism is a little more common in females than in males. At post-mortem 20 patients had rheumatic aortic stenosis, 6 had congenital lesions, but in 24 it was not possible to give a firm ætiological diagnosis.

Leonardo da Vinci (1513) was the first to show the normal aortic valve opened to give a triangular orifice.

McMillan (1955), working in our Department at St. Thomas's Hospital, has studied a number of fresh post-mortem aortic valves by cinematography. He has shown that as long as the free borders of the cusps are mobile and shut well there may be considerable calcification in the peripheral parts of the cusps and walls of the sinuses of Valsalva without limitation of flow in the valve area. Some fusion of the peripheral parts of the commissures can occur without causing symptoms. Out of 30 specimens studied the shape of the orifice could be roughly divided into certain groups which are:

(i) Early peripheral fusion with good function centrally (3 cases).
(ii) Peripheral calcification not affecting function (1 case).
(iii) Fusion of one commissure (14 cases).
(iv) Partial or complete fusion of two commissures (5 cases).
(v) Partial or complete fusion of three commissures, often with incompetence, and
(vi) Cone-shaped valve with an ellipsoid orifice at the apex, and no sign of former commissures.

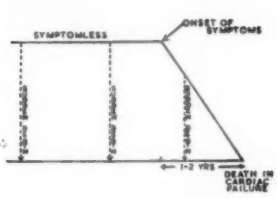

FIG. 1A.—Aortic stenosis.

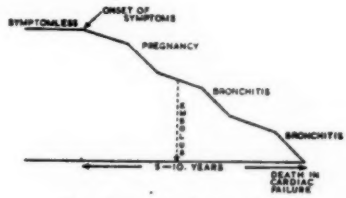

FIG. 1B.—Mitral stenosis.

The life-history of the disease differs significantly from that in patients suffering from mitral stenosis (Fig. 1). The patient is more likely to be male, and in his late forties. He is unlikely to have had serious symptoms for a long time. Once they have developed the first hospital admission may well be the last. Grant (1933) has studied the after-histories

of 43 men with aortic stenosis and incompetence for ten years. 15 died during this time. Two of the most striking features are the considerable liability to sudden death and the comparative rarity of auricular fibrillation.

Apart from left ventricular failure the two most interesting symptoms of aortic stenosis are effort syncope and angina pectoris. Angina occurs in about half the patients and is particularly prevalent in young women. The cause of the pain seems to be quite clear. Left ventricular work is greatly increased, the mean coronary filling pressure reduced, the cardiac output fairly small and fixed, and diastole is shortened. I think that it is a little unnecessary to invoke a sucking action at the coronary ostia due to the jet of blood entering a dilated ascending aorta.

The mechanism of effort syncope is not clear. I doubt if it is due to an arrhythmia, although presumably ventricular fibrillation is the cause of sudden death. Syncope can be initiated by emotion, effort and heat in anyone with a fixed cardiac output. Although the blood flow tends to be low and rather fixed, effort syncope is uncommon in mitral stenosis and hypertensive heart failure, because the blood pressure does not fall. In the former, chronic pulmonary capillary congestion exists, leading either to immediate disabling pulmonary symptoms or to reflex systemic vasoconstriction. In the latter the systemic vasoconstriction is not readily released on effort. Effort syncope, however, is not uncommon in primary pulmonary hypertension. The minute output again tends to be fixed but the blood pressure falls on effort, presumably when muscle vasodilatation occurs, because there is no pulmonary capillary congestion to inhibit its occurrence. Perhaps dilatation can be similarly initiated in aortic stenosis because of the normal and only slowly rising pulmonary capillary pressures. In 2 patients suffering from aortic stenosis whom I have observed fainting there was a bradycardia and the episode appeared to have the quality of a vasovagal attack.

I do not wish to dwell on the physical signs but I should like to make a plea for the abandonment of attaching diagnostic importance to the presence or absence of a systolic thrill in the aortic area. It is surely more sensible to feel the carotid arteries or the aortic arch at the root of the neck. Coarse vibrations felt there are diagnostic of aortic stenosis and are quite unlike the smooth thrill felt in an aortic to-and-fro murmur due to predominant aortic incompetence. The hearing of the murmur over the olecranon processes is no more than a clinical *tour de force*. If the murmur is loud enough it will have wide radiation. An important point to recognize is that if aortic stenosis is very severe blood flow may be insufficient to produce a murmur. This is sometimes seen in the operating theatre, when pressures are simultaneously measured in the left ventricle and aorta. If the cardiac output is sufficiently reduced there may be no pressure gradient across an aortic stenotic valve. A useful sign is an early systolic click associated with post-stenotic dilatation of the ascending aorta.

Valve calcification (Fig. 2) is very common although I know of no means of assessing

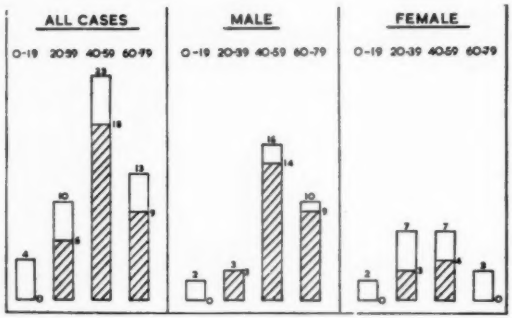

FIG. 2.—Calcified valve in aortic stenosis.

whether it is in the valve or the valve ring. It is best seen with the image intensifier but ordinary fluoroscopy is so satisfactory that if it had been invented after tomography it would have been hailed as an advance.

A great deal has been said about pulsus bisferiens in combined aortic stenosis and incompetence. It may be a very useful sign but varying pressure of the palpating finger may give the impression of pulsus bisferiens where none exists. The most important

measurement in the peripheral pulse is delay in the systolic upstroke time. This is prolonged to between 0·175 and 0·3 second in five cases of aortic stenosis (Fig. 3) and may revert to normal after successful valvotomy.

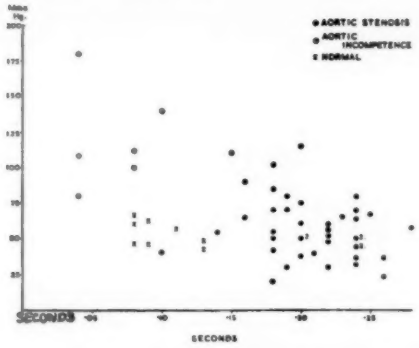

FIG. 3.—Brachial artery pulse pressure and systolic upstroke time.

In 1955 Gorlin joined us at St. Thomas's Hospital in a hæmodynamic study of a number of patients with aortic valve disease. Some of the deductions were made by a combination of cardiac catheterization and study of other hearts in McMillan's artificial perfusion system. With the advent of direct left ventricular puncture either through the chest wall as Brock practises or via a bronchoscope and the insertion of a fine polythene tube as we have been doing, these deductions have been found to be substantially correct. They are that:

The "critical" orifice area in pure aortic stenosis is 0·5 sq. cm., in mixed stenosis and incompetence less than 1·5 sq. cm. With these respective degrees of stenosis left ventricular systolic pressure is elevated to 200–250 mm.Hg with transvalvular pressure gradients of 100–150 mm.Hg. Because of the inability of the coronary flow to increase in proportion to the demands of ventricular work, due to low coronary perfusion pressure, the ventricular systolic pressure seldom exceeds 250 mm.Hg when no further stroke work can be done. In view of the large gradient between the aorta and ventricle in diastole, regurgitant orifice areas no greater than 0·5 sq. cm. were capable of more than doubling total ventricular output and work. Although left ventricular stroke work is increased at rest (two to four times normal) the pulmonary capillary diastolic pressure is near normal in 80%.

There are four stages of the disease:

Stage I: The valve orifice area is greater than 0·5 sq. cm. in pure cases and greater than 1·5 sq. cm. in mixed cases. The only physiological deviation will be a prolonged systolic upstroke time. The patient is free of symptoms.

Stage II: The valve orifice area is 0·5 sq. cm. or less in pure cases and less than 1·5 sq. cm. in mixed cases. Resting left ventricular diastolic pressure and blood flows are within normal limits, but on effort the diastolic pressure rises. Stroke output and work are fixed. These patients are free of symptoms except with unusual but varying degrees of effort. The limitations here are mainly hydraulic in nature.

Stage III: Orifice areas are the same but the myocardium usually shows signs of generalized patchy fibrosis from years of impaired coronary flow. The huge load borne well in Stage II is no longer tolerated on slight exercise. The resting left ventricular diastolic pressure is within normal limits or elevated slightly and blood flow is invariably decreased. Effort causes elevation in diastolic pressure, a fixed or falling output, and often acute right ventricular failure as well. These patients are limited by symptoms, first of left- and soon of right-sided failure. Thus it is not until late in the disease when the muscular component fails that symptoms become severe and the disease runs an accelerated course.

Stage IV: Terminal bilateral cardiac failure.

I should like to submit that patients should be operated upon while still in Stage II, before serious symptoms and myocardial fibrosis have appeared. This means that the majority of patients will be children and young people in whom gross valvular calcification has not yet occurred. The best operative results appear to be in young people with non-calcific congenital aortic stenosis. The worst results are in middle-aged patients in whom the valves are usually heavily calcified. It must be stressed again that any blind procedure

which leads to increased incompetence even with some lessening of stenosis is a disservice to the patient.

If operation is decided against, apart from the usual medical measures thyroid ablation is often worth while. It is best carried out with radio-iodine. Following treatment, angina is usually much improved, dyspnœa is less and sometimes the heart size decreases.

I have deliberately avoided discussing subaortic stenosis because, despite what people tell me, I believe it is a very rare disease and its diagnosis inaccurate.

Mr. Andrew Logan (Department of Surgery, University of Edinburgh):

The Surgery of Aortic Stenosis

The views which I shall express on the surgery of aortic stenosis are based on an experience which is small in relation to some of the published figures. For example, Bailey (1956) quoted 450 cases of aortic valvotomy and Harken (1956) 70 cases. I have performed aortic valvotomy in only 31 cases. 7 of the patients had congenital aortic stenosis; 17 had acquired aortic stenosis without significant incompetence or other valvular lesion; and 7 had aortic stenosis combined with mitral stenosis.

The records of the first 6 patients with congenital stenosis have already been published (Marquis and Logan, 1955). Each underwent pre-operative angiocardiography in an attempt to exclude subvalvular stenosis since it seemed inappropriate to attempt enlargement of a subaortic ring by the same technique as was used for the separation of fused cusps. All were operated upon more than three years ago. None has died. In all, the signs of aortic stenosis were reduced. In 5, however, aortic incompetence was produced or increased, and in 2 the incompetence was severe. The single patient who had no reflux after operation still has none and is well. The result in her case is good enough to indicate that the aortic cusps were flexible and well-formed and that valvotomy achieved extensive separation of the cusps accurately in the line of the commissures. The occurrence of slight to severe, but not lethal, aortic incompetence in the other 5 cases, along with a reduction of stenosis, suggests that in these, too, considerable separation of the cusps in the correct line was obtained, but that the cusps were ill-formed rather than that a cusp was divided at operation. The most severe incompetence occurred in a boy of 13. He still has severe incompetence and the heart is larger than it was 6 months after operation, but whereas he was, at 13, a weedy boy 14 lb. underweight he is now, at 16, 3 st. heavier, up to normal weight, asymptomatic and leading an energetic life. In all, an improvement in cardiac function and in general health has lasted for three years after valvotomy. It remains to be seen how long the heart will compensate for reflux before a comparison can be made with the calculated effect of unrelieved stenosis. Meantime, there is no reason to change the opinion that valvotomy for congenital aortic valvular stenosis should be reserved for those patients who are in danger of sudden death or of deterioration which might prejudice the outcome of a later operation. The risk of incompetence does not justify withholding operation in growing children who show the electrocardiographic pattern of extreme left ventricular hypertrophy and in adults who show progressive left ventricular hypertrophy with increasing cardiac size.

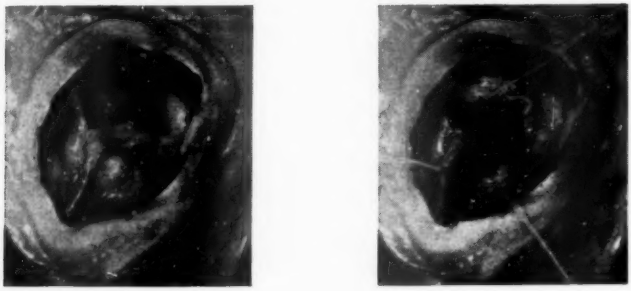
The seventh patient in the congenital group was not investigated by angiocardiography. At that stage it was assumed that severe aortic stenosis was almost certainly valvular and not subvalvular. Inspection of the heart at thoracotomy raised no suspicion that the stenosis was subvalvular. The same blind transventricular approach was used. It was immediately obvious that a different condition had been encountered because the obstruction, instead of being disrupted with ease, strongly resisted the opening of the dilator. I exerted a degree of force quite inappropriate to valvotomy and succeeded in widely opening the dilator. There was no thrill of reflux or evidence of other damage and the heart's action remained good. The state of the child gave no cause for anxiety until sudden death occurred five hours later. At autopsy a fibrous ring was found 0·7 cm. below the lowest part of the aortic cusps, which were normal. The ring had been ruptured posteriorly and

the tear which extended into the ventricular wall passed upwards in the aortic wall between the right and left posterior cusps, then above the left coronary orifice. None of the cusps was damaged. Death may have been the result of obstruction of the mobilized left coronary orifice although there was no pathological evidence that obstruction had occurred.

The 17 patients with acquired aortic stenosis and no other major valvular disease were selected in the belief that the duration of their survival without operation was likely to be less than eighteen months. The records of some of these also have been published (Logan and Turner, 1954). All had more than one of the triad, syncope, angina, and congestive heart failure. Only 2 had uncalcified valves.

Of these 17, 9 are dead, 1 during operation, 3 within three weeks of operation, and 5 from six to thirty months after operation. The immediate death was the consequence of neglect of the elementary precaution of controlling the ventricular incision with a tourniquet. The search for the orifice among the calcific masses of the valve was more prolonged than usual, blood leaked continuously, ventricular fibrillation supervened and normal rhythm could not be restored. Of the 3 early deaths, 1 was from pulmonary infarction three days after operation. The patient had intractable cardiac failure for which a year before I had ligated the inferior vena cava. She had a severe degree of hepatic cirrhosis. One patient died nine days later from coronary thrombosis with a large cardiac infarct. 2 of the patients who died later had been temporarily improved and the others followed the uninterrupted course of severe aortic stenosis. 2 were examined *post mortem*. Both had rigid valves, one without evidence of division. One heart weighed 900 grams and the other 1,100 grams.

Of the 8 survivors, 1 did not have a valvotomy because I was unable with the maximum permissible force to rupture a calcific ring surrounding the valve orifice. All the others have some increase of aortic reflux. One has a left homonymous hemianopia, the result of calcific embolism. Because of a technical difficulty the head vessels had not been occluded during valvotomy. One is not obviously improved. 5 have lost their important symptoms and follow normal activities. One is asymptomatic. Pre-operatively he was dyspnœic and suffered from angina and syncope. He had been in congestive heart failure. For five weeks after operation he remained in heart failure but three months later returned to office work and has remained well for three years.



That is, in 17 cases of acquired aortic stenosis there were 4 early deaths, 5 late deaths, 2 unimproved and 6 with improved cardiac function, one of them much improved. None had a severe degree of aortic reflux.

The 7 patients with combined aortic and mitral stenosis were all initially improved. None died and none had severe aortic reflux. Since the gradient across the aortic valve was not measured, I have no means of apportioning the benefit to the two operations or of indicating how the aortic valve was affected.

If the selection of cases of aortic stenosis for operation is restricted to those in which cardiac impairment is so severe that death is imminent, the question arises whether surgical intervention by blind valvotomy is profitable. The opinion has been given that we merely deduct a few months from one patient's life and add them to that of another without a net gain. Taking the worst group, that of pure acquired aortic stenosis, that is clearly not so. In the whole group there were few years to come and all of them bad. There have already been three good years and ten fair years, which compares well with the results of the surgery of carcinoma.

The technique used in all cases was the same. Through a left thoracotomy a two-bladed expanding dilator with a spread of 4 cm. was introduced through an incision in the anterior wall of the left ventricle and placed in the aortic valve under the guidance of external palpation of the origin of the aorta. The dilator was opened as far as that could be done with a reasonable amount of force or until the aortic wall was stretched over it. Then the dilator was withdrawn and the ventricular wall was repaired. This is an exceedingly crude method of valvotomy but I can say that by the use of a similar technique in mitral stenosis the commissures are more often and more completely divided, and with less damage, than I can achieve by any other way. The dilator sometimes selects a commissure when I am unable to recognize it by digital palpation. It is at least possible that the same would be true in aortic stenosis. The absence of sudden severe post-operative aortic incompetence suggests that in none was a cusp completely divided. I am unconvinced of the need for a three-bladed dilator or of the likelihood that the blades will occupy the commissures. Again comparing the mitral operation, the valvotomy is simply a matter of tearing by stretching and, whatever the direction of the stretch, the tear occurs in the weakest line which is fortunately usually the commissure. The amount of force required to tear a cusp is so great as to be easily recognized and avoided. If the aortic cusps are malformed or destroyed no technique at present available will make their function good

If the cusps are well formed the dilator will probably separate them as effectively as any other instrument (Fig. 1A and B).

A B

FIG. 1.—Acquired aortic stenosis without calcification after valvotomy. A, Valve closed; B, Open. The appearance of rigidity is the consequence of fixation. In the fresh state the cusps had almost normal mobility.

Bailey (Bailey *et al.*, 1956) began to approach the aortic valve through the ascending aorta for two reasons: because he had encountered ventricular fibrillation with the trans-ventricular route, and the thick friable ventricular wall had sometimes been difficult to repair. He did not by the change eliminate trouble from ventricular fibrillation and bleeding but continued to use the trans-aortic route for the sake of avoiding injury to the ventricular muscle and of using the finger both for the performance of the valvotomy in some cases and the assessment of the quality of the valvotomy in all. I believe that the expanding dilator usually makes a less traumatic valvotomy than the finger because each blade provides counter-pressure for the other, whereas the finger must pull upon the pedicle of the heart or against externally applied pressure. Digital palpation of the valve after valvotomy would certainly be helpful in prognosis and might sometimes lead to modification of the state of a commissure after the first dilatation. Whatever route is used, ventricular fibrillation is likely to occur in some cases. The massive thickness of the left ventricle and the small left ventricular cavity make effective cardiac massage, as judged by the presence of a radial pulse, difficult or impossible and electrical defibrillation must be used without delay.

With the increasing use of refrigeration and of pump-oxygenators to permit open cardiotomy in other conditions it is to be expected that they should be used for aortic valvotomy under vision. In the United States, Lewis *et al.* (1956) and Swan (1956) have used refrigeration and Lillehei *et al.* (1956) the pump. In the short time afforded by refrigeration I doubt that with knife or scissors I could make as accurate a dissection of the commissures as competence of the valve demands, even in an uncalcified valve with well-formed cusps. Where the cusps are deformed or the commissures obscured or calcified I should prefer to rely on the dilator for their separation. For the division of a subaortic stricture, however, a visual approach may be desirable and the three to five minutes afforded by refrigeration may be adequate for this. Probably neither refrigeration nor the pump-oxygenator is necessary for the correction of aortic valvular stenosis so far as that can be done now, just as they are unnecessary for the correction of mitral stenosis. But the visual approach through the aorta with the pump-oxygenator has importance for the future since it will be by that method that the aortic valve will be assessed and repaired or replaced by a prosthesis when an efficient and durable one can be constructed.

It is clearly important in cases of congenital aortic stenosis to know pre-operatively the site of stenosis. For this purpose some reliance has been placed on angiocardiography although evidence that it would demonstrate a subaortic stricture is lacking. Some help might be derived from manometry of the left side of the heart by left ventricular puncture as practised by Brock *et al.* (1956). In manifestly severe acquired aortic stenosis measurement of the systolic gradient across the aortic valve before operation cannot contribute much. If, as is likely, the maximum opening of the valve is completed with one dilatation, measurement of the gradient during operation, before and after valvotomy may aid prognosis but nothing else. When aortic stenosis complicates mitral stenosis, however, measurement of the gradient across the aortic valve after mitral valvotomy is required for the decision on proceeding to aortic valvotomy. For lack of that investigation I have on two occasions

omitted aortic valvotomy at the time of the mitral operation and been obliged to repeat the thoracotomy a few months later. The principal value of pre-operative measurement of a pressure gradient and blood flow at the aortic valve is probably in the assessment of patients who, having undoubted aortic stenosis and left ventricular hypertrophy are yet asymptomatic and have little valvular calcification. It is in this group that the best result from valvotomy is to be expected but the prognosis is so uncertain that the achievement by operation cannot be estimated. There is no obvious way of overcoming this difficulty but to find a large enough number of these cases by routine cardiac examination and, having overcome hesitation to use ventricular puncture in asymptomatic patients, to select an arbitrary degree of severity of stenosis as indicated by the integration of pressure gradient and blood flow at the aortic valve; then, rather than operate on all with more severe stenosis (a course which could give information only about the undesirable consequences of valvotomy) or continue to observe the natural course in all, to make control series for operative and conservative management.

Summary

(1) Although the results of aortic valvotomy in patients who have been gravely damaged by aortic stenosis are poor they are worth while.

(2) The blind transventricular operation probably gives a valvotomy as accurate as other methods but the trans-aortic route must be expected to be required in due course for replacement of the valve.

(3) In symptomatic pure aortic stenosis, measurement of the pressure gradient across the aortic valve during thoracotomy can contribute to prognosis but in combined aortic and mitral stenosis it may be necessary for a decision on the need for aortic valvotomy.

(4) The use of aortic valvotomy should be extended to asymptomatic patients investigated by measurement of the pressure gradient and blood flow across the aortic valve and known to have severe stenosis, but an attempt should be made to compare the prognosis with and without valvotomy.

Dr. J. F. Goodwin (speaking at short notice in place of Professor J. B. Duguid):

I propose to discuss the study of aortic stenosis by means of the cardiogram and arterial pulse tracing, and wish to present the results of some work (with which I have been closely associated) by my colleagues, Drs. Abdin, Doyle and Neilson, at the Postgraduate Medical School.

Abdin (1957) has studied the cardiograms of 53 cases of aortic stenosis (25 of whom are living), and compared them with 19 cases of coarctation of the aorta, 15 cases of hypertension, and 4 cases of hypertension associated with ischæmic heart disease. Deep T-wave inversion (greater than 5 mm.) in left præcordial leads was found in 26 of the cases with aortic stenosis, but in only one of the hypertensive and coarctation cases respectively. By contrast, it was found in 3 of the 4 cases with ischæmic heart disease and hypertension. T-wave inversion was found to be appreciably greater in cases of aortic stenosis than in those with hypertension who had equal R-wave voltage, and equivalent degrees of left ventricular hypertrophy at autopsy. This disproportionate T-wave inversion suggested that some factor other than myocardial hypertrophy was responsible, and the finding of ischæmic lesions in the myocardium in the absence of coronary artery disease in 13 cases of aortic stenosis at autopsy suggested that this factor was cardiac ischæmia, which results from deficient coronary blood flow due to the obstruction to the outflow of the left ventricle. The presence of very similar degrees of T-wave inversion in the cases with ischæmic heart disease and the known association of anginal pain with aortic stenosis harmonize with

this view. In 6 cases of aortic stenosis and 3 of hypertension an **RS** pattern was found in V_5 in association with signs of left ventricular hypertrophy. All had pathological evidence of right as well as left ventricular hypertrophy, supporting the findings of Pagnoni and Goodwin (1952).

Doyle and Neilson (1957) have studied the relation of the systolic upstroke time of the peripheral arterial pulse to the pulse pressure in aortic stenosis with and without incompetence. In aortic stenosis the systolic upstroke is usually prolonged and the pulse pressure usually low, but close correlation with the severity of the stenosis is often not obtained. When the pulse pressure was related to the upstroke time during changes induced by the Valsalva manœuvre, or during atrial fibrillation, cases of severe stenosis showed a considerable reduction in upstroke time for a given change in pulse pressure. In mild cases and in those with significant associated incompetence, there was little change in upstroke time for an equivalent change in pulse pressure. The reduction in upstroke time in relation to fall in pulse pressure was considerably less after successful aortic valvotomy. Expressed in another way, patients with severe aortic stenosis showed little alteration in rate of rise of the systolic upstroke during the Valsalva manœuvre, while those with incompetence showed considerable alteration. The fall in pulse pressure during the Valsalva manœuvre is probably due to a fall in stroke volume, and hence the marked reduction in upstroke time when the pulse pressure falls suggests that the systolic upstroke time is a resultant of the stroke volume and resistance at the aortic valve. The form of the arterial pulse in aortic stenosis is mediated, at least partly, by changes in peripheral resistance, since pulses of equal size recorded at various stages during the Valsalva manœuvre were often of different contour.

Measurement of the systolic upstroke time in relation to changes in the pulse pressure in a number of cardiac cycles offers a better guide to the severity of stenosis than measurement of the resting tracing.

Mr. W. P. Cleland said that he had performed aortic valvotomy on 15 patients during the last three years. In only 1 of these was the ætiology believed to be congenital. In 9 there was pure calcific aortic stenosis, and in 5 there was mitral valve disease in addition to the aortic stenosis. All these patients belonged to Dr. Daley's Stage III.

He would entirely agree with Dr. Daley that his Stage II cases were likely to give better results with surgical treatment, but he disagreed that the Stage III cases should not be submitted to operation, as the follow-up of his own small group indicated.

Of his 15 patients, 3 died either at operation or in the immediate post-operative period—2 from cardiac arrest and 1 from a calcific cerebral embolus.

Of the survivors, only 1 has died. The remainder have been followed-up for periods of six months to three years and all have maintained their original improvement.

The majority of the patients had symptoms of angina, syncopal attacks and dyspnœa, and considerable relief of symptoms was obtained in the majority. This improvement was associated with equivalent objective signs of benefit.

The transventricular approach was employed in all, using a triradiate mechanical dilator. Interference with the myocardium was reduced to a minimum and blood loss from the ventricle was very carefully avoided. Lack of attention to these two details was certainly responsible for two of the operative deaths.

The effects of the operation were determined by measuring the gradient across the aortic valve and by determining the systolic upstroke time of the pulse wave. The measurement of the gradient gives a valuable idea of the degree of obstruction and the amount of relief obtained, provided conditions at the time of successive measurements are as nearly similar as possible.

Mr. Cleland was quite satisfied with a 50% reduction in gradient even though the latter was still high. Repeated attempts at dilatation in an attempt to reduce the gradient often resulted in troublesome or fatal cardiac irregularities.

The follow-up of these cases has suggested that a fairly conservative approach is quite justified. He has not felt the need to approach the valve through the aorta but considers the performance of aortic valvotomy under direct vision in a bloodless field and a motionless heart is probably likely to be the operation of choice in the future.

Dr. Ronald Gibson said that at The Brompton Hospital and at Guy's Hospital, direct puncture of the left ventricle was performed in 60 patients. The results in the first 28 cases had been analysed in detail by Dr. Peter Fleming and himself (1957). The procedure was simple and safe, but the systolic pressure gradient across the aortic valve obtained by this method must be interpreted with caution. This gradient depended not only on the size of the valve orifice, but also on the stroke volume, which is related to cardiac output, heart rate and the degree of aortic regurgitation. For example, he had found that with an estimated valve size of 0·25 sq. cm. at operation the systolic gradient at left ventricular puncture varied between 30 and 210 mm.Hg. These results are considered to be due to differences in stroke volume. A gradient of up to 100 mm.Hg had been found with dominant aortic regurgitation. However, all cases with a systolic gradient of 120 mm.Hg or more had dominant aortic stenosis. There was, therefore, little correlation between height of a pressure gradient and the surgeon's estimate of the valve size. In the absence of significant aortic regurgitation there was a fair correlation between the surgeon's estimate of the valve size and the calculated aortic valve area. The left ventricular ejection period was prolonged in all cases, but degree of prolongation gave no indication of the degree of valve obstruction. Therefore they considered that paradoxical splitting of the second heart sound did not necessarily indicate severe aortic stenosis. On the other hand, it was found that the degree of prolongation of the corrected brachial upstroke time was related to the severity of the stenosis.

A direct relationship had been found between the systolic gradient and the degree of left ventricular hypertrophy on the electrocardiogram in all the cases in this series, irrespective of whether stenosis or regurgitation was the dominant lesion.

REFERENCE

FLEMING, P., and GIBSON, R. (1957) *Thorax*, **12**, 37.

Mr. Ian M. Hill:

I have carried out 12 aortic valvotomies in adults, 2 in isolated aortic stenosis and 10 combined with mitral valvotomy, all by the transventricular approach at normal temperatures.

The 2 isolated cases were severely disabled, 1 with right and left failure and the other with angina. The case with failure had a good result and now two and a half years later is beginning to slip back again. The anginal case died of irreversible ventricular fibrillation at operation, one mass of calcium in the valve producing partial rupture of the aortic wall when pressed against it by the dilator, leading to a hæmatoma about the origin of the left coronary artery.

Electromanometer pressure readings have been taken in all cases at operation; but the gradient across the aortic valve is not always helpful in assessing the degree of stenosis under these conditions as the operative handling of the ventricle may grossly alter the output and therefore the gradient across the valve. Usually after mitral valvotomy the aortic gradient increases, but where the left ventricle has been manipulated it may even fall despite a good mitral valvotomy. Direct sounding of the aortic valve through the apex of the left ventricle is a more reliable assessment and in the 10 cases mentioned and another 6 in whom the aortic valve was sounded, but not dilated during mitral valvotomy, there was no mortality and no morbidity in this method of handling the problem. The functional results have been good.

Mr. D. N. Ross said that Sir Russell Brock had performed about 130 aortic valvotomies (1957), mostly by the transventricular route with good results. He agreed with Mr. Cleland that there was danger in prolonged manipulations with the dilator in situ while trying to abolish the gradient entirely. This was likely to precipitate ventricular fibrillation. The overall mortality figures were approximately 10%, the figure being higher in the earlier cases and lower now.

In addition, he had operated on about 15 cases of congenital aortic stenosis under direct vision through the aorta with the aid of hypothermia.

There had been a surprising number of cases of subaortic stenosis encountered—about 11 cases or approximately 10%. At present there is no entirely satisfactory method of demonstrating this lesion pre-operatively and attempts had been made to do catheter withdrawal tracings via a LV puncture needle. The present attitude is that calcification of the

valve is so common in isolated aortic valve stenosis in patients of 30 years of age that subvalvar stenosis is suspected in any patient of this age who does not have a calcified valve on screening. At operation, in a suspected case, withdrawal pressure records are taken with a catheter and these show an "infundibular" type of tracing below the valve. Subvalvar stenosis is generally of a diaphragmatic nature—consisting of a ring of puckered endocardium about 1 cm. below the valve and this is split by means of blunt transventricular dilatation.

REFERENCE

BROCK, R. C. (1957) *Brit. med. J.*, i, 1019.

Mr. B. B. Milstein:

I should like to add two points which have emerged from Sir Russell Brock's experience. The first is the hopelessness of operating on patients in intractable cardiac failure from aortic stenosis. Such patients were submitted for operation early in his series and the mortality was extremely high. These cases are now rejected as beyond hope of surgical treatment. Patients who have been in right- or left-sided heart failure but who respond to medical treatment are not subject to the same operative risk and very good results have been obtained in these advanced cases but it is desirable to wait as long as possible, preferably three months after the attack of cardiac failure, before proceeding to operation.

The second point concerns the results of operation. This is not entirely a matter of duration of life after operation. Anginal pain and syncope, for example, can usually be completely relieved. The effect on exertional dyspnœa is variable. Some patients may die subsequently from left ventricular failure and this is not surprising when one sees the gross hypertrophy of the left ventricle and the extreme degree of fibrosis in the muscle which is present in advanced cases. These changes are clearly irreversible. Nevertheless, these patients' lives may be made tolerable by the relief of angina or syncope as a result of operation.

Dr. C. J. Gavey mentioned the value of the symptoms of weakness and ready exhaustion of fairly sudden onset, in drawing attention to the possibility of serious deterioration in the prognosis of aortic stenosis. Such symptoms were so often due to anxiety that there was a risk of overlooking their alternative origin in the falling cardiac output due to aortic stenosis.

Dr. Gavey stressed the difficulty of deciding whether or not to offer surgery in the more advanced valvular lesions, especially since certain mechanical estimations of function, however carefully performed, could sometimes be misleading.

Mr. I. K. R. McMillan said that he had carried on his investigation of the function of stenotic aortic valves beyond the figures quoted by Dr. Daley and that his experience now included some 50 cases. The classification of the type of orifice still fell into six main groups, which were as follows:

(i) Early peripheral fusion with good function centrally (4 cases).
(ii) Peripheral calcification, not affecting function (2 cases).
(iii) Fusion of one commissure (24 cases).
(iv) Partial or complete fusion of two commissures (8 cases).
(v) Partial or complete fusion of three commissures, often with incompetence (8 cases).
(vi) Cone-shaped valve with an ellipsoid orifice at the apex, and no sign of former commissures (3 cases).

He pointed out the risk in group 4 when doing a blind valvotomy of tearing the relatively normal commissure and producing incompetence while not splitting the fused calcified commissures, and suggested that direct vision surgery of the valve would be advantageous in these cases.

(Latin Proverb).

"What is food to some is black poison to others."

It is very remarkable that in spite of the striking character and widespread distribution of allergic diseases no one seems to have studied them particularly until John Bostock (1828) of Guy's Hospital wrote a treatise on "Hay Fever" under the title of "Summer Catarrh".

If we accept the term allergy as meaning "altered capacity to react" the use of the word should be extended to include all forms of hypersensitive reactions, whether antigen antibody reactions have been proved to occur in them or not. Clinically the two types of reaction are indistinguishable and occur often in the same patient. I hope that this wide use of the word will be generally adopted.

PATHOLOGY

THE allergic reaction induced by histamine released in the tissues by the allergen antibody union shows five characteristic features:

(i) Vascular dilatation.
(ii) Loosening of endothelial cement and escape of fluid from the surface of the tissue.
(iii) Increased activity of the seromucinous glands.
(iv) Eosinophil infiltration, mostly in the subepithelial tissues, but also migrating through the surface to appear in the secretion.
(v) In the later stages after repeated attacks:
  (*a*) General hyperplastic thickening and œdema.
  (*b*) Massive localized œdema presenting as polypi.

INCIDENCE OF ALLERGY

There have been many surveys of the incidence of allergy in general and it appears that it differs from one country to another and also seems to differ in different classes and types of the same community.

For example, allergy generally would seem to be more prevalent in America than in England, while hay fever, which is common in England and America, is unknown in Japan.

The most important reasons for these differences are the variations in the intensity of concentration of allergens, and of stress and environmental factors in predisposing to allergy. In America there is an immense crop of ragweed which prolongs the pollinizing season, and hay fever afflicts the Japanese who have migrated there (Hara, 1939).

As an average figure it is stated by Vaughan (1934) that 10% of Americans are frankly allergic, and 50% give histories of transient episodes of minor allergy. Bray (1937) estimated that 10% of the British population were allergic.

I have investigated the number of allergic patients seen in the course of my practice over the years 1929 to 1939 and 1946 to 1956. In the first decade there were 593 allergic patients,

828 *Proceedings of the Royal Society of Medicine* [Vol. 42

in a total of 5,050 patients of all types: in the second decade there were 1,239 allergic patients in a total of 8,735 patients, giving a percentage of 11% allergic in the first and 14% allergic in the second decade.

The earlier writers were quite convinced that the incidence was greater in the more intelligent than in the less intelligent groups, but Piness and others (1937) have denied any significant difference. I am convinced that the level of intelligence is an important factor, for when I was investigating the nose, throat and ear conditions of 600 mental defectives over the course of several years at Stoke Park Colony, I did not find a single case of asthma or nasal allergy, and only one patient who had any suggestion of allergy, and that was a high grade moral imbecile with nasal polypi. This is in accord with the findings of Leavitt (1943) who did not discover a single case of asthma among 5,000 institutionalized epileptics and mental defectives. Susceptibility to allergy seems to vary with type of pigmentation. It is common experience that the fair-skinned and particularly red-haired persons are more susceptible than dark-haired.

As laryngologists the factors that will interest us most are:

(1) *The Site of the Reaction*

This may be (*a*) the nose, (*b*) the sinuses, (*c*) nasopharynx, (*d*) oropharynx, (*e*) larynx and trachea, or (*f*) bronchi.

The clinical picture differs in each of these sites.

(2) *The Commonest Groups of Allergens*

Allergens are usually divided for descriptive purposes into (*a*) exogenous and (*b*) endogenous.

The exogenous are subdivided into:

(i) Inhalants: Pollen, dust, bedding, animal emanation, &c.

(ii) Ingestants: Wheat, eggs, milk, &c.

(iii) Drugs and other inorganic agents, smoke and fumes of tobacco, coal, washing powders, &c.

(iv) Physical agents: Light, heat, cold, humidity and touch.

(v) Products of bacteria, viruses, moulds, parasites.

The endogenous are subdivided into:

(i) Emotional and endocrine.

(ii) Bacteria, viruses, moulds and parasites multiplying in the body.

(iii) Altered tissue protein, exudates, transudates, inflamed and injured tissues.

During the last three years we have been undertaking a detailed investigation of cases of nasal allergy attending my Outpatient Clinic. In a group of 168 patients with nasal allergy there were 71 cases with nasal allergy alone, 59 with nasal allergy and asthma and 38 with nasal allergy and other allergies.

In these patients the relative frequency with which groups of allergens were responsible was as follows:

Inhalants	135 cases (80%)
Ingestants	59 cases (35%)
Physical agents ..	36 cases (21%)

(3) *Predisposing Factors and Triggers that Initiate the Reaction*

We also investigated the factors that might have predisposed the tissues to allergy. These factors fell into the following groups:

(i) *Heredity.*

(ii) *Infections*, including coryzas, zymotic epidemics and local infections of the nose and throat, such as rhinitis and sinusitis, pharyngitis, tonsillitis and adenoiditis .. 5[illegible]%

(iii) *Mechanical factors*, such as direct trauma by blow or surgery or indirect trauma by the pressure of mucous membrane against mucous membrane, nasal obstruction or the drying and arrest of the mucous sheet by air jets due to deviation of the nasal septum .. .. 2[illegible]%

(iv) *Psychological*, including those in which the onset followed immediately on some emotional shock .. .. 1[illegible]%

(v) *Pregnancy and menopause* .. .. [illegible]%

(vi) *Environmental and occupational*, including patients who were exposed to occupational dusts and fumes .. .. [illegible]%
or, in the case of mould allergy, those who lived in old houses .. .. 3[illegible]%

It has been suggested that mould allergies are particularly common in damp climates. The district in which I work has a high rainfall, and being near a large estuary and several rivers, usually has a high atmospheric humidity. Thus our figures of 40% compare with those of Van Leeuwen (1924) for Holland, who found 50% of asthmatics allergic to fungi. But Fraenkel (1938) in Germany, where the climate is dry, found only 16% were sensitive to fungi.

If we consider these factors it seems reasonable to assume that, given a receptive soil, as provided by a strong hereditary predisposition, the initiation of allergy is likely to follow exposure to a heavy concentration of potent allergens at a time when tissue resistance is lowered, and the surface laid open to the entrance of allergens. This depression of resistance may be general—due to chill, fatigue, emotional disturbance or general disease; or local—due to inflammation, trauma or drying of the mucous sheet. Of all the factors the most important is infection.

As experimental evidence of this a very interesting observation was made by Burky in 1934. Working with bacterial products on rabbits, he was able to show:

(i) Classical shock in the sensitized animal.

(ii) Passive transfer.

(iii) Positive reaction in the Dale uterine muscle strip.

(iv) Arthus type reaction (Arthus, 1903).

He noticed that when immunizing rabbits to a staphylococcal toxin the animal became sensitized to the culture medium broth. One of the strange features about allergy is that while clinical allergy is so common and widespread it is practically impossible to sensitize human beings or animals experimentally to any of the common allergens, except perhaps poison ivy. Burky found that he could, by using the staphylococcal toxin, sensitize rabbits to ragweed, and even to their own crystalline lens or muscle protein.

Thus through the agency of staphylococcal toxin an individual might during infection become sensitized to other allergens. Swift and Schultz (1936) have produced similar results using diphtheria and staphylococcal toxin. Also Swineford and Holman in 1949 were able to show many skin reactions in sensitized individuals using nucleoprotein and polysaccharides from 14 different bacteria, the carbohydrate fraction producing an immediate reaction and the protein a delayed one.

There are many clinical examples of infections with associated allergic skin reactions and local allergic reactions in different organs. Scarlatinal rashes and glomerulo-nephritis, rheumatic carditis and many syphilitic lesions are examples of this type.

Allergy, once established, is augmented and encouraged to spread from one shock tissue to another by repeated exposure to the allergens, and by depression of the patient's general and local resistance. The more frequent the attacks the easier it becomes to elicit them. It is often noted that single allergens may not be sufficient alone to cause a clinical reaction, but when there is simultaneous exposure to others, attacks come on. It must also be remembered that with the same allergen and the same individual the site of reaction may shift in the course of time; and that different allergens in the same patient may affect different tissues. A striking example of this is provided by the patient who during the hay season suffers from bronchial asthma and in the ragweed season from nasal allergy.

(4) *The Clinical Picture*

General Features

Acute allergy.—The clinical picture is that of an inflammation with the following five special characteristics:

(i) The excessive irritation and œdema of the reaction compared with the small amount of the allergen producing it.

(ii) The explosive nature of the onset of the symptoms on exposure to the allergen, the short latent period and the abrupt cessation of irritation and rapid recovery of the tissues on elimination of the allergen.

(iii) The absence of tissue destruction or suppuration and the watery nature of the discharge.

(iv) The eosinophilic response.

(v) The absence of pyrexia and general toxæmia.

Chronic allergy develops when acute attacks follow one another so rapidly and for such a long period of time that the tissue cells proliferate and lead to hyperplasia, while the œdema becomes fixed and leads to general thickening of the tissues and also to the development of polypi (Fig. 1).

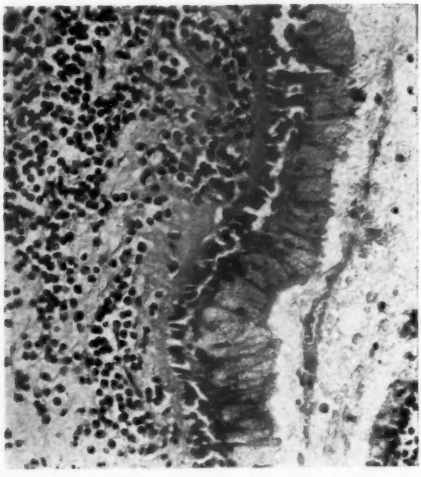

FIG. 1.—Nasal polyp showing œdema and eosinophil infiltration. H. and E. ×182.

Local Features

Acute nasal allergy is divided for clinical purposes into: (*a*) Seasonal or pollinosis, due to pollens. (*b*) Perennial, due to the remaining allergens.

The two groups may be combined. The difference is of importance in both treatment and prognosis.

In nasal allergy the patient is often sensitive to a number of allergens. The inhalants are the commonest causes in adults, but in children the food allergens, particularly wheat, eggs, milk and chocolate, are more frequently responsible. At both ages physical allergens, particularly changes in temperature, the effect of wind and the alteration of nasal reflexes as in excitement or exertion, are responsible for sudden outbreaks of allergic reaction. In a few the nose may be so hypersensitive that touching the lip is sufficient to set off a paroxysm of sneezing, while in a considerable number the lightest touch with a probe directly on the nasal mucosa causes a violent protective reflex with sneezing, lacrimation, rhinorrhœa and mucosal swelling.

During the active phase the patient suffers from paroxysms of sneezing. The mucous membrane is characteristically swollen and boggy causing obstruction of the airway and is bluish in colour due to œdema, vascular engorgement and blood stasis. The secretion is copious and watery and contains eosinophils. During the quiescent phases the appearance may be normal. When the allergens are mainly bacterial or physical agents the mucous membrane is often red in colour and eosinophils are absent from the secretion.

Chronic nasal allergy.—The characteristic features are those of permanent nasal obstruction and viscid nasal discharge with episodes of superadded acute allergic manifestations on re-exposure to the allergens. From these characteristics it is not surprising that the commonest allergens causing this type of allergy are bacteria and house dust.

Nasal sinus allergy is much less common than nasal allergy, and is nearly always the result of spread from the nose. When it does occur primarily it is usually due to foods. In many cases the swelling of the ostium leads to retention of secretion and secondary bacterial infection. In due course untreated cases of this type develop a bacterial allergy to add to the complexity of the picture. Polypi soon form and the disease beginning in one sinus gradually spreads, by obstruction and infection, to the other sinuses. In spite of the obstruction

and the gradual expansion of the nasal and sinus chambers by the pressure of the enlarging polypi there is very little pain or general malaise.

Nasopharyngeal and pharyngeal allergy are much less common than nasal allergy because of the thicker mucous membrane and the protection afforded by the nasal passages.

It is seen most commonly in children when allergy may play a part in causing excessive œdema and hyperplasia of the adenoids and tonsils. It should be suspected when diffuse lymphoid hyperplasia resists treatment and recurs repeatedly in spite of every care; bacterial allergy then usually plays a part, as well as sensitivity to inhalants and ingestants.

In adults the usual complaint is of tickling and irritation of the palate. There may be hypersensitivity to very hot, very cold or highly spiced food, which in severe cases cause coughing and choking. As with other allergies of the nose and bronchi the patient is often woken up by an attack in the early morning, or this begins on waking or on rising from bed. The triggers that initiate the reaction then are the changes of temperature and the changing of the patient's metabolism and particularly the rise in metabolism and sudden activity in the upper respiratory tract after rest.

The following is the history of such a case.

A woman aged 58 complained that for eight years she had had severe paroxysms of dry tickling cough from the throat lasting ten minutes. After consulting many doctors she was finally treated by ultraviolet light and before the course was finished she had developed also violent attacks of sneezing and rhinorrhœa. The attacks came on at any time of the day or night and she was often woken by them in the early morning. They were induced by change of temperature, a close atmosphere, tobacco smoke, laughing and eating sugar or cheese. They were relieved by hot whisky and particularly by liquorice. During the paroxysm she was unable to talk.

The only physical signs were those of definite sepsis in both small buried tonsils. Touching the tonsils immediately induced an attack. Skin tests for inhalants and ingestants were negative. She was relieved by antihistamines.

Of interest in this case was the allergization to ultraviolet light during treatment and the patient's observation of the special effect of liquorice.

Angioneurotic œdema provides another type of pharyngeal allergy, in which obstruction is the chief feature, and foods are the most frequent allergens.

Laryngeal allergy is seen in children in the form of croup. In adults it presents as paroxysms of dry cough, which may even prevent phonation, and possibly in an extreme form may cause vertigo and loss of consciousness. This is one of the causes of "laryngeal vertigo". The typical cough reaction, like that of asthma, is sometimes most severe in the early morning or following exertion or laughing. Angioneurotic œdema may also occur in the larynx and cause obstruction as it does in the pharynx. It is probable that cases of chronic hypertrophic laryngitis seen in stokers and workers in the paint industry represent localized physical and chemical allergies.

(5) *Diagnosis and Special Methods of Diagnosis*

(*a*) *The history is of special importance*, particularly if the patient is seen in a quiescent period.

(*b*) *Routine general clinical examination.*

(*c*) *Specific skin tests.*

I must confess to having been very sceptical of the value of skin tests in my earlier days. Perhaps I was biased after being consulted by a lady who informed me that while she was living in California she was submitted to 420 skin tests, and that she proved sensitive to 140 of them. With advancing experience I have learned to regard them with much greater respect, and I now consider that they often provide most valuable information. They seem to be most dependable for inhalant allergens, much less dependable for ingestants, and of very little value in bacterial allergy.

In my recent series of 168 cases of nasal allergy we obtained positive skin tests in all but 10. At the same time control tests in 128 clinically non-allergic individuals gave positive results in 24; the remainder were negative.

The interpretation of these tests is often difficult and can only be considered with the history and clinical picture. They are not sufficiently reliable for accurate quantitative assessment and the degree of allergization of the skin and of the upper respiratory tract may be different. The tests record the effect of single allergens while the clinical effect is, as we have seen, often due to the action of multiple allergens simultaneously.

(*d*) *Intranasal tests.*—The best technique of intranasal testing is that of the powder puff. Wool is wound on to a carrier and dipped in the powdered allergen. This is held to one nostril and the patient is instructed to sniff with the other nostril closed. They are of value when the skin tests are inconclusive.

(*e*) *Diet elimination tests.*

(*f*) *Examination of nasal secretion.*—We have found it best for the patient to blow secretion into a sterile cellophane handkerchief which is screwed up tightly in a screw-cap bottle for transport to the laboratory where a differential cell count is made. Hansel (1936) maintains that over 10% of eosinophils indicates allergy but since the eosinophils are only present in the active phase their absence does not exclude allergy. When the eosinophils are very numerous the secretion may resemble pus macroscopically (Fig. 2).

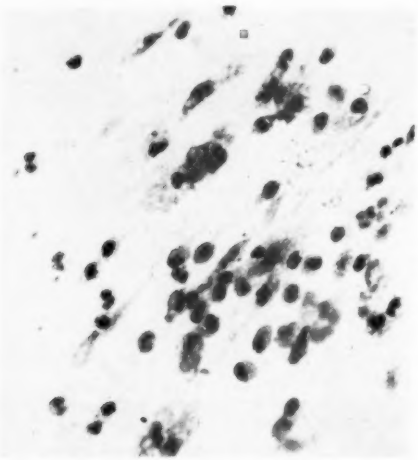

FIG. 2.—Smears of nasal secretion to show eosinophilic pus. Leishman × 390.

(*g*) *Bacteriological examination of secretion.*—Smears should be taken directly from the middle third of the nose under direct lighting and using a sterile nasal speculum to avoid contamination from the anterior third of the nose. Positive cultures indicate active infection, but failure to obtain a culture does not exclude the presence of infection.

(*h*) *Radiographs of the nasal sinuses* should be taken in all but the minor cases. The presence of allergic changes in the sinus mucous membranes are shown in the slightest degree by mottled clouding, and in the more severe degrees by definite polypoid changes or complete opacity, the last being due either to polypi or to polypi and retained allergic secretion or pus.

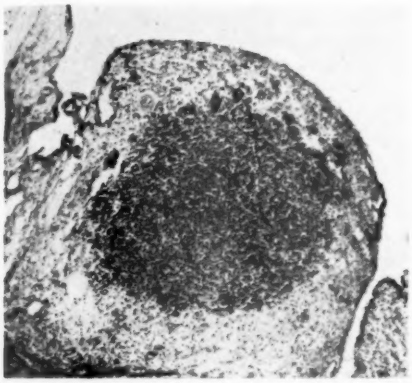

FIG. 3.—Antral mucous membrane showing eosinophil granuloma in the submucosal layer with fibroblasts in the stroma. H. and E. × 49.

(f) *Histological examination.*—In very complicated cases I have found it useful to take a biopsy specimen from the inferior turbinal with a very fine aural granulation forceps. Under local anæsthesia it is quite painless, heals completely in a day or two and causes no disability.

The relative degrees of allergic and inflammatory reaction are well seen and an assessment of the degree of chronic change can also be made.

In inhalant and ingestant allergies eosinophil infiltration will be seen in the active phase, whereas in infective and bacterial and physical allergies eosinophils are absent.

(6) *Treatment*

Methods of treatment fall into the following groups:

(1) Elimination of the predisposing factors. (2) Avoidance of the allergens responsible. (3) General treatment with vitamins, acids, calcium, &c. (4) Specific hyposensitization, including the use of bacterial vaccines. (5) Palliative treatment with: (*a*) Antihistamines. (*b*) Hormone therapy. (*c*) Sympathetic stimulants and parasympathetic depressants. (*d*) Glycyrrhetinic acid. (6) Ionization. (7) Cauterization. (8) Psychological.

General Considerations in Treatment

It is important to remember above all that we are treating a patient and not only his disease. In selecting treatment care must be taken that the cure does not prove more unpleasant than the disease. It is by no means uncommon for minor allergy to subside spontaneously but it is important that severe allergy should be checked by all reasonable means. The longer it is allowed to continue the more severe it is likely to become and the greater the risk of spread to other tissues, the development of multiple allergies and of superadded infection. Short attacks of up to half an hour do not need treatment.

In seasonal allergy if the seasons are short and the attacks not severe it is justifiable to rely on antihistamines, hormone therapy and the other groups of drugs.

In perennial allergy we should eliminate predisposing factors as far as possible and build up the general condition to reduce the sensitivity.

In these cases the treatment of infection is of the greatest importance. Then the allergens should be identified by the history and specific testing and elimination diets and cultures. The patient is given instructions how to avoid, as far as possible, contact with them. This may be all that is necessary, but if it does not give sufficient relief specific hyposensitizing injections should be used. In our series improvement was obtained in 50% of cases by these measures. The most successful results in hyposensitization are achieved in seasonal pollinosis. By annual pre-seasonal courses of inoculation in increasing doses 70–80% of sufferers can be rendered comfortable. Treatment should be continued for at least two years after complete freedom.

Treatment of the predisposing factors.—Apart from heredity the two main predisposing factors to upper respiratory allergy are obstruction and infection. I am convinced now that because of their hypersensitive nervous state, allergic patients suffer much greater discomfort from moderate degrees of deviation of the septum and of sinusitis than the non-allergic and one's standards of indications for operations should be adjusted accordingly. This does not mean that drastic sinus surgery should be undertaken if a moderately severe sinusitis is discovered in an allergic patient.

If some infection persists in spite of the most careful treatment, then an autogenous vaccine should be given. Autogenous vaccines are often of great therapeutic value in the infected allergic patient provided that all foci have free drainage: they should not be used for chronic sinusitis without adequate drainage.

Polypi deserve special consideration. Their presence is almost certainly an indication of allergy. The small sessile polypi which develop on the middle turbinal and also in the accessory sinuses will shrink in many cases with adequate treatment of the allergic factor. But if those in the nose do not respond quickly they should be removed to restore a complete nasal airway and to allow ciliary action and recovery of the protective mucous sheet. Simple allergic polypi in the sinuses do not require surgical treatment unless they become subject to recurrent attacks of inflammation or block the sinus ostium.

Chronic sinusitis with allergy and polypi in the sinuses and in the nose should be treated by operation. The polypi should be removed from the sinuses as well as the nose and adequate drainage established. It is of the greatest importance to make certain that no foci of infection remain. As many of these patients have a bacterial allergy they continue to suffer severely if even a very minor focus is overlooked.

We have found operations necessary in 15% of our cases and have obtained relief in 80% of cases treated by operative and specific allergic treatment.

(7) *Palliative Treatment*

General considerations.—Antihistamines, hormones, sympathetic stimulating and parasympathetic depressant drugs are useful to tide a patient over a severe exacerbation, and also for treatment of short seasonal allergies, but they are not really curative and the symptoms recur when the drug is stopped. In some instances, however, prevention of reactions by such means for a matter of months or years has been sufficient to allow the shock tissues to recover and the patient's symptoms have not recurred on ceasing the drugs. But such a fortunate result is rare.

Antihistamines.—There is now a long list of antihistamine drugs which differ in quite minor degrees from one another. The duration of action of most antihistamines is only three to four hours, but Phenergan will last up to twenty-four hours. Unfortunately most of these drugs also cause drowsiness of variable degree when given systemically, but they are also valuable when used locally.

In order to counteract the drowsiness antihistamines can be combined with an analeptic, as in Plimasin, which contains Methyl Phenidylacetate 5 mg. and Pyribenzamine 25 mg. The former is intermediate in action between caffeine and amphetamine

In severe allergy the dosage required is so large that the undesirable side effects are too great before the patient has reached the necessary concentration to block all the histamine.

For some years there was a vogue for desensitization with histamine, but it is now very rarely employed.

DRUGS ACTING ON THE PERIPHERAL NERVES

Sympathetic Stimulants	*Parasympathetic Depressants*
Adrenaline	Belladonna
Ephedrine	Atropine
Phenylephrine and other synthetic drugs	Hyoscyamus
Ergotamine	Stramonium
Caffeine	
Aminophylline	

Local anæsthetics.—Cocaine, Novocain, and other local anæsthetics, depress local sensitivity and suppress allergic reactions.

Sympathetic stimulants.—Of the proprietary preparations, Fenox, which contains the two vasoconstrictors phenylephrine hydrochloride 0·25% and naphazoline nitrate 0·025%, is the most powerful and long-acting, but its indiscriminate use has had a remarkable habit-forming effect. I have seen a dozen or more patients who, having begun to use these drugs locally as drops, have continued to apply them every three or four hours for months and in some cases for years. Several of these patients have even woken up once or twice every night for further application. As the effect passes off the nasal obstruction becomes complete and the patient is frantic until relieved by a further application. The nasal reflexes are paralysed and the constrictive effect of other drugs diminished (Fig. 4).

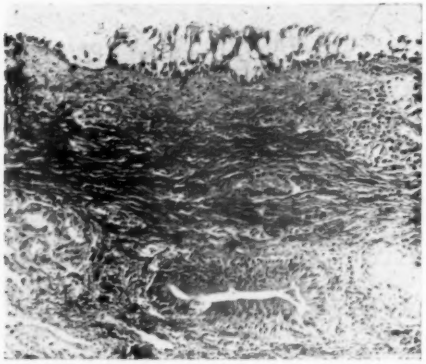

FIG. 4.—Nasal mucosa from a case of Fenox addiction showing an unusual degree of fibrosis in the upper part of the submucosa replacing the basement membrane. There is intense vascular engorgement, patchy denuded epithelium and the remainder shows mucous distension. Eosinophils are absent. Aniline blue trichrome ×85.

If the Fenox is discontinued the reaction subsides in the course of several days but in order to overcome the habit the patient may have to be admitted to hospital and assisted with sedatives and treatment of the allergy and the nasal airway restored by correction of abnormalities.

Hormones.—The hormones cortisone and hydrocortisone may be used generally or locally in a spray or snuff, these drugs are powerful suppressors of the allergic and inflammatory response to infection. They cause a rapid disintegration of eosinophil cells and lymphocytes in the blood and release many antibodies. They have a number of undesirable side-effects, chief amongst which are salt and fluid retention leading to œdema and moon face.

By systemic treatment good results in nasal allergy were reported by Stewart (1953) and more recently Herxheimer and McAllen (1956) have reported success using a hydrocortisone snuff for hay fever.

Recently two synthetic analogues of cortisone and hydrocortisone, prednisone and prednisolone have been introduced with four or five times the potency of the previous drugs. They are also much less likely to induce undesirable side reactions and should prove a useful addition to our choice of treatment. Their effect on allergic œdema is so great that systemic treatment with these drugs is reported to have caused even fully-developed polypi to disappear.

More recently still a new anti-inflammatory agent has been described in extract of liquorice. The active principle is glycyrrhetinic acid and is used locally. Its molecular structure bears a close resemblance to that of hydrocortisone and there are preliminary reports of its anti-inflammatory action in skin diseases (Colin-Jones, 1956). Liquorice has been used as a constituent of sedative throat lozenges for many years.

Cauterization and ionization.—It is unfortunately true that the preceding treatments do not give relief in all cases, and then zinc ionization and light cauterization (Francis, 1932) are of some value. Linear cauterization is also the best and safest method of reducing the thickness of the mucous membrane in chronic allergy. None of these methods should be employed until the best result has been achieved by the other measures.

Conclusion

Finally, although the understanding of the essential nature of allergy still evades us, we are fortunate in having a wide choice of different methods of treatment. With the rapid advance in biochemistry and biophysics the day may not be far distant when a specific curative measure will be found to relieve the millions of sufferers from this miserable complaint. In the meantime there are already valuable methods of treatment that can give very adequate relief to the majority of patients.

But to succeed, our investigation must be thoroughly performed and treatment meticulously carried out with the closest collaboration between the allergist, pathologist and laryngologist.

I am greatly indebted to Dr. H. Saphier, who has undertaken the detailed investigation of many of my patients in the allergy research clinic at the Bristol General Hospital. I wish to thank Dr. A. L. Taylor for his help and advice on the pathological problems, and Dr. E. Price for the preparation of the photomicrographs.

Mr. F. C. W. Capps said that in tackling so difficult a problem, the President had given them an authoritative survey for reference.

Mr. C. Gill-Carey said that lack of accurate means of assessing the results of treatment had been his main problem. In a high percentage, both the nasal examination and the statements of patients were indeterminate. Nasal biopsy, carried out in a number of cases, had also been unreliable as a means of assessment.

Mr. H. V. Forster said that many years ago he had read that on this side of the Atlantic ragweed pollen might appear as an autumn irritant. The pollen was said to disperse over great distances and even to high altitudes where observers had collected it using the aeroplane.

Had the President noticed in his overall clinical assessment of the allergic adult patient a rather high quality of the individual teeth apart from their regularity?

When examining a child, who after all rarely spoke for himself, it was a matter of the highest priority for the laryngologist to be on the look-out for signs of allergic nasal catarrh. It was to be separated from the adenoid problem where one might see a quiescent nose with adequate passages striving hopelessly to pass air across a wall of post-nasal adenoid. The intrinsically dirty nose was often a state independent of adenoids.

A picture less hopeful was that of established purulent sinusitis with a history of infantile bronchiectasis to remind the laryngologist of his duty to co-operate with his physician colleague not least, when he had discovered a case of typical nasal allergy with its permanently wet nose and pale waterlogged inferior turbinates.

He would agree with the President that the surgical treatment of this body, which may have been harshly treated in olden days, should be most conservative. It was part of a superb air-conditioning mechanism and yet would often respond gratefully to linear cautery with the galvanic point, a minor operation done so conveniently under local surface anæsthesia in the adult but unfortunately calling for a general anæsthetic in the normally apprehensive child.

Mr. Philip Jory said that in a number of cases an allergic upset preceded the onset of the common cold. For some years he had been prone to develop a severe cold after long out-patient sessions, but had found that if he took an antihistaminic as soon as he felt the first symptoms he could almost always prevent the cold from developing. However, once the cold had become established the anti-histaminic appeared to have no curative effect.

Mr. W. A. Mill mentioned that wines and sherries not uncommonly gave rise to allergic rhinitis and he had met a patient in whom whisky had the same effect.

Mr. W. O. Lodge asked if the President, on looking through his case-books, had noticed whether most young males in particular grew out of their allergies or died at an early age from bronchiectasis and whether any significant proportion of patients with recurrent nasal polypi developed frontal sinusitis in adult life or—eventually—carcinoma.

Mr. R. D. Owen asked whether, in cases who came complaining of sneezing and wheezing and had real polypi, *conservative* treatment was found satisfactory. If it was decided to operate, was the operation conservative, dealing with just the polyposis, or was it a more radical operation in the form of transantral ethmoidectomy?

The President, in reply to Mr. Mill, said that he had had several patients who were allergic to alcoholic liquors, and that the commonest of all was sherry.

In reply to Mr. Lodge, he agreed that the young asthmatic presented a difficult problem, but that if nasal function was restored, the infective foci eliminated and the allergic factors carefully treated, a considerable number could be satisfactorily relieved of their symptoms. He commented that carcinomatous changes in nasal polypi were very rare.

In reply to Mr. Owen, when nasal polypi were associated with polypoid changes in the sinuses and complicated by chronic or recurrent infection, he advised opening the affected sinus and removing the polypi and thickened mucous membrane.

In reply to Mr. Forster, the President said that ragweed pollen was probably the commonest cause of pollinosis in the United States. Its season was the autumn, but in his experience it was rare in this country. He had not noted a particular quality of individual teeth among allergic patients.

SYMPOSIUM: THE USE OF METAL IN BONE SURGERY

Mr. G. K. McKee (Norwich):

History.—The story of the use of metal in bone surgery has not been a particularly happy one. Pioneers such as Lane and Lambotte were striving after perfect reduction and secure fixation in the treatment of fractures, but their efforts were spoilt by the use of unsuitable metal. The use of metal in bone surgery presents two problems:

A. Corrosion or the reaction of the metal in the body tissues.

B. The indications for the use of metal in the treatment of bony injuries and diseases.

Both these problems are closely related because the indications for the use of metal will increase as the corrosion rate decreases, i.e. as more suitable metals or metallic alloys are found.

It is impossible to deal with either completely, so I propose to limit my comments to a report on some corrosion tests carried out for me by Mr. D. H. McCracken of the Engineering Department of the City of Norwich, and to some of my own personal experiences in the use of metal in bone surgery.

A. Corrosion Tests on Metals Used for Internal Fixation

It is assumed that the corrosion of metals in the body is largely due to electro-chemical action. The tests were therefore designed to compare the relative rates of electro-chemical attack on two types of stainless steel and on the non-ferrous alloy Vitallium.

If two different metals are in contact and are immersed in an electrolyte such as a body fluid, one metal will become electrically positive relative to the other. Current will flow from metal to metal through the point of contact from the positive metal to the negative metal. The circuit is completed by the current flowing through the electrolyte, from negative metal to positive metal. Thus an electrolytic cell is formed in which the negative metal is the anode and the positive metal is the cathode.

If the electrolyte contains Cl ions these will migrate to the anodic metal and give rise to chemical attack. The result is usually oxidation of the attacked metal. Some metals, such as those under consideration here, tend to form oxide films which have a high resistance to penetration by ions. Should a perfect oxide film be established this will suppress all further attack and the metal is said to have become "passive". The metal which is "cathodic" experiences no attack under these simple basic conditions.

If two identical metals are used to form a cell then no electrical potential difference is created between them, no current flows and there is no attack. In practice it is virtually impossible to produce metal components of identical material. Plates and screws for example will be produced from different metal stocks and although of the same nominal composition there will inevitably be some slight differences. Surface working during machining operations will itself create some degree of electrical potential. The creation of a passive oxide film on the anodic metal must therefore be the main barrier against corrosion.

It has been established that the presence of molybdenum in an alloy is an aid to the establishment of a barrier film of oxide and recommendations have been made that if stainless steel is to be used for internal fixation it should contain some 2½% to 3½% molybdenum.

Production of screws is simplified if one of the "free-cutting" stainless steels such as Firth's EMS is used. This contains only 0·3% molybdenum. There is an obvious danger of strong corrosive attack if EMS screws are used in conjunction with molybdenum steel plates.

Materials Tested

Firth's FMB	C 0·12,	Si 0·2,	Mn 2·0,	Ni 8/12,	
	Cr 17/20,	Mo 2·5/3·5.			
Firth's EMS	C 0·12,	Si 0·6,	Mn 1·2,	Cr 18,	Ni 10,
	Mo 0·3,	Ti 0·6,	Zr 0·25.		
Vitallium	Co 65,	Cr 30,	Mo 5.		

Cells were set up with the metals as electrodes in various combinations in an electrolyte, and the strength and duration of the currents produced were measured. From the experiments the following conclusions can be drawn:

Vitallium appears to be quite free from corrosion. Presumably a completely passive film is built up very quickly and the film remains stable.

With the various stainless steels, corrosion must be expected. The worst conditions are when two different steels are used in conjunction. Plates and screws made of the same material will corrode, even when both contain 2½% to 3½% molybdenum. The screw is anodic and, therefore, suffers greater attack than the plate. Vitallium screws used with FMB stainless steel plate are not attacked; the plate being anodic does show some evidence of corrosion but not more than when used with a stainless steel screw of the same composition.

As a result of these experiments I have been using Vitallium screws and stainless steel plates ever since 1942 and have never seen any reaction around the screws, although there has often been considerable corrosion around the plate. The only difficulty with regard to the use of Vitallium screws is that, after being in for some years, they tend to bond on to the bone and may be extremely difficult to remove. In many instances, however, where screws of stainless steel have been used with a nail and plate of the same composition, FMB, there has been considerable reaction around where the screws and plate are in contact and the screws become loose in time. The experience in the use of these metals in the body over a period of fifteen years or so has confirmed the conclusions arrived at by Mr. D. H. McCracken.

B. Indications for the Use of Metal in Bone Surgery

Stainless steel of the variety known as FMB appears in practice to be quite satisfactory where a temporary fixation is required, e.g. in cases of fractures and arthrodesis operations, but where a permanent metallic insert is required to remain tightly bonded on to the bone as a functioning prosthesis, for example in the various types of arthroplasties, then undoubtedly chromium cobalt alloy is not only the most satisfactory, but in my opinion is at present the only material to use.

A lag-screw arthrodesis of the hip (McKee, 1957) is a good example of the use of stainless steel for fixation and compression; fixation was sufficient to avoid the use of plaster in 76% of the cases. The nail and plate for pertrochanteric fractures and the Küntscher nail for fractures of the femoral shaft are further examples of the use of stainless steel as a means of temporary fixation.

Many years ago, soon after cup arthroplasties had become popular in 1939, I designed an *artificial hip-joint*, but it was not until a lag screw had been used for an arthrodesis of the hip that it was realized that the most satisfactory way of securing an adequate hold on the ilium was by a large coarse-threaded screw. In fact this type of screw obtains such a firm grip that the idea to develop a ball and socket joint at the hip level, so as to retain a certain amount of mobility, was a fairly obvious one (Fig. 1). In the first series the lower end of the joint was fixed by a plate to the lateral aspect of the femoral shaft in the same way as in the lag-screw arthrodesis. Three artificial hip-joints were made up in this way (Fig. 2), and they all proved very satisfactory to start with, but in each case the stainless steel screws eventually loosened or the neck of the stainless steel plate fractured with resultant failure.

These 3 cases were failures because of the use of unsuitable metal, but they convinced me that the artificial hip-joint offered unique advantages as a form of arthroplasty, especially in cases where the acetabulum was corroded. A design for the manufacture of an artificial hip-joint entirely in chromium cobalt alloy (Vinertia) was developed, using a larger ball, and the suggestion of Mr. John Bunyan to use a tulip cup with three petals to grip the ball eliminated the complicated screw rim which had been previously used (Fig. 3).

This design has been used in 5 cases since May 1956, and the acetabular portion has been found to be most satisfactory; the design of the femoral portion has, however, had to be altered. First of all, a femoral blade, like those used on Thompson's prosthesis was tried, but as the first cases were salvage operations for failed acrylic prosthesis, the grip in the hollowed-out neck of the femur was not felt to be adequate, and eventually a broad coarse screw was used, long enough to traverse the whole neck, and engage the thick strong lateral femoral cortex; this gives an exceptionally secure fixation even where the neck of the femur is just a shell (Figs. 3 and 4). It is too early to make any extravagant claims, but with the use of Vinertia there is every reason to expect that it will last in the body for many years.

The first few cases were fairly desperate ones where pain was a prominent symptom; the roof of the acetabulum having gradually eroded away and the acrylic prosthesis being broken or loose. The replacement by an artificial hip-joint seemed to offer a better answer to this problem than any other form of arthroplasty because it reconstructed the acetabulum and the results so far show that these patients have steadily improved month by month as regards losing their pain and increasing their activities. The fixation obtained by the latest design has been so satisfactory that its application has been extended to bilateral cases in old people, and to unilateral cases if arthritic changes are present in the lumbar spine.

The follow-up of these cases so far indicates that the artificial hip-joint offers a functional result comparable with arthrodesis, but without the disadvantages of a completely fixed hip. The range of movement obtained is not as full as in a normal joint, but it does enable the old patient to sit down in comfort. Before this type of operation is carried out, symptom

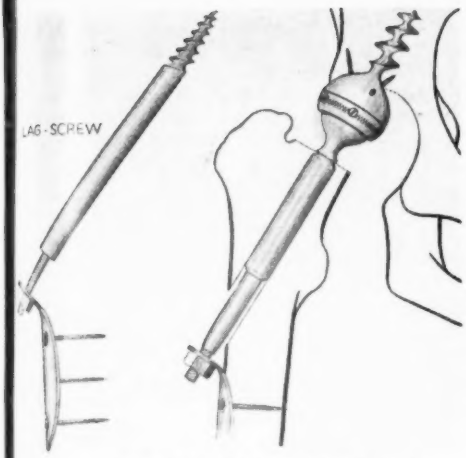

FIG. 1.—The first artificial hip-joint, derived from a lag-screw.

must be of a considerable degree of severity, and if in doubt the patient must be kept under observation for several months or even a year or two before operation.

The artificial hip-joint does, however, help to solve the problem of the failed acrylic prosthesis especially where the acetabulum has become eroded.

Mr. John Charnley (Manchester): *The Reaction of Bone to Metal*

I wish to consider the mechanical factors, that is to say simple mechanical stresses and strains, which may be concerned in the loosening of metallic fixation in bone.

There are two different aspects to be considered: (1) the short-term problem, seen in the internal fixation of fractures, where successful union of the fracture renders the internal splint functionless, and (2) the long-term problem, seen in prosthetic replacements, where the metallic implant is expected permanently to bond itself to bone and share in the transmission of stress and strain without loosening.

I shall confine my remarks to the mechanical causes of the loosening of metallic fixation because I do not believe that electro-chemical reactions which can occur between metals of slightly dissimilar composition present anything more than a subsidiary problem. While it is obvious that all forms of corrosion must be eliminated in prostheses which are to remain permanently in the body, the problem is quite different in the short-term function of internal fixation in the union of fractures. Electro-chemical reactions are situated at a considerable distance from the fracture site, and I think it would be more profitable to re-study the whole problem of internal fixation in relation to the biology of fracture union rather than transfer blame to small technical defects in modern apparatus. We must not forget that Arbuthnot Lane established the internal fixation of fractures even though he used plates of reactive steel held by brass screws, a combination infinitely worse than any we use at the present moment.

When we consider the mechanical factors responsible for the loosening of metallic fixation, I suggest that the following features are worthy of special consideration:

(1) *The reaction of bone to metal in the absence of transmitted stress.*—It is no uncommon experience to find it impossible to extract screws from a plated fracture if there has been an interval of months or years after union has taken place. One explanation of this difficulty is that new bone grows into the "flutes" of the self-tapping end and so locks the screw against rotation, but this small amount of new bone would present no great resistance to shearing if the rest of the screw were free to turn in the bone. Difficulty in extracting stainless steel screws is even harder to explain than in cobalt chromium alloy screws, because the latter have a matt finish and one can imagine that the encroachment of new bone on such a rough surface would produce much greater frictional resistance than would be possible by the encroachment of new bone on to the highly polished thread presented by a stainless steel screw.

It seems reasonable to accept as a fact that, in the absence of transmitted stress following the union of a fracture, living bone can sometimes grip the polished surface of a non-toxic metal with a greater force than at the time of its insertion. We can therefore deduce that there is no fundamental antagonism between a relatively inert metallic surface and living bone in contact with it, and therefore that any resorption of the bone in contact with such a metallic surface is most likely to be the result of transmitted mechanical stress.

(2) *The reaction of bone to metal, with transmitted stress, in the presence of slight motion between metal and bone.*—If, as a result of technical difficulties, a metallic internal fixation is slightly loose at the end of an operation, it will never spontaneously tighten; it will, in fact, continuously and progressively become looser and the result will almost invariably be a failure.

It is difficult to be sure whether the progressive loosening of unsound mechanical fixation is the result of simple mechanical friction between the metal and the bone, or whether it is a biological process of resorption; it is probably both. A common example of this type of loosening is seen when a 4 mm. Steinmann nail is inserted through the tibial tubercle for the treatment of a fractured shaft of femur by traction. At the time of insertion this nail may be quite tight in the bone, but only too often the stirrup which is attached to the nail has a defective swivelling mechanism which prevents the stirrup turning freely on the nail without transmitting a torque to the nail and so loosening it in the bone. The same argument is against using the Kirschner wire for skeletal traction. Progressive loosening occurs even more quickly than with the Steinmann nail also because of the much higher loading, in terms of pounds to the square inch.

Motion between metal and bone and the tendency to induce mild bacterial infection.—When metal is moving against a bone surface there is always a tendency for bacterial infection to supervene, which introduces an additional cause for loosening of the metal. In the case of a Steinmann nail in the tibial tubercle the tract of infection through the skin is obvious.

But much less obvious is the spontaneous appearance of infection in cases of internal fixation where no communication with the skin exists. Hey Groves (1921), in experiments on the plating of fractures in cats, observed that when metallic fixation was inadequate, his experiments often became infected spontaneously. When, however, he used a long plate, and thereby obtained effective internal fixation, his experiments healed without infection. He decided that short plates, permitting a certain amount of motion between metal and bone, caused a collection of serous fluid at the operation site which later attracted bacterial infection.

I believe that this observation can be transferred to the surgery of the human subject. The size of the metallic implant is not related to the tendency to become infected; it is safer to have a bulky metallic fixation which is mechanically effective than a small implant which is inefficient. This is one reason why I believe that implants used in arthroplasty will always have a significant post-operative infection rate in comparison with soundly conceived procedures designed to achieve arthrodesis, because in the latter movement between metal and bone is avoided.

(3) *The reaction of bone to metal, with transmitted stress, in the absence of motion between bone and metal.*—It is an elementary engineering axiom that stress cannot exist without strain; i.e. if a force is applied to a structure the latter will be deflected or distorted according to the magnitude of the force and the elasticity of the structure. The essential feature is that, up to a certain point, during the application of stress to bone through a metallic fixation a molecular distortion of the bone can take place without any movement occurring between the surface of the metal and the bone itself. It is obvious therefore that stress can be applied to bone only up to certain limits of elasticity; beyond this point, crushing of the bone will occur and an infinitely small degree of mechanical loosening of the fixation will result; thereafter a train of events will follow, causing progressive loosening.

Where stress is applied to bone in *constantly the same direction*, without motion between metal and bone, living bone can frequently resist the action of powerful mechanical forces for several months. My observations are contrary to the accepted idea that living bone will melt away when a metallic object is pressed against it, just as a wire will cut through a block of ice. In compression arthrodesis of the knee I invariably apply a force exceeding 100 lb., yet it is a common experience to find that one, or both, of the nails may still offer resistance to extraction four weeks later. Calculations show that the load on the transfixed cortex exceeds 1,500 lb. per sq. in., and it is astonishing, but true, that after four weeks under this force such a nail often can still be tight in the bone.

FIG. 1.

Fig. 1 shows how differently cortical bone and cancellous bone react under high mechanical pressure. In an ankle-joint fused by compression the tracks of the nails through which the compression force was originally inserted are still clearly visible in the X-ray. It will be observed that the hole in the dense cortical bone of the lower end of the tibia shows no reaction whatsoever; the hole is perfectly circular and shows no ovality, as one might expect if some absorption took place. The nail extracted from this site was quite firm four weeks after the operation. This lack of reaction strongly suggests that the cortical bone at this point of the tibia is extremely inert. On the other hand, the track of the distal nail through the cancellous bone of the talus shows that there has been a considerable sclerosing reaction under the influence of the pressure. It will be observed that the response of the cancellous bone is *not an osteoclastic response;* it is on the contrary the reaction of sclerosis resisting pressure.

Observations on spring-loaded screws.—I have had considerable experience with the application of spring-loaded pressure to cancellous bone, using screws with large-diameter helical threads. If the screw is protected from angulating strains and a pure longitudinal pull is applied, the spring will retain its pressure for even as long as one year before the spring opens to its full length. It is too early at the moment to make any positive calculation from these observations, but it is my impression based on calculations of the total surface area of the helical threads that, provided the pressure is constantly in one direction and no movement takes place between metal and bone, cancellous bone can resist a pressure of probably more than 25, and something less than 50 lb./sq. in. for longer

than six months before finally yielding to the pull of the spring. When the screw is first inserted the traction force will be exerted principally on the first one or two helices and will thus shield the remaining helices from the full force of the spring. If this force is too great for the mechanical strength of the bone some collapse will occur until all the helices receive approximately the same thrust.

I take this opportunity of making the suggestion that experiments with spring-loaded screws applied to suitable animals would yield fundamental information on the reaction of living cancellous bone to pressure in the absence of movement. This could be done in the absence of fractures which in the human subject always complicate the interpretation of extrusion of the screw under spring-loading.

Osteoclasis and remodelling.—The reaction of bone to the stress applied to it through a metallic fixation depends on the duration of the stress. Three phases of duration can be distinguished. The earliest phase is that of simple mechanical loosening, caused by forces too great for the strength of the bone, or by forces acting in irregular directions which the fixation may not be designed to resist. This type of mechanical loosening will occur within minutes, hours, or days of the operation. If the force acts continuously in one direction, the second phase, I believe, is an osteogenic reaction designed to resist the applied stress. Cortical bone shows very little osteogenic reaction, but cancellous bone reacts vigorously. This osteogenic phase I believe lasts from one to two months. Beyond this time the third phase commences, which is the process of "remodelling". Here a balanced process of osteogenesis and osteoclasis is in action simultaneously with the object of neutralizing the applied stress. This phase lasts very many months and it is the mechanism underlying Wolff's law of the adaptation of bone architecture to function. If a spring-loaded compression screw is applied to bone this final phase (remodelling) will permit the screw slowly to extrude until all spring pressure is abolished and equilibrium is again attained. It is to be clearly understood that in this process the cancellous bone engaging the screw moves with the screw—a process quite different from the mechanical shearing of bone under excessive force.

Conclusions

The short-term problem.—Healthy cortical bone is remarkably inert during the first four weeks and can resist pressure between 1,000 and 2,000 lb./sq. in. without mechanical collapse or biological resorption. This resistance is only possible if no friction occurs between the metal and the bone.

Close texture cancellous bone can resist pressure of over 25 lb./sq. in. during the first four weeks and this resistance is accompanied by a vigorous osteogenic response. Even more than cortical bone, cancellous bone is only able to resist pressure in a constant direction and in the absence of friction.

The long-term problem.—After the initial period of one or two months the reaction of bone to an implant is totally directed to neutralizing local mechanical pressures by the process of "remodelling". Just how small is the minimum pressure needed to start this process of remodelling is unknown; it is probably exceedingly small because it is well known that even cortical bone will remodel under the gentle pressure of a ganglion if the latter presses against it for several years. It would therefore seem unlikely that a permanent metallic prosthesis, intended to carry the weight of the body, could ever be constructed with a method of attachment to the bone designed to diffuse the load over a large surface area such that the pressure would be reduced below that which would initiate remodelling. The problem is rendered all the more impossible when one realizes that any bone-to-metal bond would be exposed to a multitude of stress reversals in a variety of unpredictable directions.

Groves, E. W. H. (1921) On Modern Methods of Treating Fractures. Bristol.

Mr. J. H. Hicks (Birmingham): *The Relationship between Metal and Infection*

The use of metal in orthopædic surgery is frequently criticized. Some of the criticisms are justified: others are not. One that requires careful scrutiny is the suggestion that metal causes infection.

There is no question that corroding metal has often caused inflammation, particularly in the early days of its use. I am careful to use the word "inflammation" because I believe a mistake has been to assume that inflammation signifies infection. Inflammation can be caused in other ways than by infection, however; it can be caused by mechanical irritation and by toxic chemicals. I suggest that, in fracture surgery at least, infection has in fact never been a common cause of inflammation and that often it has been assumed guilty when the real cause has been overlooked.

The toxic chemicals referred to are the products of corrosion of metal, namely, compounds of iron, chromium, nickel, molybdenum or manganese. At least two of these

are known for their poisonous properties in other spheres. Our experience at the Birmingham Accident Hospital of about one hundred cases in the outbreak of 1950–54 described elsewhere (Cuter and Hicks, 1956) was (i) that corrosion could give rise to inflammation in the absence of infection (Hicks, 1958); (ii) that corrosion enabled organisms, both pathogenic and non-pathogenic, sometimes to persist harmlessly in wounds long after they would ordinarily have disappeared; and (iii) that only in a small proportion of cases may corrosion have encouraged secondary infection.

We also realized that the inflammation caused by corrosion, or by corrosion with secondary infection, was indistinguishable, except by histological and sometimes by bacteriological examination, from the inflammation caused by pure infection. Fig. 1, showing a typical corrosion reaction, illustrates the impossibility of distinguishing clinically.

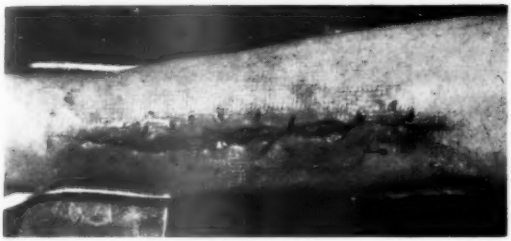

FIG. 1.

In this particular case a few staphylococci were present but in such small numbers as to make it probable that they were not pathogenic but secondary invaders. (No antibiotic had been given.) In some of our other cases, when there had been no opportunity for secondary infection, no organisms at all could be found. Naked-eye examination of the tissues was also misleading for the metal was surrounded by what appeared to be typical septic granulation tissue. Only on histological examination were differences recognized. In other cases corrosion presented as a collection of brown fluid which from its naked-eye appearance was called an infected hæmatoma. Again culture revealed that some contained no pathogenic organisms and that a few contained no organisms at all.

The distinction between the inflammation due to toxic chemicals and the inflammation due to bacterial infection is important if treatment is to be correct. The remedy for corrosion is to remove the metal together with its corrosion products, and the remedy for infection is equally specific. Similarly in prevention, it would be quite useless to tighten up aseptic regime in theatre if the real cause for the inflammation were unsuitable metal. This, I suggest, is what we actually have been doing.

Stainless Steels in Surgery

Most of the trouble in surgery has come from the use of unsuitable stainless steels. Only ordinary steel and vanadium steel were used in England for the manufacture of plates

TABLE I.—STEELS USED IN SURGERY. IN CHRONOLOGICAL ORDER

Not a stainless steel	**Vanadium steel**	Ordinary steel plus 0·1% vanadium
Stainless steels	**Chrome steel**	(Approx.) 13% chromium, no nickel
	18/8 (syn. F.S.L.)	(Approx.) 18% chromium, 8% nickel
	S.Mo. (syns. FMB, molybdenum steel) ..	As above plus 3% molybdenum
	EMS	As 18/8 plus 1·6% manganese

Corrodible steels are printed in **heavy type.**
Non-corrodible steels are printed in ordinary type.

(Note that in the conditions obtaining in the body the term "stainless" is no guarantee of freedom from corrosion.)

and screws until about 1935. These metals are now known to have a high incidence—perhaps 100%— of gross corrosion. The change-over to 18/8 stainless steel for plates and screws was not complete until 1938. For Smith-Petersen type nails during these years chrome steel was used and this continued, alternatively with 18/8, until 1941. Thus, from 1935 to 1941 two different steels were being sold under the name "stainless", one (the chrome steel) having a high rate of severe corrosion, and the other (the 18/8 or so-called "non-toxic") being relatively safe. The post-war years have been marred by EMS (Cuter and Hicks, 1956). This was a stainless steel with a corrosion rate of up to 40% introduced for certain screws unintentionally in 1950 and sold under the label of "non-toxic" over a four-year period. There has not been any long unbroken period, therefore, during which exclusively safe metal has been sold in this country.

All these changes have been slow to reach the patient and, what is worse, they have been incomplete. Steels from every period covered by this survey have been found in the theatre

stocks of some hospitals. Chrome steel and vanadium steel do not even require the stimulus of a dissimilar metal to start corroding. Inflammatory complications may therefore still arise from the use of unsuitable metals, and if the surgeon is unaware of the danger he will naturally conclude that his wounds are becoming infected.

Next I want to show how, as a result, the mistaken idea has been built up that bone is peculiarly susceptible to infection.

Lane was one of the first to assume that the inflammatory reaction he was seeing after plating was due to infection. The no-touch technique was his attempt to carry oligosepsis to an extreme. Surgeons failed to consider the possibility that the steady undercurrent of inflamed wounds might be due to some entirely different cause. A paper by Dahl-Innersen in 1928 represents the uncritical attitude that has persisted ever since: he accepts that infection was the cause of the trouble without ever considering the bacteriology. The signs and symptoms of osteitis which he lists include all the effects that we now know to be produced by pure corrosion, by pure infection and by the two combined.

I suggest that for the first forty or fifty years of this century corrosion occurred with great regularity, that it was always mistaken for sepsis and that the whole tradition that bone is particularly susceptible to infection is based upon a fallacy.

It might be argued that even if this is correct it does not matter: unnecessarily elaborate precautions will have been taken for the past forty years but apart from the extra work involved no harm has been done. This is not true, however. A firm teaching based upon the fear of infection has grown up banning internal fixation as a routine treatment for compound fractures. But if any group of fractures is likely to benefit by internal fixation it is the severest group, which will contain most of the compound fractures. Thus the present teaching denies to these fractures a treatment most likely to be useful.

At the Accident Hospital, even before the recent outbreak of corrosion was dealt with, we were convinced that internal fixation had a large place in the treatment of fractures. Of the shaft of the tibia in adults we internally fix two-thirds of the compound fractures and only one-third of the simple fractures. There are no definite rules for selection; this represents a general tendency of the six surgeons to treat worse fractures more drastically.

The result of this policy has *not* been an overwhelming incidence of infection (*see* Table II). Although internal fixation of compound fractures resulted in an infection-rate two

TABLE II

Infection* in internal fixation:	
Simple fractures	4 in 67 (6%)
Compound fractures	7 in 47 (15%)
For comparison, infection* in compound fractures not internally fixed	4 in 30 (13%)

*Infection was defined as: cellulitis, delayed healing of wound, ulcer or sinus lasting over three months or requiring other major treatment or delaying union. There was no case of osteitis and no case of late amputation primarily due to infection. Infection. due to skin slough has been considered separately (*see* below re skin necrosis).

and a half times that of simple fractures, the compounding wounds may be becoming infected because they are compound and not necessarily because they are internally fixed. This is supported by the analysis of compound fractures *not* internally fixed which, on the same definition of infection, show a rate nearly as high. The 2% difference between the fixed and the conservatively treated compound fractures might be more than accounted for by our tendency to select the worse fractures for internal fixation and the less severe ones for conservative treatment. So far as these figures go there is, therefore, no substantiation for the belief that metal greatly increases the liability to infection in compound fractures.

This is not the whole story and it would be wrong to hide the following facts: When the analysis for sepsis was being carried out another complication came to light which proved to be much more serious. This was skin necrosis. Skin necrosis resulting in full thickness slough occurred in a disturbing number of cases. 7 out of the 8 late amputations in all fractured tibias were necessitated, partially or entirely, by skin necrosis and the infection that followed it. Although 2 of these 8 amputations had received conservative treatment it must be admitted that the incidence is higher among the internally fixed than among the conservatively treated fractures. The main argument of this paper remains unaffected since this complication is not due to the metal as such but only to the operation for putting it in. Whereas the problem of corrosion has almost been solved, however, the problem of skin necrosis still has to be dealt with before the internal fixation of fractures, simple or compound, can be considered really satisfactory.

Dr. J. M. Zarek (London): *Some Engineering Considerations in Metallic Osteosynthesis*

Metallic osteosynthesis has been of great interest to the surgeon for many centuries. Petronius (*in* Bates, 1950) in 1565 used gold to repair cleft palates and in 1775, Lapeyode and Sicre (*in* Venable and Stuck, 1947) used metallic wires for the fixation of fractured bone. In this century the advances in metallurgy have stimulated the surgeon to make a more extensive use of new materials. Some of the new techniques proved to be successful but others resulted in failures exposing the existence of problems which were often not appreciated, and in any case seldom investigated. A great number of these problems are of a metallurgical or engineering nature, and, although of primary importance, for obvious reasons have received very little attention from the medical scientist.

Apart from the bio-mechanical problems affecting the bone a great number of problems exist with the implant itself. Here we have such problems as the material to be used, design, method of manufacture and the final treatment of the implant.

The mechanism of how metallic implants are tolerated by the living tissue is not yet fully understood. Clarke and Hickman (1953) surveyed the past literature and investigated *in vitro* the possibility of correlating the electrical potentials of metals and their behaviour in biological fluids and suggested that there was a relationship between the anodic back EMF, the corrosion of metals and their behaviour in the living body. Difficulties arise, however, from the fact that implants made of what would appear to be the same material do not behave in exactly the same manner from one case to another. In this country stainless steel of the 18/8 Type (FMB) has been used quite extensively in the operating theatre and examples of the use of this material will therefore be given to illustrate my thesis.

The following examples illustrate some of the points. Fig. 1 shows a Moore's stainless steel (18/8) hip prosthesis which failed a few weeks after insertion. Being of a complex and irregular shape it was made in two parts. The larger part of the sphere was machined and "force-fitted" and welded on to the lower part which, it appears from the macrograph (Fig. 2), was cast. Because of the lack of correct heat treatment the cast material in the lower part, after etching in aqua regia, shows a marked change in its structure suggesting a change of its physical properties. Also it shows much larger grain structure than the upper part. Points A and B show the weld. It is very important to remember that some stainless steels undergo structural changes when heated in the range of 500°–800° C. When a zone of the welded object reaches that range of temperature, its effect on the steel is referred to as "weld decay", and results in a rapid attack of grain boundaries in a corrosive medium. The part at C, D and E, because of the sudden change of cross-sections, is liable to "freezing in" of internal stresses during the non-uniform process of cooling. Points C, D and E show a high degree of intergranular corrosion of the material which is due to the effect of the above factors.

Fig. 3 shows an acrylic prosthesis of the upper part of the femur in which an intramedullary

FIG. 1.—Stainless steel Moore's prosthesis.

FIG. 2.—Macrograph of the section of the upper part of the prosthesis shown in Fig. 1.

FIG. 3.—Acrylic replacement of the upper part of the femur with a stainless steel intramedullary nail.

stainless steel nail was used as a method of fixation. When the prosthesis failed examination of the nail showed high degree of corrosion of the part (A) which was covered by the plastic while that part which was in direct contact with the bone or tissue was unattacked. In this example the part of the nail covered by the plastic, because of differential oxygenation, has become anodic (lack of oxygen) in relation to the rest of the nail and caused rapid corrosion.

The above simple examples show how important the problem of design and manufacture of a prosthesis is towards a successful surgical procedure. From the engineering point of view further problems, such as fatigue or stress corrosion, are sufficiently well understood to be considered in design. However, in relation to the reconstruction of the human body further points must be considered. At the present moment we do not have a criterion of compatibility of metals to the living cell, we do not know yet why some materials although non-toxic cause post-operative complications. The answer may lie within the field of surface potentials of metals and the electrical properties and the requirements of the living cell.

It is known that when a metal is immersed in an electrolyte a potential difference is set up between the metal and the solution. We have found that the surface potential of stainless steel depends not only upon its composition but also upon its mechanical state and the treatment of the surface during the polishing process.

Experiments (Zarek, 1957) have shown that the surface potential of stainless steel is affected by mechanical working and by the type of polishing used in the finishing process.

Further, it may be of interest to note that stress, whether static or fluctuating, not only increases the rate of corrosion, but has also a very marked effect upon the surface potentials.

Finally, to emphasize the interdependence of some of the factors discussed above let us analyse some of the less obvious problems involved in the use of such a simple implant as a screw and a plate. First let us consider the shape of the thread to be used. The conventional V-shaped form of thread used in engineering is an ideal "stress raiser", producing at the root a high concentration of stress. In engineering practice it is accounted for by using a sufficiently large screw to carry safely the required load. In the human body this would mean larger degree of interference with the living system. So the shape of the thread to be used in bone should be such as to produce as little stress concentration as possible and to keep the size of the screw to a minimum. Further, the fact that concentration of metallic ions at the root of the thread, when in situ, may be different from that at the top of the thread and so establish a gradient of potential resulting from the changes of concentration polarization should not be overlooked. Fig. 4, a photo-elastic model subjected to uniform bending, shows that the effect of a V-shaped thread on the stress concentration in the core of a screw is much greater than in the rounded thread.

FIG. 4.—Photo-elastic model subjected to pure bending showing the effect of shape of notch (or screw thread) on stress concentration.

In present-day practice the lower surface of the head of the screw is conical in shape to fit the countersunk part of the plate. Corrosion is frequently set up in that part of the screw and plate. However well the plate and the screw may be matched, it is difficult to drive in the screw so that the conical surface of the head of the screw will be in continuous contact with the plate, as this will only happen when the longitudinal axis of the screw is at a right angle to the plate. All other positions will give a local contact between the screw and the plate and so produce a high pressure point of contact, causing local plastic deformation of the metal and subsequent corrosion. A spherical surface of contact between the screw and the plate would minimize this source of trouble.

Finally—the screw and the plate should be subjected to a surface treatment which will produce in both the same potential and of the required magnitude for the body to tolerate it. But what is the required value? The answer to this question must come from the biological scientist and then the complex problem of compatibility will no longer be studied in isolation (Zarek, 1957).

Acknowledgment.—My thanks are due to Mr. J. W. Rourke, B.Sc., for obtaining some of the experimental results, and to Professor J. Trueta, Mr. H. L-C. Wood and Mr. A. C. Bingold for helpful discussions. Part of the work described here has been carried out with the assistance of a Nuffield Foundation Grant which is gratefully acknowledged.

DISCUSSION ON THE CLINICAL AND RADIOLOGICAL ASPECTS OF SACRO-ILIAC DISEASE

Dr. M. Thompson: It is unusual for the sacro-iliac joints to be spared in ankylosing spondylitis, although such cases do undoubtedly occur, and account for approximately 1% of all patients with the disease. Thus Hench *et al.* (1947) quote 9 such patients in a series of 1,035; Knuttson (1950) 1 patient in a series of 147; Forestier *et al.* (1956) 2 patients in a series of 200. In my own experience of 163 patients I have known 2 such cases. The first of these patients was a woman aged 52 years with a history of peripheral arthritis and spondylitis dating from the age of 32, associated with severe psoriasis. She was anæmic and debilitated, and had ankylosis of cervical, thoracic and lumbar spines, but the sacro-iliac joints were unaffected. The second patient was a man aged 66 years who had suffered from a peripheral arthritis of the rheumatoid type for eighteen years. Classical spondylitic changes in the cervical region had developed later; the remainder of the spinal column and the sacro-iliac joints were spared.

These occasional atypical examples of spondylitis can be distinguished, on radiological and clinical grounds, from the group classified by Forestier and Rotes-Querol (1950) as suffering from senile hyperostosis of the spine.

Reference must also be made to senile changes in the sacro-iliac joints. Fibrous obliteration of these joints, occurring more or less as a normal phenomenon of advancing age, has been described (Romanus and Yden, 1955). This process leads to immobilization by intra-articular ankylosis. These changes alone do not result in radiographic obliteration of the joints, but only in narrowing of the joint space. The diagnosis of senile obliteration of the sacro-iliac joints should not be considered until full clinical and radiological evidences of spondylitis have been sought and proved absent.

In ankylosing spondylitis, sacro-iliac and vertebral symptoms may be slight, and indeed gross changes leading to complete synostosis of the joints may occur in the total absence of symptoms:

A miner, aged 31 years, was admitted to hospital suffering from a dislocated femur as the result of a motor-cycle accident. X-ray of the pelvis revealed complete synostosis of the sacro-iliac joints due to ankylosing spondylitis. Further X-rays of the remainder of the spine revealed a "poker-spine" with gross syndesmophyte formation. This patient had worked uninterruptedly as a coal-hewer in low pit seams. The only features of note in his previous medical history were an episode of duodenal type of dyspepsia and an illness characterized by gross anæmia, refractory to oral iron, but which responded to intravenous iron.

However, the vast majority of patients suffering from sacro-iliitis do have symptoms. These consist chiefly of intermittent attacks of dull, deep-seated pain in the distribution of the I and II sacral nerve roots. The principal localization of the pain is in the upper and medial quadrant of the buttocks with radiation towards the hips and the posterior aspects of the thighs. The pain is frequently nocturnal or vesperal. It is occasionally sharp and acute attacks may be precipitated by vibratory shocks to the spine or by exercise after prolonged sitting, or by both, as following a long car journey. Running is awkward and a hard kick at a ball is painful or impossible.

Stiffness is a marked feature, and usually spreads in a band-like distribution across the sacrum and buttocks as far as the hips. Occasionally the patients complain of a feeling of weakness. The changes in the sacro-iliac joints are nearly always bilateral and often approximately symmetrical; but authentic instances of unilateral sacro-iliitis have been recorded in spondylitis, and unilateral disease may persist for months or even years.

There appears to be little or no correlation between the clinical and radiological severity of the lesions. Patients may be seen with comparatively minor sclerotic lesions, but with marked pain and systemic disturbance. By contrast, others may have gross and typical radiological changes of sacro-iliitis but suffer only minimal intermittent symptoms and have normal or near-normal spinal function on clinical testing.

Reference has been made by several authors to a pre-spondylitic phase in which symptoms and signs may precede radiological evidence of sacro-iliitis:

A female patient aged 25 years who had suffered from low back pain for eighteen months had already had 2 negative X-rays taken for clinically suspected ankylosing spondylitis before a film revealed dense osteo-sclerotic lesions in the regions of both sacro-iliac joints. Erosions and pseudo-widening were demonstrated by oblique views, and the subsequent course of the illness, with progressive symptoms and signs, raised E.S.R. and anæmia, gave full confirmation to the diagnosis of ankylosing spondylitis.

Physical signs may be present at this stage of the illness, i.e. the phase of sacro-iliitis, but Boland and Present (1945) found them in only 50% of their series of 100 patients. Forestier *et al.* (1956) elicited signs of the "sacro-iliac syndrome" in 47% of their 200 patients.

The patient may walk with a limp or with a slightly stiff waddling type of gait and there may be wasting of the gluteal muscles. Local tenderness, when present, is found just below and medial to the posterior superior iliac spines, over the only part of the auricular cartilaginous portion of the joint that is not completely protected by bone. Numerous manœuvres used to induce pain on mobilization of the sacro-iliac joints have been described (Table I). None of them is absolutely pathognomonic of sacro-iliac disease;

TABLE I.—TESTS FOR SACRO-ILIAC DYSFUNCTION

Erichsen
With patient supine on a firm surface, the anterior superior iliac spines are pressed towards each other. Pain provoked in the sacro-iliac region(s) indicates a positive test.

Fabere sign (Patrick)
With patient supine, the leg is flexed at knee and hip, abducted, externally rotated and then, with the pelvis steadied by a hand on the contralateral anterior superior iliac spine, the hip is pushed into a position of extension. Pain is provoked in both hip and sacro-iliac disorders.

Gaenslen
Patient lies on one side and flexes the underlying thigh and knee. The examiner then hyperextends the upper leg with the knee extended. If pain is produced, it indicates a lesion of the sacro-iliac joints on the hyperextended side.

Laguere
With patient supine, the knee is flexed and the hip flexed and abducted. The examiner then presses down upon the contralateral anterior superior iliac spine, and upon the flexed knee. The adductors of the hip are put under tension and the iliac portion of the sacro-iliac joint is forced against the sacral surface.

Lewin
With patient supine on a firm surface, the examiner exerts pressure on both anterior superior iliac spines, forcing them laterally. This puts a stretching force upon the anterior sacro-iliac ligament.

Mennell
Tenderness just medial to the postero-superior iliac spine, indicating a lesion of the superior sacro-iliac ligaments.

Yeoman
With patient prone, the knee is flexed, a firm grasp taken of the ankle and the hip pulled into extension. The examiner's other hand is placed over the contralateral sacro-iliac joint to fix the pelvis. This manœuvre stretches the anterior sacro-iliac ligament and elicits pain in a lesion of the joint.

some are non-specific, and their interpretation may be difficult. The corresponding hip or the lumbo-sacral articulation may well be mobilized simultaneously; so that unless it is certain that there is no disease of these structures and unless the patient can accurately localize the induced discomfort to the sacro-iliac joints, the tests are negative. These manœuvres are designed either to manipulate the obliquely situated joint surfaces in a shearing or scissors-like action, or else to separate the anterior or posterior margins of the joints.

The actual radiological progression of changes in the sacro-iliac joints in ankylosing spondylitis is now well known. The process is initially patchy and destructive, the joint margins become ill-defined usually in the lower or central portions of the iliac surface; with blurring of the otherwise sharply defined subchondral bone. Pseudo-widening of the joint occurs at this stage owing to marginal decalcification and then marginal erosions; and scattered patches of decalcification along the linear margins of the iliac surface may give rise to the rosary effect described by Scott (1942). At the same time, varying degrees of sclerosis and new bone formation occur with bridging of the joint. This marked polymorphism of the radiological signs correlates well with the observed pathological features of the disease; inflammatory, destructive and reparative processes occurring simultaneously within the same joint. When healing is complete, the joint space becomes completely bridged and obliterated. At this stage, sclerosis decreases and ultimately the area becomes osteoporotic.

The evolution of the full range of sacro-iliac joint changes may vary from a few years to twenty years. Indeed, sometimes the changes appear to become arrested and this is especially liable to occur in women, in whom restricted and abortive cases of spondylitis have been described (Thompson, 1954).

Sacro-iliitis occurs not only in classical ankylosing spondylitis, but in several other conditions, listed as syndromes of pelvo-spondylitis (Table II).

Pelvo-spondylitic, and especially sacro-iliac, changes occur in psoriatic arthropath-

TABLE II.—SYNDROMES OF PELVO-SPONDYLITIS

Ankylosing spondylitis	Syphilitic
Reiter's syndrome	Post-recurrent rheumatic fever
Psoriatic arthropathy	Familial with arterial calcification
Brucellosis	Post-juvenile rheumatoid arthritis
Fluorosis	Associated aortic valve disease; iritis;
Paraplegic	and peripheral rheumatoid disease

The lesions vary from typical gross and diffuse ankylosing spinal changes to localized sclerotic lesions in the sacro-iliac joints. Their presence may be clinically overshadowed by changes in peripheral joints. In a personal series of 30 patients suffering from psoriatic lesions and arthropathy, sacro-iliac lesions were identified in 8, i.e. 26·6%. Wright (1956) identified abnormal changes in 37% of his 32 patients with this disease.

A similar pelvo-spondylitic syndrome may occur in Reiter's disease. At present the radiological features alone do not appear to suffice to differentiate the psoriatic or post-urethritic types of pelvo-spondylitis from classical examples of ankylosing spondylitis but further study of larger series of patients may reveal some distinctive patterns and points of differentiation.

One other condition characterized by roentgenographic sacro-iliac changes is *osteitis condensans ilii*, first described by Sicard *et al.* in 1926. The radiological appearances consist essentially of osteo-sclerotic lesions principally occurring in the lower margin of the iliac portion of the joint. The joint margins remain intact, though the sacrum may also be involved. The changes may be unilateral or bilateral.

The principal points of differentiation between osteitis condensans ilii and ankylosing spondylitis are shown in Table III. Radiographic oblique views, postero-anterior views

TABLE III.—PRINCIPAL POINTS OF DIFFERENTIATION BETWEEN OSTEITIS CONDENSANS ILII AND ANKYLOSING SPONDYLITIS

Osteitis condensans ilii	Ankylosing spondylitis
Rare in males	Predominantly in males
Onset after pregnancy common	Onset not related to pregnancy
Chief symptom is pain; stiffness not marked	Stiffness often as marked as pain
Restriction of spinal movements slight or absent	Restriction of spinal movements commonly present
Lesions may be unilateral	Unilateral lesions very rare
X-rays show dense sclerotic lesions on lower margin of iliac border, with less common sacral lesions. Joint margins intact	X-rays show marginal decalcification of joint; loss of definition of the subcortical bony layer; patchy sclerosis and pseudo-widening of the joint space
Other radiological lesions very rare and probably not significant	Coincident radiological evidence common in spine and other joints, or develops later
Systemic symptoms absent	Systemic disturbance common
E.S.R. normal	E.S.R. raised

and tomography have been used in order to demonstrate the joint margins and the extent of the lesions.

The nomenclature "osteitis condensans ilii" has little to commend it. There is no evidence of osteitis on histological examination of affected tissue (Baker, 1953), and the changes are not restricted to the ilium, the sacrum commonly being involved. Sacro-iliac osteosclerosis would be a preferable term.

The status of the condition as a disease entity is still in question. No theory of ætiology has proved to be completely satisfactory. Thus it has been ascribed to urinary infection (Szabados, 1947), osteo-chondritis (Ude, 1952), post-partum endarteritis of the iliac vessels (Gillespie and Lloyd-Roberts, 1953), ante- and post-partum ligamentous relaxation (Hare and Haggart, 1945), atypical ankylosing spondylitis (Baker *et al.*, 1950) and trauma (Shafar, 1953; Layani *et al.*, 1951). It may be that several entities are encompassed within the framework of this unusual sacro-iliac lesion.

Although the majority of authors consider that osteitis condensans ilii can cause back pain and therefore deserves consideration as a clinico-pathological entity, doubts have been cast by others who feel that it is an osteosclerotic condition of no clinical significance. Occasional lack of correlation of symptoms with the site or dimensions of lesions demonstrated radiographically is not altogether surprising as such discrepancies occur in ankylosing spondylitis and, indeed, it might be expected that the most painful phase would occur prior to the development of the sclerotic lesions.

Further clinical, pathological and serial radiographic studies may shed more light on the natural history, but in this respect it is necessary to observe some caution. Serial roentgenographic examinations of the female pelvis should not be lightly undertaken in

pregnant women or women of child-bearing age (M.R.C. Report, 1956; Stewart *et al.*, 1956). Even in the male, there are dangers in irradiation of the gonads. Some reorientation of our attitude may be needed in respect of the treatment of ankylosing spondylitis by deep X-ray therapy, especially in patients suffering from mild or restricted forms of the disease who might be equally well treated by methods invoking no risk.

WRIGHT, V. (1956) Personal communication.

Dr. D. R. L. Newton: During the past ten years so much attention has been focused upon various manifestations of ankylosing spondylitis that many people now appear to believe that symptoms peculiar to spondylitis are, in fact, intrinsic manifestations of sacro-iliac disease, and perhaps some of those who deal with rheumatic disorders may not pause sufficiently often to examine fundamental issues.

Shipp and Haggart (1950) believe that the sacro-iliac joint is an amphi-arthrosis, or, in modern terminology, a secondary cartilaginous joint, but the classical work of Sashin (1930) has more recently received confirmation by Macdonald and Hunt (1952), and there can be little doubt that the joint is of the primary synovial type. It is not difficult to see why anatomical interpretations should have differed so widely. The normal life-history of the sacro-iliac joint conforms essentially to the same pattern of degenerative changes that occur in peripheral joints. After the third decade there is usually an irregular loss of superficial cartilage, with fibrillation, later leading to erosions of varying size. But the fact that the joint is exposed to tremendous compressive force with only very slight movement probably determines the more unusual result ending in a varying degree of fusion. This may occur because the opposing cartilage surfaces are firmly fixed together by debris, rather as if glued together, or because extensive areas of degenerated cartilage are replaced by a loose vascular connective tissue: in either case X-rays appear normal. True bony ankylosis never appears to occur except as the result of acquired disease.

In man, the sole function of the sacro-iliac joint would seem to be to act as a shock absorber at a point where the redistribution of weight occurs. Experiments performed in different ways by Sashin and by Macdonald and Hunt suggested that the only movements that occurred were a very slight degree of gliding, and minimal rotation about a fulcrum set approximately at the level of the second sacral segment. It appeared that no significant degree of subluxation could occur in the adult male except as the result of trauma interfering with the normal joint mechanics. In the absence of the muscle control available to most other joints, the stability of this joint depends solely upon the arrangement of its ligaments. Simple clinical tests may therefore give as much indication of an "irritable" joint as does the production of pain by the application of tension to the capsule and associated ligaments of an actively diseased peripheral joint.

The nerve supply of the sacro-iliac joint is derived from the I and II sacral nerves, from the superior gluteal nerve (L4, 5, and S1), and probably also directly from the lumbo-sacral trunk. A study of the arrangement of the sclerotomes and myotomes of the lower extremity will show why deep pain reference from the sacro-iliac joint may vary so considerably in distribution. Pain of typical "root type" accurately referred to dermatomes and perhaps accompanied by paræsthesia does not occur unless the lumbo-sacral plexus is secondarily involved by a pathological process arising from within the joint. It is important to realize that so far as quality and localization are concerned, there is nothing to distinguish deep pain arising in the sacro-iliac joint from deep pain resulting from a

lesion of comparable severity involving other structures receiving their nerve supply from the fourth lumbar to second sacral segments.

The early diagnosis of sacro-iliac disease may be of more than purely academic importance. Support for this principle may be found, for example, in the advances which have taken place in the management of tuberculosis and malignant disease. Hart and his colleagues (1949) drew attention to the improvement which frequently occurs in patients suffering from ankylosing spondylitis when a firm diagnosis is made and the nature of previously obscure symptoms explained. Unnecessary deformity may undoubtedly be prevented by commonsense management from an early stage in the disease, and some authorities believe that the process may actually be slowed down by early radiotherapy. Sharp and Eason (1954) reviewed the place of radiotherapy in the treatment of ankylosing spondylitis, and concluded that the probability of improvement was higher in patients whose symptoms were of short duration and in those in whom radiological changes were confined to the sacro-iliac joints.

The nature of many of the disorders which affect the sacro-iliac joints will become apparent on routine X-ray films, and most people will agree with the wisdom of making a radiological examination in every case complaining of low back pain or "sciatica".

Seddon and Strange (1940) in reviewing 176 cases of sacro-iliac tuberculosis found it to be a disease of young adults and with an equal sex incidence. The most frequent presenting complaints were sciatica, pain in the hip, and in the lumbar region. Buttock and thigh pain was rare. The disease was bilateral in only 5 cases, and associated tuberculosis was more common in the lumbo-sacral spine and hip than in the dorso-lumbar region, which is the most usual site of uncomplicated tuberculous disease of the spine.

"Sacro-iliac strain" is a not uncommon diagnosis, particularly in post-partum women. Many cases so labelled in fact present the history and physical signs of some form of intervertebral joint strain or derangement, often dating from their return to their normal household chores; others are certainly cases of ankylosing spondylitis or *osteitis condensans ilii*.

Osteoarthritis of the sacro-iliac joint is a common radiological finding and is frequently associated with old trauma in the region of the joint, with contralateral hip disease, and with an asymmetrical type of transitional lumbo-sacral vertebra. Sacro-iliac osteoarthritis appears to be either symptomless or completely overshadowed by symptoms more directly attributable to the predisposing condition.

An extraordinary lack of awareness of the early manifestations of ankylosing spondylitis still seems to prevail outside Departments of Physical Medicine and others dealing mainly with rheumatic disorders. During the course of a long-term follow-up study at St. Thomas's Hospital, the author has found that the average length of time taken to reach the diagnosis of ankylosing spondylitis is a little more than six years from the onset of first symptoms. Many of these cases had been given loose diagnoses, such as sciatica, rheumatism and fibrositis, and treated by many methods in various places. In the case of patients first seen in the Physical Medicine Department at St. Thomas's, not having been previously investigated or treated elsewhere, the average time taken to reach the correct diagnosis was nine months from the onset of the first symptoms. This great discrepancy exists in other centres, too, and must be accepted as evidence that the average physician and surgeon is still unaware that many cases bear no resemblance whatsoever to the classical textbook description of the disease.

Hart and his colleagues (1949) enunciated their four cardinal diagnostic features of ankylosing spondylitis, these being spinal stiffness, diminished thoracic expansion, raised B.S.R., and radiological sacro-iliac changes. A number of early cases will probably be missed if these signs, important though they may be, should universally be regarded as early, and invariably associated, manifestations of the disease.

The comprehensive review of the varied symptomatology of ankylosing spondylitis given by Baird (1955) is worthy of careful study. Among the most important features must be mentioned the alternation of buttock and thigh pain from side to side; the aggravation of symptoms after rest, particularly first thing in the morning, after which stiffness is "worked off"; the various forms of chest tightness and soreness; and tenderness of bony points, particularly the ischial tuberosities. Moreover, in the presence of other good evidence, a diagnosis of ankylosing spondylitis should not be discarded just because the patient is a female, or over 35 years of age.

Bickbeck and his associates (1951) drew attention to the importance of iritis as a presenting symptom in ankylosing spondylitis. It now seems that by the time the eye disorder appears other evidence of spondylitis is usually manifest to those who know where to look for it, and iritis is in fact the occasion for the diagnosis and seldom the presenting symptom. An unexplained iritis or large joint swelling, particularly if involving the knees, should always direct attention to the sacro-iliac joints.

The painful heel is now a well-known feature of spondylitis, and Davis and Blair (1950) suggest that all men between the ages of 18 and 30 presenting with calcaneal periostitis and spurs have spondylitic changes in their sacro-iliac joints.

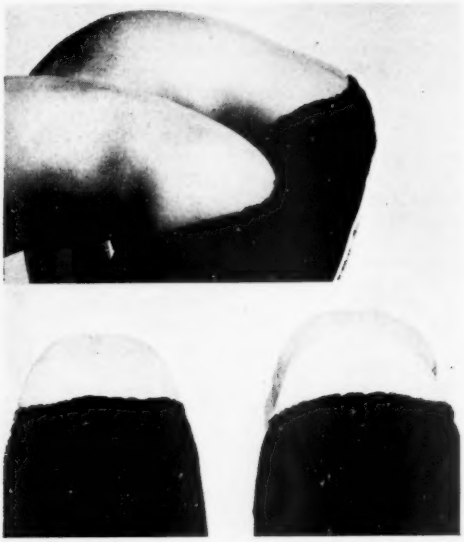

FIG. 1.—Normal control (behind and right) and spondylitic patient (front and left) bending to touch their toes.

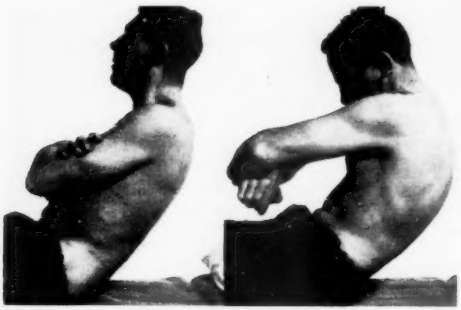

FIG. 2.—Spondylitic patient (left) and normal control rising from the supine position without the aid of their arms.

FIG. 3A, B and C.—Clinical sacro-iliac tests.

Posterior calcaneal bursitis is another frequent accompaniment and was the presenting symptom in a man of 64 years of age seen recently. He had had a duodenal ulcer for twenty years, a gastro-enterostomy five years ago followed by a stomal ulcer, and was now regarded as somewhat neurotic because of his many aches and pains. He had had calcaneal bursitis for a year, some chest soreness for six months, and recently some morning backache and pain in the right thigh, which he said he could "work off" by breakfast time. Clinical sacro-iliac tests were strongly positive and X-rays (previously reported as normal) showed bilateral spondylitic changes in the sacro-iliac joints. He also had symptomless bilateral calcaneal spurs.

One very common misconception is that a man who can touch his toes cannot be suffering from ankylosing spondylitis. It may, in fact, be very difficult to decide when there is limitation of lumbar spinal movement, particularly in the presence of a normal dorsal spine and hip-joints (Fig. 1). Cyriax (1954) has pointed out that lateral movements may be the first to appear reduced. Richardson (1955) has observed that the early spondylitic may only show obvious loss of lumbar mobility when he attempts to sit up from the supine position unaided by his arms (Fig. 2). Both these signs may precede by a long time the well-known flattening of the lumbar spine with a dorsal kyphosis which so commonly occurs in spondylitis. This flattening is due to the absence of the compensatory lumbar lordosis that occurs in other conditions which cause a dorsal kyphosis.

With the exception of bony points in ankylosing spondylitis, tenderness is a most inconstant and unreliable sign in sacro-iliac disease.

The clinical sacro-iliac tests described here have proved negative in all cases of sacro-iliac ankylosis, or in those where the disease has been present for many years and is presumably quiescent. Correct indication of which joint was actively involved was given in a high proportion of the cases in my series during the first four to five years that the disease was present. False positives have been rare and usually due to errors of interpretation. Many of the tests described in the literature involve either putting the lumbar spine into a position of strain, or placing a stress on other structures, such as the hip-joint. There is considerable disagreement as to the method by which these various tests should be performed, despite the fact that to be of value they should be simple in their application. No attempt appears to have been made to work out a simple method or to correlate the results thereby obtained with clinical, radiological and pathological findings. A detailed description of our tests is therefore given:

The first two tests are quickly performed while the patient is lying supine (Fig. 3A, B). In the first, the examiner applies pressure firmly, in a posterior direction, on both ilia in the region of the anterior superior spines; and in the second, laterally on the iliac crests, the application of pressure being towards the mid-line of the body. The surface on which the patient lies must be firm because otherwise no stress differential will be created between the anterior and posterior parts of the pelvis. In bed, for instance, the whole pelvis will sink back as one piece, concurrently placing a flexion strain on the lumbar spine. This is one common reason for a false negative result, and may be avoided by the use of fracture boards, or even the floor. A positive result is indicated by pain referred *laterally* into the lumbo-sacral or sacro-iliac region, into the buttock, or into the thigh. A patient with a low threshold for discomfort may wince, and on enquiry will state that it hurt him at the site of pressure; alternatively he may complain of mid-line tenderness where the sacrum was in contact with the surface of the couch. These complaints do not, of course, constitute a positive finding. In patients with a marked lumbar lordosis it will be necessary to fill in the space between the couch and the lumbar spine with a folded blanket or small pillow thus eliminating any concomitant lumbar spinal movement. The third test is performed with the patient lying prone (Fig. 3C). Pressure is applied to the central part of the sacrum by the "heel" of the hand. As in the other two tests, a positive result is indicated by *lateral* pain reference.

In all three tests the pressure must be applied evenly and with gradually increasing force, though at the final point of the antero-posterior and postero-anterior tests the examiner may be using almost his entire body-weight. Any attempt to apply force suddenly, or with a jerk is likely to cause unwanted lumbar spinal movement, and may lead to a false positive result. In cases in which marked activity is present in the sacro-iliac joint the sudden application of great pressure produces severe pain; in these cases quite gentle pressure evokes sufficient response for the interpretation of the test.

It has been found that when all three, or two together of these three tests, are positive it is almost always possible sooner or later to demonstrate radiological abnormality of the joint. One positive test out of the three should not immediately be dismissed as irrelevant, since this has occurred in some patients in whom radiological abnormality has later appeared, and in others in whom activity has been somewhat dubious though radiological abnormality was undoubted.

The survey referred to in this paper was aided by a grant from the Endowments Fund of St. Thomas's Hospital. I wish to thank Dr. P. Bauwens and Dr. J. H. Cyriax for their advice; Dr. J. W. McLaren for providing radiological and other facilities in his Department; and the radiographers for much time-consuming work. I am particularly indebted to Dr. R. G. Grainger, who has been entirely responsible for the radiological work involved in the survey.

Dr. Ronald G. Grainger (St. Thomas' Hospital, London): *Radiological Aspects of Sacro-iliac Arthritis*

The sacro-iliac joint is the most difficult major joint both to demonstrate and to interpret radiologically. The radiographic technique is so important that I shall begin by emphasizing some of the more important technicalities.

For a satisfactory projection of the whole length of the sacro-iliac joint, the central X-ray must always be directed perpendicular to the plane of the sacrum, and the X-ray tube must be tilted to a degree dependent on the lumbo-sacral lordosis.

Fig. 1: These two films were taken of the same patient, supine on the table. A is taken with the tube at right angles to the table top (the usual lumbar spine or pelvis projection) and shows marked foreshortening of the sacro-iliac joint. B is taken with the tube angled upwards at 45 degrees and shows the full length of the joint, and consequently a much better joint space. We must not assess the sacro-iliac joints on films taken for the lumbar spine or for the pelvis if there is an appreciable lumbar lordosis, for, apart from the foreshortening, the joints will be considerably under-exposed. Films must be well penetrated as under-exposure may either obscure early joint changes or may simulate disease.

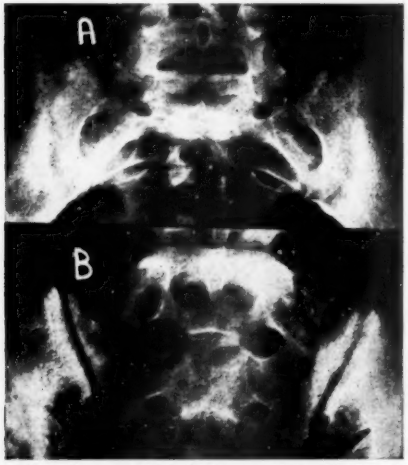

FIG. 1.—A, Central X-ray perpendicular to table top, demonstrating foreshortening and under-exposure of the sacro-iliac joints. B, Central X-ray perpendicular to sacrum of same patient, demonstrating the full length of the sacro-iliac joints.

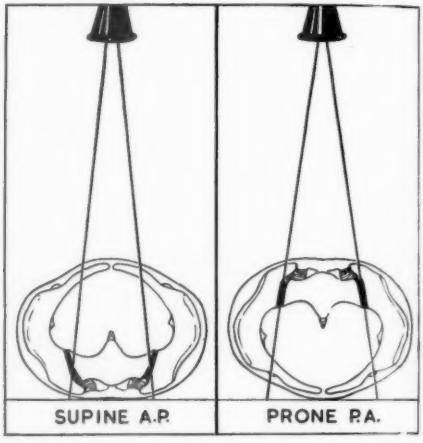

FIG. 2.—Demonstrating the geometric advantage of the prone over the supine projection.

The sacro-iliac joint approximates to a *plane joint* and the X-ray beam should ideally pass in this plane, parallel to the articulating surface and straight through the joint space.

Fig. 2: This objective is much better achieved by placing the patient in the *prone position* (P.A.), for in this position the diverging X-rays tend to pass *through* the divergent joint spaces instead of *across them* as happens in the supine position (A.P.), which is the standard projection. Because of the increased object-film distance, a fine focus X-ray tube should be used (if possible) to secure good bone detail.

Oblique views.—These are often unsatisfactory, particularly in spondylitis, because the obliquity of the joint space varies (from 3 degrees to 37 degrees) from patient to patient, from one side to the other in the same patient, and always considerably in the same joint according to the level of cross section.

In fact, it may be an anatomical impossibility to obtain a satisfactory single oblique view of the whole joint. Oblique films are of considerable value in sclerotic conditions which provide radiographic contrast with the joint space, but their diagnostic value is not predictable and they seldom provide information which cannot be obtained from supine and prone films which are so much more reliably obtained.

Tomography is a very useful technique for demonstrating the joint space, cavitation of bone, sequestrum formation or the extent of bone sclerosis. It is of little value in visualizing fine bone detail or the articular cortex, and is therefore seldom useful in the early diagnosis

of spondylitic sacro-iliitis. Tomography is of considerable use in differentiating sclerotic spondylitic changes from *osteitis condensans* and also in the assessment of joint tuberculosis.

The juvenile joint.—The appearance of the sacro-iliac joint depends greatly on the age of the patient, for until the age of 17–25 years the subchondral white line of cortical bone cannot be visualized. The juvenile joint lies more in the sagittal plane and appears as a single, broad, poorly-defined fissure, without a limiting line of articular cortex but with a finely-serrated bone margin (Fig. 3). In the mature joint the articular cortical bone is well defined and can be seen, on good films, as a thin white line in nearly every joint. The varying obliquity of the joint can be recognized in the A.P. and P.A. films, the anterior joint border being of course on the outer side. The upper posterior bone margins (A, B) are *not* in the synovial joint, but are united by the posterior fibrous interosseous sacro-iliac ligament. There may sometimes be an accessory synovial joint at this site.

FIG. 3.—Normal sacro-iliac joints at 9, 11 and 30 years.
N.B.—A, B, are non-articular bone margins.

ARTHRITIS OF THE SACRO-ILIAC JOINT

Destructive arthritis of the sacro-iliac joint occurs in a variety of conditions but they fall naturally into two ætiological groups: (i) the so-called collagen group of diseases, led by spondylitis but also including Reiter's syndrome (in which it is a common complication), and rheumatoid arthritis (in which it is rare), and (ii) arthritis of known bacterial origin of which tuberculosis is the most important, but which also includes pyogenic (usually staphylococcal) infection, gonorrhœa and brucellosis.

The similarity of the radiological changes in the sacro-iliac joints and in non-articular peripheral bone (particularly pelvic) in such apparently different conditions as ankylosing spondylitis, Reiter's syndrome and paraplegic states, suggests the possibility of a common ætiological factor. This may well be a common mode of assault from a pelvic inflammatory focus (e.g. prostatitis) with lymphatic spread. I think that this possible ætiological factor in the pathogenesis of ankylosing spondylitis, has received, at least in this country, an inadequate investigation and an approach somewhat lacking in enthusiasm.

The following is a brief review of the radiological features of the most important member of each group—ankylosing spondylitis and tuberculosis.

Ankylosing Spondylitis

The radiological changes of all bone and joint lesions in ankylosing spondylitis closely reflect what appear to be the two essential pathological processes.

Table I: First, *the destruction of peripheral bone and c rtilage* by overacting inflamed

TABLE I.—JOINT CHANGES IN ANKYLOSING SPONDYLITIS

(1) Bone and cartilage destruction	A.—Loss of cortical white line	(2) Bone formation	A.—Para-articular sclerosis (mainly iliac)
	B.—Articular erosions		B.—Ligamentous ossification
	C.—Para-articular porosis and blurring		C.—Diminishing joint space
	D.—Widening of joint space	(3) Healing ..	A.—Completion of bony ankylosis
			B.—Loss of sclerosis
			C.—Reconstruction of normal trabeculation

pannus (or periosteal tissues) and secondly, *the metaplasia into bone* of these invading connective tissues. This osteoblastic metaplasia extends beyond the previous confines of the bone and results in bone ankylosis of joints and in the whiskery fringing of spondylitic osteopathy—best seen in the ischial tuberosities. Both processes go on simultaneously and when affecting joints stimulate a reactive sclerosis in the surrounding bone.

These are progressive but self-limiting processes and they result in healing with complete fixity of the joint. This loss of movement reduces the osteoblastic stimulus: the sclerosis disappears and gives way to osteoporosis. The new bone trabeculæ form in lines of

weight-bearing, continuous from sacrum to ilium, but sometimes remnants of the joint space and/or cartilage may persist radiologically as well as microscopically.

By the time most spondylitics present for radiological examination the sacro-iliac joints show definite involvement and radiological diagnosis is easy. With increasing clinical suspicion of the disease, more and more patients are now presenting with early, and perhaps equivocal radiological signs.

Early Radiological Signs

The thin line of subchondral articular cortical bone is destroyed in *any* destructive arthritis in *any* synovial joint, but this sign becomes more valuable in sacro-iliac disease because the radiological demonstration of this joint is so limited.

FIG. 4: This is *not* a case of spondylitis but is an acute staphylococcal arthritis and shows

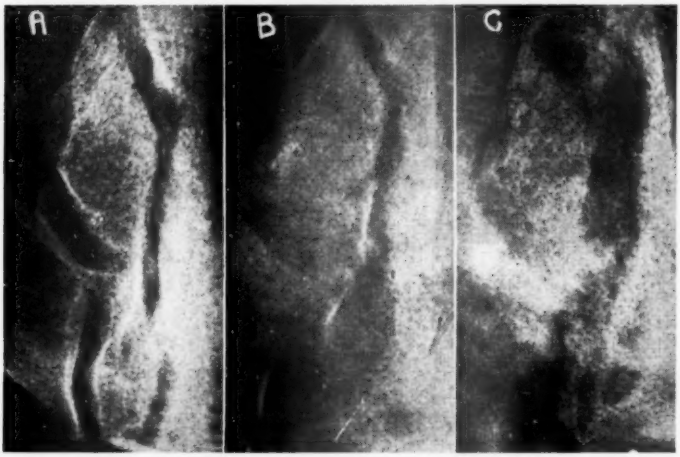

FIG. 4.—Progressive destruction of articular cortex in staphylococcal arthritis of the sacro-iliac joint. "A" shows joint before onset of disease.

the partial destruction of the articular cortex (B) prior to the complete disorganization of the joint (C). One can see flakes of cortex in process of destruction (B). This joint formed a staphylococcal abscess which invaded the pelvic cavity, involved both ureters, and caused death from uræmia.

Destruction of this white cortical line in spondylitis, usually occurs first on the anterior joint border on the iliac side, but the sacral cortex, particularly inferiorly and posteriorly may persist for some time.

Fig. 5: This patient presented with bilateral calcaneal fasciitis and spur formation and one year's history of low back pain. This film was thought by the first observer to be within normal limits but there is, in fact, loss of articular cortex leaving a finely serrated margin. Some articular cortex remains on the lower posterior part of the left joint.

Fig. 6: This patient developed his first low back pain in 1953 during a relapse of ulcerative colitis. This rather underexposed film, taken four months later, was reported by a most competent radiologist and accepted by the clinician, as being normal. There is, in fact, destruction of the iliac articular white line and a para-articular band of slight sclerosis. The change was bilateral and a diagnosis of ankylosing spondylitis is justified. Two years later the changes were quite obvious with a slight increase in joint space, blurred joint margins and a considerable increase in density of the sclerosis (which takes the identical pattern of the less-marked change, two years previously).

The finding of similar increase in joint space with blurred joint margins may resemble very closely the normal adolescent joint. If this change is bilateral and symmetrical in patients between 17 and 25 years, a final diagnosis may have to be deferred until more bone destruction or sclerosis has occurred.

Fig. 7: More localized destruction of bone may take the form of small articular erosions which may be arranged in rosary fashion. This patient has a two-years' history of low back pain. The erosions are predominantly unilateral (right-sided) in the lower ilium but there is bilateral sclerosis despite a normal joint space.

Following the destruction of articular cortex, the trabecular bone pattern of the ilium

FIG. 5.

FIG. 7.

FIG. 8.

becomes blurred, sometimes porotic but usually sclerotic, and fine bone detail is lost.

Fig. 8: This man has had spondylitis for five years. The lower posterior sacral articular cortex is intact (right) but there is now a diminishing joint space, and a blurred woolly trabecular pattern in the poorly-demarcated iliac sclerosis.

Unilateral Sacro-iliac Involvement

Although the sacro-iliac changes are usually bilateral and symmetrical, spondylitis may first be radiologically manifest as a unilateral sacro-iliitis.

Fig. 9: This patient has had low back pain for two years with severe generalized restriction in spinal movement and a high B.S.R. Radiologically the left sacro-iliac joint is normal with a well-defined articular cortex throughout, but on the right side there is loss of the cortical line, slight increase in joint space, poorly defined articular margins and a blurred sclerotic bone pattern.

Fig. 10: This is another case of well-proven ankylosing spondylitis commencing as a unilateral sacro-iliitis, but there are now early sclerotic changes in the right ilium with a blurred and distorted trabecular pattern.

These early unilateral radiological changes may be indistinguishable from early tuberculous disease, but in the case of spondylitis the other sacro-iliac joint becomes involved within the next two or three years. This asymmetrical development may persist throughout the course of the disease. Tuberculous sacro-iliitis remains unilateral, progresses more rapidly and presents several distinguishing radiological features.

The three earliest signs in the radiological picture are: (i) destruction of the white line of articular cortex (particularly of the anterior iliac border), (ii) blurring of the joint margins and a blurred iliac trabecular pattern, and (iii) iliac sclerosis, usually in the caudal part of the joint.

If the clinical picture remains suggestive in the absence or uncertainty of these signs, it is

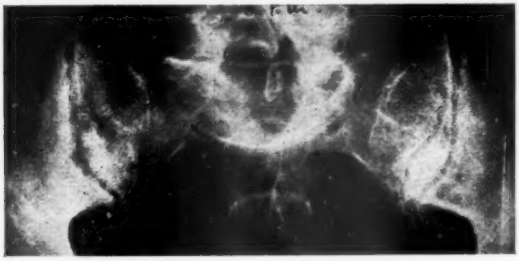

FIG. 9.

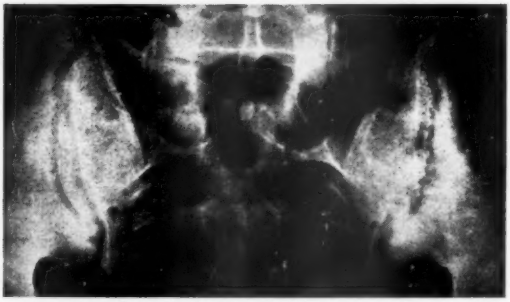

FIG. 10.

FIGS. 9, 10.—Two examples of ankylosing spondylitis commencing as unilateral sacro-iliitis.

important to maintain continuous radiological observation of the joints for as long as two to three years. There may well be this long delay before radiologically normal or doubtful joints show unequivocal signs of ankylosing spondylitis.

Tuberculosis of the Sacro-iliac Joint

A series of radiographs was presented demonstrating the radiological features of tuberculous disease of the sacro-iliac joint, emphasizing its natural history and progression, and the radiological features which distinguish it from spondylitic sacro-iliac disease.

The main differentiating features of the three commonest lesions of the sacro-iliac joint are summarized in Table II.

TABLE II

	Osteitis condensans	Ankylosing spondylitis	T.B. S.I. Joint
Age in yrs.	25–40	20–30	15–30
Sex	Female (95%)	Male (85%)	Equal
Symmetry	Usually bilateral	Bilateral (99%) symmetrical	Unilateral
Bone destruction	No	Yes	Yes: cavitating
Bone formation	Ilium. extensive defined	Ilium. sacrum ligaments	Ilium. sacrum
Joint space	Normal	Destroyed	Destroyed May be local
Sequestra	No	No	10%
Abscess + sinus	No	No	75% May calcify
Other skeletal lesions	No	Yes (80%)	Yes (40%)
Terminal state	No ankylosis	Slowly to bony ankylosis	Bony or fibrous ankylosis

DISCUSSION ON HYPOPHYSECTOMY FOR CANCER

Mr. Hedley J. B. Atkins (Department of Surgery, Guy's Hospital):

The Value of Hypophysectomy compared with Adrenalectomy for Advanced Cancer of the Breast

In 1945 Huggins (Huggins and Dao, 1953) performed total adrenalectomy on a series of patients with advanced cancer of the breast, but as all these patients died, they were not reported and I was unaware of this work when in 1947 I performed subtotal adrenalectomy on a series of 7 patients with advanced cancer of the breast who previously had had bilateral oophorectomy. The impression formed was that if sufficient adrenal tissue was removed to have an effect upon the breast cancer, the hazard to life was so great that it was not worth while doing, and this method of attack was allowed to lapse until it received fresh impetus from the discovery of cortisone which made total adrenalectomy safe. From then on, until 1953 when Luft and Olivecrona (1953) published details of encouraging results from hypophysectomy, adrenalectomy with bilateral oophorectomy became the standard method of treatment for all advanced cases of cancer of the breast for whom no further treatment by direct surgery, radiotherapy or hormone administration was admissible. The results were moderate and were similar to those which have now been reported from many centres all over the world.

Following this period, my colleague Mr. Murray Falconer began to operate upon certain of these cases by hypophysectomy; the choice of the operation being made at this time on grounds of expediency and depending very largely on which doctor sent the patient up and to whom the case was originally sent. It soon became apparent that this method of treatment was at least as likely to succeed as adrenalectomy and we decided in concert with Dr. K. S. MacLean, the Assistant Director of the Department of Medicine at Guy's, and my own assistant, Mr. J. L. Hayward, to compare the results of these two methods of treatment on a scientific basis (Atkins *et al.*, 1957).

The material which we used came from the Breast Clinic at Guy's, where we see approximately 80 new cases of breast cancer each year. When a suitable patient presented herself and a decision had been made that one or other of these operations was appropriate, the choice was made by a process of random selection. Paired cards, eventually to the number of thirty of each category, were placed in a box and whichever card was withdrawn, that operation was performed. In this way, a completely unselected series of 30 cases operated upon by adrenalectomy could be compared with 30 cases operated upon by hypophysectomy. No ethical problem was involved because we were all completely open-minded about the outcome of the investigation and we all would have been willing to have the choice of operation determined in this way had the decision involved our own relatives. It is only in the later stages of such an investigation, when one method of treatment appears to be drawing ahead of the other, that doubts of this sort begin to obtrude, but once started, it would be completely unethical to desist until the matter had been settled one way or the other beyond reasonable doubt.

We were fortunate at the Breast Clinic in that for the last six years we had used a method of assessing the results of treatment on cases of advanced breast cancer devised by Walpole and Paterson (1949) and known as the Mean Clinical Value (M.C.V.). M.C.V. assessment is particularly applicable to those diseases which, like advanced carcinoma of the breast, have many manifestations that show a varying response to treatment. It gives a numerical value to the effect of treatment which enables a clear-cut picture to emerge and one which can be compared statistically with other methods of treatment. The principle is to examine

all the manifestations of a case about to be treated and to measure them. These measurements may be made upon clinically obtrusive lesions such as lumps in the breast, the glands or the skin, by means of the direct application of calipers and tape measure to the part, or in the case of skeletal lesions they are made from the X-ray photographs. A base-line is thus devised for each lesion and any departure from this base-line as a result of treatment is assessed subsequently at four-weekly intervals. Subjective symptoms, with the exception of pain, are not used as factors in determining response to treatment, and pain is used only if the difference in degree of pain experienced is such as admits of no uncertainty.

Having established a base-line for each feature of the disease, the patient is started on treatment. In the cases under discussion this would be either by adrenalectomy with oophorectomy or by hypophysectomy. At each subsequent four-weekly visit, the lesions are severally assessed. If a lesion has undoubtedly improved it is given a mark of 2; if it has undoubtedly worsened: 0, and if it remains the same, or if there is any doubt: 1. The marks are then added and divided by the number of lesions to give an average mark for the response to treatment of the patient as a whole. The average mark would range between 0 and 2, and, being an awkward figure to handle, the result is multiplied by the factor 6 so that the range is between 0 and 12. It is this figure which is termed the M.C.V.

Having determined the M.C.V. for a patient at each four-weekly visit during treatment, a chart can be drawn of the patient's progress giving a picture of her response to treatment, impossible to achieve by the most careful description. Moreover, this sequence of numbers can be compared with the sequence of numbers derived from another patient treated perhaps by another method, so that the effect of treatment in the two cases can be readily contrasted.

In this enquiry, the method was extended so that a whole series of sequences derived from 30 patients treated by one method was compared with the whole series derived from the 30 patients treated by the other. In this way, approximately 1,000 integers derived from one series could be compared with 1,000 integers derived from the other and there was a chance that a statistical difference would emerge. Had we used, for instance, the number of months survived as an indication of response to treatment, only one integer would have been available for each patient—namely, the number of months survived. Consequently, in our series 30 integers would be available for comparison with 30 integers and it would be many years before differences could be detected on a statistical scale. Furthermore, the period of survival depends as much on the capricious nature of the siting of the secondaries as on their response to treatment. Thus a patient with a secondary in the brain that responded to treatment and then relapsed, might survive six months; whereas a patient with secondaries in the skin which never responded might survive eighteen months. The respective figures allotted to these patients on this basis would then give a misleading impression of the effect of treatment. It is true that in a very large series these anomalies would be ironed out, but it would prolong the investigation to such an extent as to rob it of any practical value.

As it is, our figures derived from the M.C.V. assessment are not conclusive. These figures have been analysed for us by Dr. P. Armitage of the Department of Statistics at the London School of Hygiene and Tropical Medicine, and although they are suggestive that hypophysectomy is to be preferred to adrenalectomy in the treatment of cases of advanced cancer of the breast, they are not statistically significant within the conventional range of 0·05 per cent.

There is, in fact, only a ten to one chance in favour of our results representing a real advantage of hypophysectomy over adrenalectomy, and not the twenty to one, or a hundred to one chance that we should wish to achieve before claiming that this was the case beyond all reasonable doubt.

Nevertheless, it looks very much as though hypophysectomy is going to be the better method of treatment; certainly the chances against it being less good than adrenalectomy are very great indeed. It looks as though, if you wish to disturb the rhythm of the endocrine orchestra, it is better to remove the conductor than the first violin.

Destruction of the hypophysis is certainly as effective as any method of treatment available to us at present for treating these desperate cases and it may well be better than any other. Because hypophysectomy is a relatively formidable procedure, two further considerations deserve our notice.

First, are there ways of destroying the hypophysis other than by direct surgical removal? Can we, as Lawrence and Tobias (1956) have indicated, destroy the hypophysis effectively by proton bombardment?

Secondly, is there not some pre-treatment test that can be applied to these patients to give some indication as to whether they are likely to respond?

In our laboratories at Guy's, Allen *et al.* (1957) have been working on this problem by estimations of the 17-ketosteroid secretion in the urine. If they have not solved this problem, they have certainly demonstrated a most exciting possibility, namely, that within a very short while we shall be able to say—"with this patient, destruction of the hypophysis is likely to succeed; with that patient it will be unavailing".

Whatever may be the possibilities for the future, I would wish to make the most earnest plea that they should be investigated on a scientific basis from the start and that good ideas should be tested out properly with adequate controls by random selection so that they become established or rejected within a reasonable time and do not linger on for decades until they expire of inanition.

The "radical mastectomy versus McWhirter" controversy is one that must not be repeated. Because there has been no proper control, we are no nearer the solution to this vexatious matter than we were when it was first mooted in 1942.

The place of hypophysectomy in the treatment of advanced cancer of the breast and its merits relative to other methods of hypophyseal destruction such as stalk section, the implantation of radio-active substances into the sella turcica, and proton bombardment, must be investigated in the spirit which would have informed John Hunter.

Surgeons particularly have been guilty of the gravest laxity of scientific discipline in their approach to therapeutics. We now have the tools, methods and techniques for instituting a neo-Hunterian era; let us do something about it.

Mr. Murray A. Falconer (Guy's–Maudsley Neurosurgical Unit):

Hypophysectomy and Cancer

I propose to discuss the technique of hypophysectomy, to illustrate some of its results in advanced cancer of the breast, and to consider briefly its mode of action. Luft and Olivecrona in 1953 must be credited with the first concerted attempt to determine the effects of the operation in patients with cancer. Since then several surgeons have reported their results, notably Bronson Ray in the United States and Radley Smith in this country. There is now general agreement that the operation is only of value in advanced carcinoma of the breast and in a few cases of carcinoma of the prostate. It seems of no value in other tumours such as malignant melanoma, metastatic carcinoma of the gonads, or hypernephroma.

Surgical treatment.—Of the three possible surgical routes to the pituitary gland (trans-sphenoidal, sub-temporal, and sub-frontal), only the latter gives adequate exposure. The details of operative technique vary from clinic to clinic. We perform a right frontal craniotomy under general anæthesia, and then approach the chiasmal region by lifting the frontal lobe off the anterior cranial fossa, simultaneously sucking cerebrospinal fluid out of the chiasmal cisterns. The chiasmal region has always been readily visualized without recourse to hypotensive techniques, refrigeration anæsthesia, or preliminary lumbar or ventricular drainage. All arachnoidal tissue within the concavity of the chiasma is divided, exposing the pituitary stalk and the diaphragma sellæ. If the chiasma is prefixed, some extra room can be gained by chiselling off the tuberculum sellæ. The pituitary stalk can then be cut flush with the diaphragma without prior clipping, for it bleeds very little. Next the diaphragma is incised and the pituitary is then scooped and sucked out, sometimes in one piece, but generally in fragments. Some bleeding from the cavernous sinus surrounding the pituitary fossa may be encountered at this stage, but it is seldom profuse and generally stops spontaneously once the gland is removed. We then usually instil Zenker's fluid on a patty for 2 to 3 minutes, in order to fix any remaining glandular fragments before inserting a quick-setting acrylic plate to prevent reunion of the pituitary stalk to any glandular fragments that may have eluded removal and chemical fixation.

It is our practice to perform this operation under a high cover of cortisone starting with 50 mg. by mouth about six days before operation and working up to 400 mg. on the day of the operation. Following this regime the post-operative management has usually been

smooth, and the dose of cortisone is decreased in stages to 25 mg. twice daily by mouth on the 8th day, at which it is maintained. Provided the carcinomatous condition permits, the patient is allowed out of bed by the 5th to 8th post-operative day.

Results.—The results of hypophysectomy, in our cases, have been summarized by Mr. Hedley Atkins. All the patients had breast carcinoma with widespread metastases which had failed treatment by stilbœstrol, testosterone, or similar hormones after prior treatment by surgery or irradiation. 20 of the 30 patients showed some improvement in the early stages, but after the sixth month the majority began to show, at varying periods of time, reappearance or progression of their lesions. However, 2 of the 5 patients operated on longer than three years ago are still surviving. Both regressed and one is still without recrudescence, although the other after an interval of two and a half years has exhibited fresh lesions. The results prima facie in the hypophysectomy group seemed a little better than after adrenalectomy and several have been able to return to a normal life.

There were no deaths which could be ascribed to the operation, although three died within a month from the progress of their carcinoma. Certain complications, however, occurred:

(1) In one patient the operation was not practicable owing to an abnormal configuration of the sellar region. This patient was assessed as a failure for the operation, and was subsequently submitted to adrenalectomy.

(2) Some degree of diabetes insipidus developed in most cases, generally within the first post-operative week. Sometimes Pitressin, either as snuff or by injection, was required to control it during the early stages, but in all instances it declined spontaneously within a few weeks or months.

(3) Six patients had bitemporal visual field defects of varying degree on perimetry, but only one complained of her defective vision.

(4) All patients had anosmia on the side of operation, a few had bilateral anosmia.

(5) Most patients in the course of a few weeks became myxœdematous, and were then given thyroid 30 mg. twice daily by mouth.

Mode of action.—In those cases where the operation has failed to halt the disease, or where there has been a recurrence after a remission, a possible inference is that the hypophysectomy has been incomplete. Luft and Olivecrona (1953), and also Pearson *et al.* (1956) have accepted depression of the radioactive iodine uptake of the thyroid as evidence of the completeness of the hypophysectomy. In 19 of our cases we made these studies and found values which were consistently depressed to low or very low levels. Yet in 6 of our cases which came to post-mortem and then had the pituitary fossa carefully sectioned, fragments of anterior pituitary lobe variously estimated at between 1% and 10% of the total volume of the gland have been found histologically. One of these patients had benefited considerably from the operation and died following an accident some six months later. Thus in her case regression of the disease occurred in spite of the fact that her hypophysectomy was not complete.

It is possible that, in many of our other surviving patients, the hypophysectomy, although extensive, was likewise not complete. It may well be that pituitary stalk section alone can produce comparable results, due to interruption of the portal venous circulation from the hypothalamus to the anterior lobe of the gland. Further experience is required to settle this point.

Mr. A. P. M. Forrest (University Department of Surgery, Western Infirmary, Glasgow):

Yttrium90 Implantation of the Pituitary

During 1955 we treated 45 patients with advanced malignant disease by the implantation of radon seeds into the pituitary fossa, a total dose of 10–20 millicuries (mc.) being inserted by means of a cannula introduced through the nose and sphenoidal sinus (Forrest and Peebles Brown, 1955; Forrest *et al.*, 1956). Our hope of selectively destroying the pituitary gland was not fulfilled, for the gamma radiations caused damage also to the optic chiasma and hypothalamus, producing serious loss of vision in 7 of the 45 patients and a high incidence of permanent and severe diabetes insipidus. In two patients who were admitted in coma nine months after implantation, typical radiation changes of fibrinoid necrosis of the hypothalamic blood vessels were found at post-mortem.

However, it was also apparent that, despite these grave disadvantages, a good remission

of disease could be obtained by this relatively simple method of treatment. No improvement occurred in 5 patients with malignant melanoma, 3 patients with cancer of the uterus, or 1 with sarcoma of the breast, but 10 of the 36 patients with breast cancer had objective improvement in tumour deposits as a result of the hypophyseal irradiation. 5 of these 10 patients are still alive and in remission—an average time of ninety-six weeks after implantation (Table I).

Although adjacent structures were damaged, complete necrosis of the pituitary was not found in any of the cases examined *post mortem*. Sources of gamma radiation would thus seem to be unsatisfactory. However, a radioactive isotope emitting only beta particles holds greater promise. The experimental work of Rasmussen and his associates (1953) with the isotope of yttrium, yttrium90, and its safe introduction at craniotomy into the human pituitary (Yuhl *et al.*, 1955; Evans, 1957), suggested that it might prove suitable for insertion by our technique. Yttrium90 has a short half-life of 64 hours (A.E.R.E. Cat., 1957), and emits only beta particles of high energy (2·2 MeV) which have a maximum tissue range of only 1·1 cm. (Siegel *et al.*, 1956) although owing to the rapid fall-off of the beta radiation the effective range is considerably less. The target substance, yttrium oxide (Y_2O_3) is a powder which can be compressed into rods, which when heated to 1,700° C. fuse into a ceramic mass. We use rods of 50 mg. weight (6·3×2·3 mm.), which are activated in the atomic pile to 5–6 mc. To obtain a good distribution of radiation within the pituitary, we have modified our director apparatus to allow the simultaneous insertion of two cannulas, one through each nostril. One rod is introduced through each cannula so that they lie symmetrically, one on either side of the mid-line.

[A film was shown to demonstrate the method of preparing the yttrium rods, and the

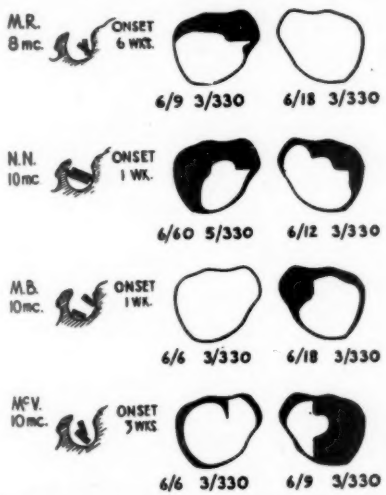

FIG. 1.—Visual damage in 4 patients following pituitary yttrium90 implantation. Visual fields and corresponding position of yttrium rods are shown for each patient.

technique of their implantation: "The Treatment of Advanced Breast Cancer. A Technique for the Implantation of Radioactive Yttrium into the Pituitary Fossa."]

Since March 1956, 34 patients with breast cancer have been treated by yttrium implantation of the pituitary. All patients have been in an advanced stage of their disease with multiple and widespread metastases, and were referred to us for treatment only when the radiotherapists considered that other forms of therapy offered no hope of palliation. One patient with massive pulmonary metastases died under anæsthesia. 4 patients developed visual defects (Fig. 1), but these did not progress and caused only slight disability. While temporary polyuria may occur during the first few weeks after implantation, only two patients have had permanent diabetes insipidus (Fig. 2). One of these had a visual defect, and in both the rods were placed in the upper part of the fossa. In 4 patients, profuse rhinorrhœa commenced 4 to 27 days after implantation. 3 patients were treated by muscle graft at craniotomy (Mr. J. Sloan Robertson), while in the fourth rhinorrhœa ceased, following an attack of meningitis. A post-mortem finding which might have predisposed to rhinorrhœa was a fracture of the sella turcica, doubtless caused by the forcible insertion of the trocar in two places. We now use a diamond steel drill to cut a clean hole in the bone. A guiding sheath is first introduced until its end strikes the outside wall of the pituitary fossa.

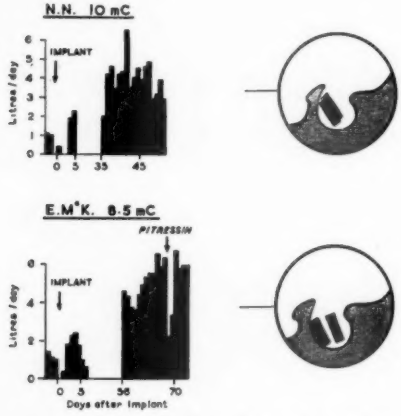

FIG. 2.—Urine volumes before and after implantation of the pituitary with yttrium90 in two patients with permanent diabetes insipidus. The position of the yttrium90 rods is also shown. Treated to February 1957: 34 patients. Severe permanent diabetes insipidus: 2 patients.

Through this sheath the cutting tool is inserted to bore a hole in the bone which allows the seed-introducing cannula, but not the guiding sheath, to enter the pituitary fossa. The length of this cannula is such that it will project only three-eighths of an inch beyond the guiding sheath, so that accidental over-penetration cannot occur (Fig. 3).

Post-mortem examination has been carried out on 7 patients at variable times after implantation. In 2, the gland was completely destroyed (Fig. 4) and neither of these had a visual defect, while in a third only a few cells remained in one lobe. The estimated extent of necrosis in the others was 90–95% of the gland mass.

None of 4 patients who had previously failed to respond to adrenalectomy had any improvement following implantation. In an acromegalic with breast cancer, the large size of the pituitary fossa necessitated an increase of the dose of yttrium to 18 mc.

Our endocrine survey of these patients includes estimates of pituitary (gonadotrophins), adrenal and ovarian (total 17-ketosteroids and their fractions[1], oestrogens and uropepsin) and thyroid (I^{131} uptake and serum cholesterol) functions. The effect of withdrawing cortisone maintenance therapy on the clinical state and steroid excretion is also determined. It would appear that the patient may benefit initially despite incomplete destruction of the gland. That later relapse may be associated with recovery of gland function was suggested by the clinical course of 2 patients who initially responded but relapsed nine and eleven months after radon implantation. At the time of their relapse there was evidence of returned pituitary function and both patients had a further remission when the adrenals were removed (Fig. 5, one case).

[1]Estimated by Dr. Ronald Hobkirk, B.E.C.C. Fellow.

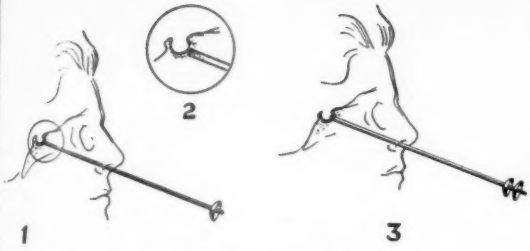

FIG. 3.—Method of cutting hole in the sella turcica to prevent fracturing of bone. (1) Guiding sheath inserted. (2) Drill penetrating sella turcica. (3) Cannula introduced through guiding sheath and drill hole.

FIG. 4.—Transverse section of pituitary thirty-four days after implantation of 11·3 mc. yttrium90 in two rods. Destruction is complete.

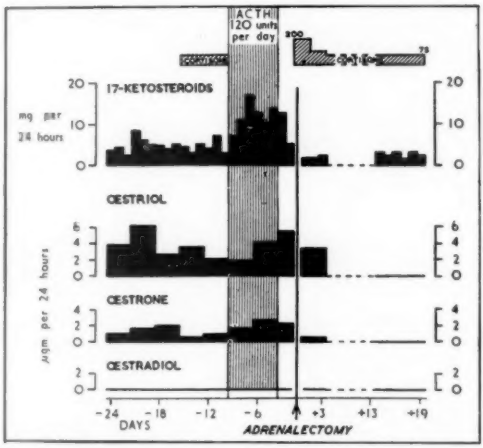

FIG. 5.—Urinary excretions of œstrogens and 17-ketosteroids in a female with breast cancer before and after removal of the second adrenal gland, the ovaries and one adrenal having been previously removed. Pituitary radon implantation had been carried out nine months previously with initial response followed by relapse. Further regression followed adrenalectomy.

Our aim is to develop a simple method of destroying the pituitary safely and completely. Until this is achieved, pituitary implantation should not be regarded as a satisfactory alternative either for adrenalectomy or for surgical hypophysectomy, except in the debilitated patient.

Mr. E. J. Radley-Smith (Royal Free Hospital):

The indications for hypophysectomy are: widespread cancer of the breast, cancer of the prostate and possibly malignant melanoma after it has been disseminated. The indication of carcinoma of the breast is well-agreed. Although some centres do not report good results in carcinoma of the prostate, I have found that it does respond in some cases excellently. The world literature on hypophysectomy for malignant melanoma is very scanty and unfavourable but in view of the difference between my own findings and those of others on carcinoma of the prostate, it is perhaps justifiable to gain further experience by applying this operation to malignant melanoma.

The methods of destruction of the pituitary gland are numerous and I personally combine as complete a surgical removal as is possible with the subsequent insertion of unscreened radio-active gold.

I agree with Mr. Murray Falconer that the pituitary can be removed surgically by retracting the frontal lobe and sucking out the basal cisterns, and I have not found it necessary to institute drainage of the ventricles or the lumbar sac. While I agree with him that retraction of the frontal lobe does give good access—and I did this in at least the first 50 cases—I am now considering that it should be replaced by partial resection of the right frontal pole. Retraction of the frontal lobe, particularly when some of the superior cerebral veins have to be coagulated, may lead to hæmorrhage into the substance of the frontal lobe especially if some unsuspected metastases are present in the lobe. This is a point in favour of resection of the frontal pole and part of the frontal lobe. Anosmia is distressingly frequent although the operation is on one side only and retracting and stretching of the olfactory apparatus must be a factor. I have tried section of the pituitary stalk only in one case, and a favourable response was obtained. When relapse occurred some months later, the pituitary gland was surgically removed. No new connection between stalk and gland had been established; histology showed that there was much surviving tissue in the gland which had been cut off from the stalk for several months.

Whereas in the Guy's-Maudsley Unit an attempt has been made to compare the benefits of hypophysectomy with those of adrenalectomy, at the Royal Free Hospital we have approached this matter from a totally different angle. While we have endeavoured to confer benefit on the patients by this operation, we have also used it as a method of learning more about the physiology of the pituitary gland and the biochemical control of patients after its removal. I am glad to acknowledge the extremely generous help from the British Empire Cancer Campaign which has enabled us to employ full-time research workers in this subject.

Patients after hypophysectomy are, I think, a good deal more easily managed and in less danger than after adrenalectomy. Indeed, one of my patients after hypophysectomy withstood a laminectomy without any more effect than would have been produced in a normal person. Another returned to hospital many months later for the removal of an acute appendix and at that operation one was able to observe the regression of the enlarged liver and its secondaries which had caused jaundice at the time of the removal of the pituitary. I agree with Mr. Falconer that the extreme diuresis following operation generally subsides.

With regard to results, in the early work on this subject cases, however unfavourable, were subjected to operation and this accounts for some of the early deaths after operation. Of those patients who survived operation for more than three months, 84% showed subjective improvement and 56% objective improvement. Although in some series subjective improvement is not even considered, I feel that it should not be ignored. In many, the pain from bone secondaries was abolished immediately after operation, although they later succumbed without X-ray evidence of recalcification of the secondary deposits. This relief from severe pain is worthy of comment.

Among the 56% who have improved objectively there has been the disappearance of jaundice, the return of a very large liver to normal and the disappearance of skin secondaries both near and distant from the primary growth. Malignant effusions in the peritoneal, pleural and pericardial cavities are not always abolished at once, if at all, but the intervals between aspirations which may have been as short as ten days before operation may be as long as three months afterwards. In a few cases serial biopsies have shown histological evidence of regression.

It is clear that we still know next to nothing about the results of this operation, but the results in the first 60 have been more than sufficiently encouraging to suggest that the work should continue. We are still hoping that the investigations will one day enable us to tell which cases will respond well to the operation and which will not. At the moment we merely have some indications of those who are going to respond well but we are disinclined to reject any case with the exception of the moribund. The use of hypothermia has made the operation much easier and has given the patients a much calmer convalescence.

Mr. W. P. Greening (Royal Marsden Hospital):

The purpose of this paper is to discuss the effect of beta radiation, using yttrium90, on the human hypophysis; and to show whether the transphenoidal insertion of yttrium90 rods, in an attempt to destroy the pituitary gland, is either a justifiable or worthwhile procedure.

We think that interstitial irradiation of the pituitary has a definite place in the treatment of selected cases. It is not a substitute for ablative surgery but an alternative procedure for those patients where a high operative mortality is expected, if they are subjected to a major operation.

Complete destruction of the gland is desirable but not essential, and worthwhile remissions may be obtained, with relief of symptoms, when a large part is destroyed.

Since metastatic cancer of the breast inevitably terminates in death, it would be as well to review the different methods of treatment at present available.

Galton, in 1950, published a report dealing with 70 cases of breast cancer treated by androgens. All his patients were in an advanced stage of the disease and were completely unselected.

He reported a failure rate of 50%, a success rate, described as successful or moderately successful, giving a combined total of over 40%. He said that of the 30 patients deriving benefit from the treatment, 21 obtained a remission lasting six months or more, 10 over one year and 3 over eighteen months. His maximum success rate was between the ages of 45 and 50, but a similar, though smaller, peak occurred between the ages of 35 and 40.

Improvement following œstrogen therapy in the post-menopausal patients is of a similar order.

Cade, in 1954, in an assessment of the results of adrenalectomy in a series of 36 patients, gave a complete absence of response in 29%, a very successful rate of 23% and a less successful, though still improved, rate of 31%. He gives an extended survival of up to twenty months, and remarks that successful results were achieved in about 52% of the patients.

The results of hypophysectomy as reported by Luft (Olivecrona and Luft, 1957), Pearson *et al.* (1956) and Kennedy (1956) show a slight increase in the success rate and a mortality corresponding favourably with that of adrenalectomy. However, in Luft's series hypophysectomy was achieved in only a few cases, and there has been a considerable improvement in his recent results, due to complete removal of the gland. The series reported by Kennedy was carefully selected, and this may account for the high rate of remission.

This remarkable uniformity of results obtained by varying methods of treatment, indicates that hormone responsiveness in breast cancer is limited to half of the patients.

Only 5 women out of 10 will benefit from *any* method which alters the endocrine balance.

These facts make it necessary to balance the magnitude of the treatment against the result that may reasonably be expected.

A mortality of 6% in both adrenalectomy and hypophysectomy, and a morbidity rate in the latter operation of similar proportions is inevitable. In both operations adrenal rests and ectopic hypophyseal tissue may be present in a significant number of cases. Any minor procedure, therefore, tolerated with ease by the patient and accompanied by a low mortality and morbidity, must be worth considering.

It seemed that a small group of patients with metastatic breast cancer who, because of their poor general condition were considered unsuitable for ablative surgery, might benefit from interstitial irradiation of the pituitary, and we were, in the first place, trying to devise a method of either completely or almost completely destroying the gland, without the hazards or inconvenience of a major operation.

50 patients, unsuitable or unfit for adrenalectomy, and possibly therefore for surgical hypophysectomy, were treated by interstitial irradiation of the pituitary using unscreened radio-active gold. As this form of treatment was regarded only as temporary palliation, every effort was made to avoid complications caused by damage to the neighbouring structures, and to select carefully the patients who might be hormone responsive.

The activity of the gold seeds used in these cases was increased from a low value at first up to 20 mc. towards the end of the series. The destruction of the gland was inadequate but the complications were few. They were damage to the parasellar nerves in 3 cases, two VI nerve and one III nerve palsy. There was one case of cerebrospinal rhinorrhœa.

The success rate and duration of the remission so produced was not considered good enough to justify continuing on these lines. For the last 30 cases we have used yttrium90, because it is a pure beta emitter and has a short half-life of 64 hr. The yttrium90 rods used are made of sintered yttrium oxide, and are 1·3 mm. diameter, and 4·0 mm. long. Each source has an activity of approximately 3 mc. at the time of implantation.

Investigations by a combination of film and ionization chamber techniques show that along the perpendicular axis, the half-value layer of tissue is 0·7 mm. It has also been shown that with an activity of 3 mc. the total dose is approximately 70,000 rad at 3 mm. from the rod; the necrotic boundary has been found to lie at this distance in a number of post-mortem sections of the hypophysis, and is a spherical volume of complete necrosis surrounded by normal tissue. The boundary transition between normal and necrotic tissue is extremely narrow.

In this series a success rate of 40% has been obtained, a figure not dissimilar to those produced by endocrine therapy and ablative surgery, although it is already apparent that the length of the remission is probably shorter.

The immediate operative mortality has been 3%, but few of these cases would have been even remotely considered fit for adrenalectomy.

One patient developed cerebrospinal rhinorrhœa and one died of meningitis eight weeks after operation. There was no apparent cause for this at post-mortem, the floor of the sella was intact and the pituitary almost completely destroyed. There are two unilateral III nerve palsies in this series, and one unilateral optic atrophy. The urinary gonadotrophin in the cases treated by yttrium90 is estimated before, and at monthly intervals after, the operation, using the method developed in the Clinical Endocrinology Research Unit in the University of Edinburgh, and we are indebted to Dr. L. A. Loraine and Professor Boyland for help and advice with these estimations.

The biological assay is based on the method of Klinefelter, Albright and Griswold, 1943, depending on the enlargement of the uterus of intact immature mice, 20–22 days old weighing 8–10 grams.

We find that 80% of cases show that gonadotrophin is completely eliminated from the urine post-operatively, in amounts detectable by this bio-assay.

In considering the technique of implanting the yttrium, the following criteria must be satisfied:

(1) There must be accurate insertion into the hypophysis.

(2) The dose must be sufficient to cause necrosis of the gland but not to affect the surrounding structures.

(3) It should be capable of being done quickly and easily without damage to the floor of the sella turcica.

(4) Unless these conditions are completely satisfied the operation should not be undertaken.

We use an image intensifier working in two planes. In the lateral view there is no difficulty but we find that a modified Townes' view in the antero-posterior projection is of great value in locating the sella.

Following the operation, in most cases little discomfort is experienced, but in some, aspirin or codeine is necessary to relieve headaches for the first few post-operative days.

The patient is kept on antibiotic cover both before and after the procedure.

Cortisone is withheld until there are signs of adrenal insufficiency. They appear at about the seventh day and are loss of appetite, nausea and vomiting. They cease as soon as cortisone is administered.

Transient diabetes insipidus occurs in most cases between the second and third weeks.

We think that damage to the chiasma or surrounding structures can be completely eliminated by accurate placing of the rods under fluoroscopic control.

DISCUSSION ON MODERN TRENDS IN THE TREATMENT OF GENITO-URINARY TUBERCULOSIS

Mr. Walter M. Borthwick:

Chemotherapy in Urinary Tuberculosis

INTRODUCTION

In 1948 a controlled trial was started in Robroyston Hospital into the value of three months' streptomycin in urinary tuberculosis. The preliminary results were given by Jacobs and myself (1950). Later, Wimsett (1952) added to these results by considering the value of three months' streptomycin and PAS. In these two communications 137 patients were considered. Briefly, the conclusions reached were that streptomycin had little or no effect on an established destructive renal lesion; in a few patients there was a possibility that the focus may become shut off although reactivation was always a possibility. Streptomycin therapy could not therefore be recommended to supplant surgery but these drugs, streptomycin alone or streptomycin with PAS, had a definite beneficial effect on secondary cystitis although streptomycin appeared to accelerate or even produce vesical contracture in some cases.

Later isoniazid became available and initially we, like many others, made the mistake of using it alone in a number of cases. Results which at first appeared promising were not maintained, and bacterial resistance developed in a high percentage of cases and in some of these the renal lesion became very vascular and the local progress of the disease alarming. With the realization that none of these drugs should be used singly came a definite planned programme, sponsored by the Research Committee of the Tuberculosis Society of Scotland, into the effects of the various combinations of streptomycin and PAS, streptomycin and isoniazid, and PAS and isoniazid in urinary tuberculosis. Eighteen months ago a fourth group was added using all three drugs.

Initially streptomycin was given for three months but we soon learned that treatment for that length of time was insufficient; we now carry it on for at least nine months and often eighteen to twenty-four months depending on the state of the disease.

TABLE I

Group 1: Unilateral renal tuberculosis; minor lesion without cystitis.

Group 2: Unilateral renal tuberculosis; major lesion necessitating nephrectomy; cystitis.

Group 3: Bilateral renal tuberculosis; nephrectomy for the more advanced lesion.

Group 4: Tuberculosis occurring in the remaining kidney subsequent to nephrectomy for unilateral disease.

Group 5: (*a*) Major bilateral tuberculous lesions; (*b*) Minor bilateral tuberculous lesions.

The grouping of the patients (Table I) followed the lines adopted by Jacobs and myself in 1950, but comparable tables of results cannot be produced where more than one combination was used in succession. Further, we have no experience on the suggested alternating regime of Ross and his colleagues (1951). It is, however, to be welcomed that different centres use different regimes so that soon we may be able to decide on the best method of attack.

TABLE II.—CHEMOTHERAPY USED IN 218 PATIENTS WITH URINARY TUBERCULOSIS

Chemotherapy	Group 1	Group 2	Group 3	Group 4	Group 5	Total
S+P	17	45	8	6	10	86
S+H	7	23	2	5	7	44
P+H	9	40	10	3	8	70
S+P+H	5	10	3	0	0	18
Total	38	118	23	14	25	218

S=Streptomycin. P=PAS. H=Isoniazid.

The results to be given concern 218 patients who had one of the four basic forms of treatment (Table II). 86 patients received streptomycin and PAS; 44 received streptomycin and isoniazid; 70 received PAS and isoniazid, and 18 the three drugs.

Patients were allocated by random selection by an independent non-medical person. Each patient after complete urological examination and definite proof of the existence of urinary tuberculosis, was placed in one of the categories. The dosage used was 1 gram of streptomycin, 10 grams of PAS and 200 mg. isoniazid daily, including Sundays.

Group 1.—In Group 1 there were 38 patients, 17 of whom received streptomycin and PAS, 7 streptomycin and isoniazid, 9 PAS and isoniazid and 5 streptomycin, PAS and isoniazid.

The lesion in the affected kidney was demonstrable by pyelography in every case and in 12 instances it consisted of a localized cavity from 2 to 5 mm. in diameter. After chemotherapy there was conversion of urine in 33 of the 38 patients. 7 of the 33 patients in whom there was urinary conversion were in the group with definite cavitation and in every case the lesion was unchanged to any marked degree. Partial nephrectomy was carried out in 2 of these 7 and the remaining 5 have been under observation up to four years without showing a relapse. Histological examination of the resected specimens after partial nephrectomy did not show any active tuberculosis.

5 patients in the definite cavity group did not show conversion and nephrectomy was carried out. All 5 had cavities approaching 5 mm. and histological examination showed active disease without any bacterial resistance in 4 but in 1 the organisms were resistant to streptomycin. In none did the disease spread to the bladder or contralateral kidney.

In the isolated renal lesion without cystitis it seems reasonable to give a combination of drugs. We would advise the cessation of therapy for seven to ten days after three months, for check-up examination. Even without conversion at this stage chemotherapy should be carried on for a further three months before re-examination. Resistance tests are necessary but non-conversion at six months with drug-sensitive organisms, usually, in our experience, necessitates surgical intervention which may be limited in its extent. The majority will, however, convert to a negative urine but it is unlikely that definite pyelographic abnormalities will show much alteration. In these the treatment should be carried on for at least eighteen months. Under adequate chemotherapy protection of the bladder and the contralateral kidney seems adequate.

There was nothing to choose between the various combinations in the results.

Group 2.—In this Group there were 118 patients forming the largest group and the type most frequently seen in practice. 45 were treated with streptomycin and PAS; 23 streptomycin and isoniazid; 40 PAS and isoniazid, and 10 all three drugs. All suffered from cystitis. At the end of treatment there was conversion in all and in none was there spread to the contralateral kidney.

In every case at the first examination it was considered that nephrectomy would be necessary and in the days before streptomycin this would have been carried out. The same routine was adopted. After three months re-examination was performed and the case reviewed. Nephrectomy was considered necessary in patients with positive urines where there were: (1) ulcero-cavernous lesions in all calyces; (2) a pyonephrotic kidney; and (3) an apparently non-excreting kidney.

In 7 patients, however, partial nephrectomy was substituted for total removal of the organ, and in 10 no operation was considered necessary. In these 10 there was conversion of the urine and the pyelographic appearances had shown marked alteration. In the initial examination it was thought that the disease affected all areas of the kidney, producing marked hydrocalicosis and marked hydronephrosis. This was probably due to kinking and œdema and it shows the value of an initial period of three months' chemotherapy before a definitive decision is made.

With regard to the renal lesion there was no difference between the four combinations but the effect on cystitis will be considered later.

In the 10 where no operation was necessary and in the partial nephrectomy cases, chemotherapy was continued for at least eighteen months. In the others the duration of treatment was nine to twelve months depending on bladder response.

Group 3.—There were 23 patients in this Group: 8 received streptomycin and PAS; 2 streptomycin and isoniazid; 10 PAS and isoniazid and 3 streptomycin, PAS and isoniazid. On initial examination all had a marked lesion on one side necessitating nephrectomy and a smaller lesion on the other. After three months' chemotherapy 22 of the 23 had nephrectomy. In one instance marked pyelographic changes had again occurred and no operation has so far been necessary for the observation period of almost two years.

The size of the lesion in the remaining kidney was small in 16 and moderate in 7 instances. In 5 deviation of the urine was necessary and follow-up has been difficult. In the remaining 18 patients there was conversion in all but 2 where partial nephrectomy was necessary

There were 5 patients who have been followed up for one to four years in whom there is a definite pyelographic abnormality although with urinary conversion.

Group 4.—This group consisted of 14 patients, 6 of whom received streptomycin and PAS; 5 streptomycin and isoniazid and 3 PAS and isoniazid.

The kidney lesions were small in 6 and definite in 8 patients. In 2 of the latter group there was complete occlusion of the lesion (1 with streptomycin and PAS and 1 with streptomycin and isoniazid) and these lesions have remained shut off for almost three years. In 7 other patients the kidney lesion at the end of treatment was unchanged but the urine free of tubercle bacilli in all but one. In this last patient a partial nephrectomy produced conversion.

Group 5.—25 patients were placed in this Group, 10 of whom received streptomycin and PAS; 7 streptomycin and isoniazid and 8 PAS and isoniazid. After treatment there were 13 patients with advanced kidney lesions unchanged from the first examination. The urine was positive in 7. In 6 others a moderate lesion on one side improved so that nephrectomy of the contralateral kidney was carried out with good result. An additional patient had a moderate lesion which improved and became suitable for partial nephrectomy and in one other instance a nephrectomy on one side and partial nephrectomy on the other were successful.

From these findings in renal disease it would appear that all four combinations are effective when used for a period of at least nine months. It seems unlikely that an established destructive lesion of the kidney will disappear but in certain cases a lesion may become shut off and the best drug to achieve this would appear to be streptomycin.

TABLE III.—EFFECT OF CHEMOTHERAPY ON CYSTITIS IN 161 PATIENTS

Isoniazid:	13 patients:	Diminished capacity:	3 patients.	
		Severe contracture:	1 patient.	

S=Streptomycin. P=PAS. H=Isoniazid.

Effect of chemotherapy on cystitis (Tables III and IV).—There is no doubt regarding the efficacy of chemotherapy on secondary cystitis. All combinations gave good results.

In a patient with slight or moderate cystitis one can expect return to normal with adequate treatment. Even with severe cystitis return to normal is possible but diminished bladder capacity or severe bladder contracture are more likely.

Table V : In 52 patients who had severe cystitis 20 returned to normal; 13 had diminished capacity of the bladder and 19 had severe bladder contracture. 39 received a combination containing streptomycin and 10 of these had a diminished bladder capacity and 18 severe bladder contracture; 13 had a combination which did not include streptomycin, 3 of these had diminished bladder capacity and 1 severe bladder contracture. There seems little doubt that contracture is more likely with streptomycin.

The choice of combination in the treatment of urinary tuberculosis should depend mainly on two things: (1) A knowledge of what each combination will do for tuberculous lesions in general; and (2) Appraisement of the type of lesion in a particular case. This may require reviewing after treatment for three to six months.

Dick (1953 and 1954) has examined all our resected specimens and reported on them without knowing what treatment the patient received; his opinions were later compared with the clinical data.

Streptomycin and PAS.—Dick found that streptomycin and PAS caused rapid cessation of activity in spreading lesions which then fibrosed. In small lesions, slight caseation in the centre may be absorbed but more often caseation occurs in larger areas and here the fibrosis of streptomycin therapy traverses this area and aids the development of hyalinized areas. In active cavity walls, fibrosis occurs and frequently the result of six to nine months' chemotherapy is a smooth-walled dense fibrous cavity, a result which according to Dick was relatively infrequent before chemotherapy. One serious drawback is that by the time renal tuberculosis is diagnosed the lesions may have been present for a considerable time and are not active. Streptomycin and PAS appear to have little effect on this type of lesion.

PAS and Isoniazid.—Adequate dosage of PAS and isoniazid appears to produce almost immediate cessation of activity in spreading lesions. The active lesion is now converted into a resolving one with increased vascularity and small hæmorrhages, removal of dead tissue and caseation and an active regeneration in the neighbourhood. Small tubercles may disappear leaving only a focus of very loose fibrous tissue and a recent lesion in a calyx or small cavity wall can be completely repaired, leaving only a slightly dilated calyx. Inactive lesions are not affected.

Streptomycin and Isoniazid.—Early on the isoniazid effect is predominant. After three months, resolution of active lesions has occurred and it is not possible to distinguish between the effect produced by streptomycin on the one hand and isoniazid on the other.

The choice of drugs to be used in urinary tuberculosis can thus be summarized:

(1) If the organism is known to be resistant, or becomes resistant to any of the drugs, the other two will be used.

(2) If there is moderate to severe cystitis, with or without ureteritis, avoid the use of a combination containing streptomycin thus, as far as possible, preventing contracture.

(3) If it is desired to close off a cavity with a narrow neck, use a combination with streptomycin.

(4) It is not advisable to give daily streptomycin for nine to eighteeen months in view of toxic manifestations, of which we have seen many, particularly in the older age groups.

(5) In the presence of secondary infection it should be remembered that PAS and isoniazid are not effective against pathogens, so that streptomycin or some other antibiotic should be used.

(6) In hospital it is very much easier to give streptomycin than at home and when the patient leaves hospital a combination of PAS and isoniazid is more suitable particularly for work and normal life.

(7) When PAS and isoniazid are being given, it is advisable to give them in a combined form so that the patient in fact takes both.

(8) Dosage: PAS 10 grams; isoniazid 200 mg.; streptomycin 1 gram daily. This last is better than prescribing streptomycin three times a week.

(9) The duration of chemotherapy should be at least nine months and often as long as twenty-four months.

(10) Drugs should be stopped for seven to ten days prior to an examination.

(11) Specimens for culture should be despatched to the laboratory for examination as soon as possible after collection.

Finally, a persistent positive urine may be due to drug-resistant organisms or the presence of small areas of calcification nestling in the apex of a cavity imprisoning colonies of organisms. A pyelographic abnormality does not necessarily indicate active disease when

the urine is free of acid- and alcohol-fast bacilli. Some "cavitated lesions" have been observed up to five years after cessation of treatment without any reactivation.

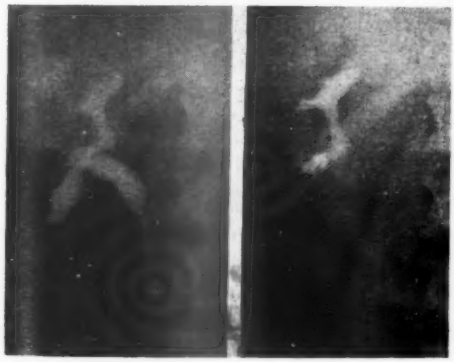
Dr. William G. Wimsett:

Cases Illustrating Effects of Chemotherapy in Urinary Tuberculosis

The following cases treated at Robroyston Hospital, Glasgow, have been selected to illustrate certain aspects of the treatment of urinary tuberculosis.

Case I.—M. A., female, aged 24.

Streptomycin was given, it being the only drug in use in 1950. Prior to treatment the bladder urine contained tubercle bacilli; capacity 14 oz.; a small tuberculous ulcer was present between the ureteric orifices. After three weeks of streptomycin 1 gram daily a routine investigation by an E.N.T. surgeon revealed slight vestibular damage. The significance of this finding not being fully appreciated the drug was continued for a further nine weeks being then withdrawn following a complaint of impaired hearing. A further examination revealed cochlear nerve damage. Study of the frequency chart showed an increase of frequency starting three weeks after the commencement of streptomycin and gradually worsening.



Conversion of the urine in this case had been obtained at the expense of the vestibular, cochlear and bladder function.

The pyelo-ureterogram obtained as a result of regurgitation of the radiopaque fluid from the bladder showed moderate dilatation due to back pressure, the kidney being unaffected. Ureterocolic anastomosis was subsequently performed by the Nesbit technique then in vogue.

Now in her seventh post-operative year she remains well and in employment.

Case II.—R. S., male, aged 23.

Following a left nephro-ureterectomy in May 1949 this patient was referred to Robroyston Hospital with a persistently positive urine.

Before After

FIG. 1 (*Case II*).

Investigation showed disease of the solitary right kidney involving the lower and middle groups of calyces (Fig. 1). Urine samples from bladder and right kidney contained tubercle bacilli, unassociated with secondary cystitis. Streptomycin was given with PAS for a period of six months: at the completion of this treatment pyelographic improvement was noted, the diseased areas having become shut off, but the bladder urine still contained tubercle bacilli. The patient was then discharged and maintained on daily PAS with isoniazid. Three-monthly investigations were performed during this period. After twelve months urine conversion resulted; chemotherapy was maintained a further six months.

Six years later the bladder and solitary kidney urines remained negative and pyelographic studies show that the lesions remain shut off.

Case III.—J. S., male, aged 24.

On admission intravenous pyelogram showed hydronephrosis of the left kidney with a large filling defect present at the upper group of calyces. There was a slight cystitis and the urine contained tubercle bacilli. From the pyelographic appearances at this stage it was considered that nephrectomy would be necessary. The case was placed in Group 2 and following our customary procedure a course of chemotherapy was given for three months.

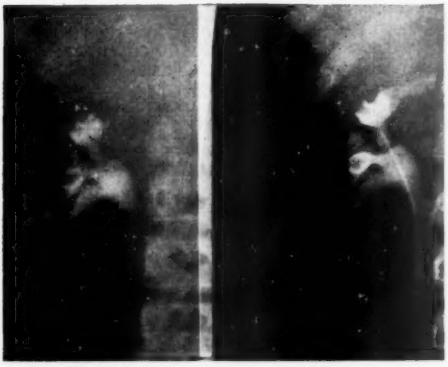
Streptomycin and isoniazid were given and at three months the urine was free from tubercle bacilli; the bladder was normal and pyelographic improvement was noted. It was therefore decided to continue chemotherapy rather than to operate. This chemotherapy was continued for a further three months, the patient after routine investigation being discharged on maintenance PAS and isoniazid for a further six months.

Two years after completion of chemotherapy the urine conversion and pyelographic improvement has been maintained.

Case IV.—J. H., female, aged 31.

Prior to treatment was found to have tubercle bacilli in the urine from the bladder and right kidney. A slight degree of cystitis was present. An ascending pyelogram showed disease of the

right kidney associated with the middle group of calyces. Streptomycin with PAS was given. After three months conversion of the urine took place, the pyelographic appearances were unchanged, the lesion persisting, and the bladder was normal.



Streptomycin with PAS was continued for a further three months, the urine conversion being maintained, the patient was discharged and had a maintenance course of PAS and isoniazid for a further six months. To date the urine is free from tubercle bacilli though the filling defect persists.

Case V.—H. G., male, aged 25.

Patient was admitted with a tuberculous epididymitis but with no urinary symptoms, and was found to have irregular filling defects involving the upper calyces of the right kidney. Tubercle bacilli were cultured from both bladder and right kidney urines; there was no cystitis.

PAS and isoniazid were given and three months later no tubercle bacilli were recovered and pyelographic improvement was noted. A further three months' PAS and isoniazid were given, the patient being discharged on chemotherapy to complete twelve months' treatment.

Eighteen months after cessation of treatment the urinary conversion and pyelographic improvement have been maintained.

Before After

FIG. 2 (*Case VI*).

Case VI.—M. R., female, aged 14.

In this case a small irregular filling defect was exhibited at the lower pole of the right kidney (Fig. 2). Urine from the bladder and right kidney contained tubercle bacilli. The bladder mucosa was normal.

Streptomycin and isoniazid were given and three months later the urine was found to be negative, the filling defect persisted but its wall appeared smoother. After six months' chemotherapy the patient was discharged and received maintenance chemotherapy for a further six months.

Three years later the urine remains free from tubercle bacilli but the filling defect in the right kidney persists.

Case VII.—A. McC., male, aged 27.

Early in 1950 this patient was found to have a minimal lesion involving the right kidney, there being no cystitis.

Following a three months' course of streptomycin with PAS the urine was free from bacilli though the pyelographic lesion persisted (Fig. 3A).

FIG. 3A (*Case VII*).—After three months' treatment.

FIG. 3B (*Case VII*).—Four years later. No drugs; no supervision.

The need for maintenance therapy was not appreciated at that time and the patient was dismissed to attend for three-monthly examinations.

Unfortunately he left the city and we were unable to trace him. Four years later he was admitted in a profoundly toxic state with advanced disease of the right kidney, ureter and bladder (Fig. 3B).

The urine from both kidneys and the bladder contained tubercle bacilli.

PAS with isoniazid was given and after one month a right nephrectomy was performed. At the completion of three months' chemotherapy the urine from the bladder and solitary left kidney was free from bacilli, cystitis was improved and the bladder capacity had increased from 6 to 10 oz.

A full course of maintenance therapy was given and eighteen months later the improvement was maintained.

Case VIII.—J. N., male, aged 26.

Early in 1951 this patient had bilateral minimal lesions involving the upper calyces. He was given streptomycin and PAS but after two months he left hospital and had no further treatment.

Six years later he was referred as an outpatient for investigation of a troublesome frequency.

Samples of urine from both kidneys and bladder contained numerous tubercle bacilli, there was a severe cystitis and the ascending pyelogram showed advanced bilateral disease with large cavities present at all groups of calyces. The patient died soon after admission.

In conclusion I have attempted to emphasize the excellent results that can be obtained in suitable cases, particularly in localized lesions, given adequate chemotherapy.

The last two cases are of interest because they illustrate the futility of short courses of chemotherapy and the need for prolonged observation after treatment has been completed.

Mr. Arthur Jacobs (Glasgow):

The Place of Surgery in Treatment

As a consequence of chemotherapy, the place of surgery in the treatment of genito-urinary tuberculosis has become modified but has lost nothing of its former importance. This will be apparent from Table I, which lists the operations carried out for renal tuberculosis and its sequelæ, on patients from the Genito-Urinary Tuberculosis Unit at Robroyston Hospital, Glasgow, during the past three years.

TABLE I.—OPERATIONS DURING 1954, 1955 and 1956

Nephrectomy and nephro-ureterectomy ..	99	Ureterocolic anastomosis ..	8
Partial nephrectomy	7	Ileocystoplasty	7
Reimplantation of ureter	2		

Nephrectomy.—Nephrectomy is still required for advanced unilateral renal tuberculosis. Operation should be preceded by a regime of chemotherapy lasting for about three months. Occasional exceptions calling for early intervention are when a superadded pyogenic infection causes toxic symptoms or a gross pyonephrosis develops. Pyelographic changes which would formerly have been regarded as evidence of widespread disease and an indication for nephrectomy, may occasionally improve under treatment and show that surgery is not required or that a partial nephrectomy is possible. Hanley and Borthwick both consider that pyelographic appearances which alter in this way are likely to result from œdema rather than from ulcerative tuberculous foci. When a kidney has been extensively destroyed, chemotherapy will not eliminate the need for nephrectomy; nor can it be envisaged that any new agent will ever have this effect, for a cavity-ridden kidney cannot be restored. In bilateral disease, therapy has actually increased the scope for nephrectomy and may permit removal of a kidney with widespread disease while relying on the drugs to deal with a lesser lesion on the contralateral side or enable it to be extirpated by partial nephrectomy. A progressive decline in the incidence of advanced lesions can be anticipated as a result of the increasing success of eradicating tuberculosis.

With regard to the disposition of the ureter, one of normal calibre and consistence can be divided at any convenient point and the secured stump allowed to drop into the wound without fear of complication. When because of dilatation or induration, ureterectomy is advisable, this can be accomplished through a forward extension of the lumbar incision. If the pedicle is first tied off, traction on the ureter through the mobilized kidney will enable a removal of the tube down to the bladder through this approach. A solution of streptomycin is instilled into the renal space and the wound closed without drainage. Only in exceptional circumstances, such as a pyo-ureter involving the extreme lower end of the pelvic segment, need a lower abdominal incision be used in addition to a lumbar one.

Partial nephrectomy.—Partial nephrectomy has an established place for a localized focus of limited dimensions which proves resistant to chemotherapy. Chemotherapy for not less than four months is advisable before operation. The response is checked from time to time by repeated bacteriological and pyelographic examinations, a retrograde pyelogram being made at the outset and again before finally deciding on partial nephrectomy. Because the smaller renal lesions are to-day often arrested, the need for resecting them is diminishing. Removal of refractory segments may, however, avoid over-prolonged chemotherapy.

Reimplantation of the ureter into the bladder.—Reimplantation of the ureter into the bladder is indicated in the presence of an organic stricture at the lower end which is causing progressive dilatation and is not associated with a bladder contracture. The necessity for this type of intervention has been encountered in two instances only in the past three years. The technique used was analogous to Leadbetter's method of uretero-colic anastomosis, the trimmed end of the ureter being united to the bladder mucosa and the muscular coats of the bladder wall approximated over the implant. Experiences have

shown that this technique of reimplantation is satisfactory; narrowing does not occur and post-voiding retrograde cystograms have demonstrated no tendency to regurgitation.

Uretero-colic anastomosis.—The serious aftermath of bladder contracture and consequent progressive damage to the remaining kidney continues to occur in spite of chemotherapy—streptomycin may indeed aggravate it. I still regard uretero-colic anastomosis as a good way of relieving the effects of the impaired bladder capacity and of saving the kidney. Lattimer (1955) who favours cutaneous ureterostomy in the tuberculous case, recently wrote: "We have followed some 20 cases done elsewhere, where ureterosigmoidostomy was performed and a tuberculous ureter was transplanted into the bowel. All of these patients with one possible exception have died within a year." This to me is a surprising statement for my own follow-up (Jacobs, 1956) showed that, subsequent to the first transplant for tuberculosis, carried out in 1936 on a female patient who died two and a half years later from reactivation of a pulmonary lesion, out of 61 on whom the operation has been performed, 30 are still living. 20 of the 30 have passed their fifth post-operative year; 6 continue well and active after periods of ten to fourteen years. Among these longer term survivors are some who had gross hydronephrosis and hydro-ureter before operation, including several with no pyelographically demonstrable function in the remaining kidney. One patient operated on five years ago when she had a moderate dilatation of the renal pelvis and a ureter of thumb-like calibre, gave birth without incident to a healthy child six months ago.

In 53% of my series who were still tubercle positive at the time of the transplant, progressive tuberculous destruction of the solitary kidney was inevitable with some, particularly in the pre-chemotherapeutic era; but relief from unbearable frequency or total incontinence was often obtained for several years. The protection which chemotherapy combined with surgery may afford to-day is illustrated by the following case summary.

A nurse, 32 years of age, was admitted to Robroyston Hospital in 1950 suffering from bilateral renal tuberculosis. After six months' therapy a left partial nephrectomy was carried out and followed by a right nephrectomy three months later. She became tubercle negative but reverted after a further six months. In spite of prolonged hospitalization and therapy she developed an increasingly severe bladder contracture and was finally voiding at 10 to 20 minute intervals night and day. In June 1955 the ureter from the remaining portion of the solitary left kidney was transplanted to the pelvic colon. Six months later she was back at nursing and has continued at her hospital post since then.

After a successful ureterocolic anastomosis and in the absence of continued tuberculous activity, general well-being can be expected. The many satisfactory long-term results obtained, even when the remaining kidney has already suffered serious damage, leaves

FIG. 1.—Retrograde cystogram demonstrating bladder contracture with reflux and dilatation of ureter and renal pelvis. Right nephrectomy for tuberculous disease five years earlier.

FIG. 2.—Retrograde cystogram of same patient twenty-seven days after uretero-ileocystoplasty. The stump of the divided ureter is outlined but there is no reflux through the uretero-ileal anastomosis.

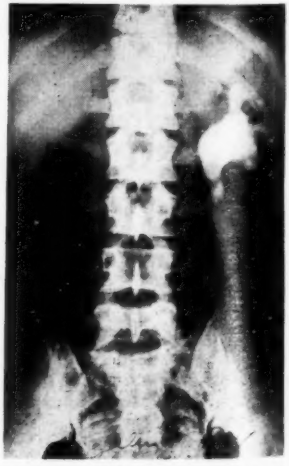


FIG. 3.—Intravenous pyelogram twenty-three days after the uretero-ileocystoplasty showing marked resolution in the pre-operative dilatation.

open to question the justification of transplanting the ureter into an isolated ileal loop as an alternative. The wet external stoma, however perfectly fashioned, is an inevitable handicap.

Ileocystoplasty.—A desirable alternative to any form of urinary diversion is a restoration of the bladder so that it can function as an adequate urinary reservoir. Ileocystoplasty or uretero-ileocystoplasty shows great promise of proving a satisfactory substitute for ureterocolic anastomosis in selected cases. I have now operated on 12 patients, 8 of whom had a tuberculous contracture. In 7 with an associated dilated ureter and demonstrable regurgitation, a closed loop of ileum was joined to the bladder and the ureter implanted into the loop (Figs. 1, 2, 3); in the remaining one, ileocystoplasty alone was done. An account of most of these cases has recently been given (Jacobs, 1956). The operation is of necessity a rather prolonged one for the ileal loop has to be isolated, the continuity of the ileum restored, the loop anastomosed to the bladder, and in the majority, the ureter isolated and anastomosed to the loop. The multiple steps of the operation, although very well borne, carry an increased liability to post-operative complications. The functional results to date are, however, proving very satisfactory. Patients who were incontinent, or nearly so, have acquired intervals of several hours between micturition. Resolution of the dilatation in the renal pelvis and ureter without continuing regurgitation has generally taken place and electrolyte disturbances are minimal. Professor Wells (1956) in his presentation on "The Use of the Intestine in Urology" collected in his survey 50 cases on whom vesical enlargement with an ileal loop had been performed for tuberculous contracture. He considered that the results were generally proving satisfactory though the duration of the follow-up, averaging twelve months, was a short one. Pyrah (1956) also considers that ileocystoplasty can be a preferable procedure to ureterocolic-anastomosis for the relief of this condition.

Conclusion.—Chemotherapy has reduced the need of surgery for small renal lesions, but has increased its scope in other directions. Definitive surgery, with less post-operative difficulties, is now possible on patients who would formerly have been unsuitable. This applies particularly to those suffering from bilateral renal tuberculosis, disease in a solitary kidney and sequelæ resulting from the infection.

Mr. Howard G. Hanley (St. Paul's Hospital, London; Harefield Hospital) and **Dr. Raymond Parkes** (late of Harefield Hospital):

Some Observations on the Modern Treatment of Renal Tuberculosis [*Abridged*]

The following data are based upon our observations of 104 patients with renal tuberculosis treated under sanatorium conditions during the two-year period from August 1954 to August 1956.

Table I shows that 37 patients had already undergone a nephrectomy before admission

TABLE I.—104 PATIENTS WITH RENAL TUBERCULOSIS

Nephrectomy before admission to Harefield ..	37
Previous nephrectomy in bilateral disease ..	24
Total No. with bilateral disease..	55
Total No. with one kidney or bilateral disease	70

to the sanatorium. 8 of these were presumed to be unilateral lesions, but were admitted post-operatively in conformity with a modern trend in the management of this disease. Others had tuberculosis of the bladder, prostate, vesicles, or epididymides, or bone and joint or pulmonary lesions.

Routine management.—Ideally, no drug treatment was started until the diagnosis had been confirmed by culture or guinea-pig inoculation. Having established the diagnosis, we proceeded upon the assumption that the urine could be rendered tubercle free in all cases in the absence of certain complications.

These complications have proved to be, (1) obstruction or poor drainage leading to caseation and (2) of much less importance, drug resistance.

In general, if the urine can be rendered tubercle free there is no indication for surgery while under no circumstances did we consider operating until a repeat urine culture had been grown, so that at least six weeks' drug therapy preceded any surgery. In all but the most obviously destroyed kidneys we preferred to wait for three or four months.

A period of preliminary observation is essential in nearly all cases because it must be

stressed that neither the activity of the disease nor the degree of renal destruction can be assessed by one set of X-ray films.

It is not at all uncommon to find that the first excretion pyelogram shows clubbing of all of the calyces in one kidney, but that within three or four months of starting antibiotic treatment, the radiological changes have improved so much that most of the initial changes could not possibly have been due to actual tuberculous ulceration.

Our researches with the X-ray image amplifier lead us to conclude that many of these early signs of clubbing are due to mild back pressure or œdema, not ulceration, and as such are reversible.

Such a case is illustrated in Fig. 1. This woman was admitted to a hospital for removal of the right kidney shown in Fig. 1A. Fortunately for her she developed a hæmoptysis and was promptly transferred for sanatorium care. Within three months she had a sterile urine, which has remained sterile ever since. The excretion pyelogram taken five months later, Fig. 1B, shows rapid emptying of all of the calyces with no evidence of any serious cavitation. [Urine remains sterile. March 1957.]

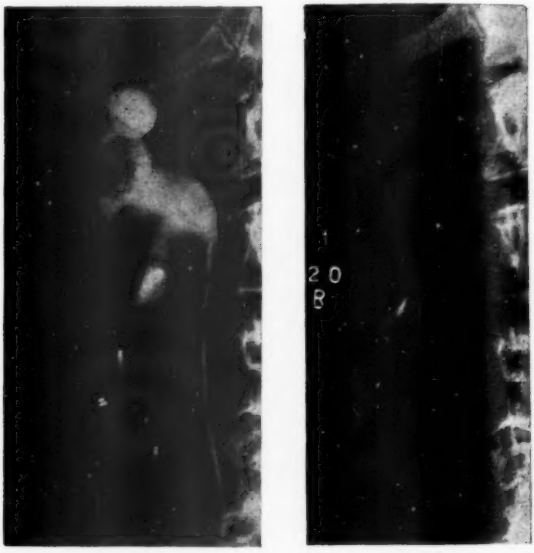

FIG. 1A. FIG. 1B.

FIG. 1.—A, Retrograde pyelogram before commencement of anti-tuberculous drug therapy. B, Excretion pyelogram five months later. Note rapid excretion of medium with no gross cavitation.

One can only repeat that any estimation of *tissue destruction* can only be based upon a series of X-rays taken over several months, while the only reliable guide to the *activity of the disease* is the absence or otherwise of tubercle bacilli in the urine.

Drug treatment.—During the period under review there was a gradual change from the Ross and Gow fortnightly courses of streptomycin and isoniazid alternating with PAS and Ethizone, to a more continuous regime of streptomycin 1 gram daily, isoniazid 400 mg. daily and PAS 17–20 grams daily given together or in pairs for prolonged periods.

No serious toxic manifestations were noted while drug resistance has not been a problem.

Only 2 of our cases proved resistant to isoniazid and this was overcome by increasing the dosage to 400 mg. daily. We now use this dose routinely and are prepared to increase it even further if necessary.

Bacteriological control.—Three consecutive early morning urines are cultured for tubercle bacilli every month whilst the patients are in hospital. Catheter specimens are taken from female patients. If any secondary infection is present sulphafurazole is prescribed for five days prior to the collection of the urines, and we have found that this reduces the percentage of contaminated Lowenstein cultures.

It is our impression at the moment that a lesion responds more satisfactorily to antibiotic therapy if some combination of the drugs is administered continuously over long periods, rather than when short two- or three-month courses are interrupted by a period of rest. We have therefore not stopped drug treatment before collecting urine specimens until two consecutive sets of monthly cultures have proved negative. Before obtaining the third set of cultures, all drugs are stopped for five days. So far, this third set of cultures has always remained sterile.

There is much controversy about the need to stop treatment before culturing urine for tubercle bacilli. It has been asserted that even small quantities of anti-tuberculous drugs in the urine will prevent the growth of tubercle bacilli on culture. If this were so, continuous drug therapy should result in negative cultures almost from the commencement of treatment. However, this has not been our experience, and we found that in spite of

a high concentration of drugs in the urine, tubercle bacilli would usually continue to grow on culture for several months after treatment was started.

Response to Drug Treatment

Reference to Table II shows that 60% of the positive cultures were converted to negative in four months and 80% in six months.

Table II.—Response to Drug Treatment

71 Patients Admitted with Positive Urine Cultures

Months	.. ..	2	3	4	5	6	7	8	9	
Conversion to negative		15	13	15	7	7	0	2	1	Total 60

43 converted to negative in 4 months = 60·5%
57 „ „ „ „ 6 „ = 80%

11 patients have remained positive:
10 for 6–8 months
1 for 22 months
of these 11, 9 are bilateral, 9 have extra-urinary lesions, 5 are over 50 years, 4 are in spinal beds or frames, 2 are paraplegic, 1 has a permanent cystotomy.

The 11 resistant cases were either in the older age groups with long-standing fibrotic disease (frequently having histories of several short courses of antibiotics in the past) or had multiple extra-urinary lesions. Tuberculous disease had been present for more than seven years in all of these 11 patients.

Apart from these truly chronic cases, the response to conservative drug therapy has been so satisfactory that surgery is never considered unless some complication occurs. We have not yet failed to sterilize the urine from a kidney unless there has been some serious degree of obstruction to drainage resulting in an area of caseation.

Indications for Surgery

Provided that the urine can be rendered tubercle free with drugs, the only indications for surgery would appear to be (*a*) to correct obstruction and promote drainage, and (*b*) to excise closed caseous areas. Tuberculosis heals by fibrosis, and this fibrosis, if occurring in certain situations, leads to obstruction which is not in the patient's best interests.

Obstruction at the neck of a calyx will lead to a pyocalyx and has been considered the chief indication for a partial nephrectomy. However, many of these closed-off calyces will eventually open up and drain into the calycine system. When this occurs we do not consider that surgery is necessary provided that the urine is tubercle free. Histological examination of such calyces after removal will show considerable evidence of healing.

Obstruction at the pelvi-ureteric junction is the most serious problem of all. During the course of treatment one has watched the "healing process" close off the pelvis slowly and inexorably although the urine may have been rendered sterile.

Obstruction at this site has been the chief indication for nephrectomy in our experience.

Obstruction at the uretero-vesical orifice calls for re-implantation of the ureter early, not when the kidney is already showing serious back pressure changes. It is vital, however, to be sure that ureteric dilatation is not due to reflux rather than a stricture. Inability to pass a ureteric catheter tells us nothing, but a micturating cystogram may be of great help. Re-implantation of the ureter is contra-indicated if the bladder is showing signs of contracture. An ileocystoplasty is a much more rational procedure in such cases.

Drug penetration in obstructed lesions.—We have noted on several occasions that streptomycin, isoniazid or PAS may not be detected in the contents of the completely closed-off pyonephrosis after removal, although the concentration of these drugs in the urine from the other kidney has been high. Also in these sealed-off kidneys one may frequently find active tubercle bacilli in the contents of the cavities in spite of prolonged treatment. It would appear that once the pelvi-ureteric junction, or even the neck of a calyx, becomes completely sealed off, the physiology is altered in that, even if excretion and reabsorption of fluid continues in the glomeruli and tubules, the amount of drug excreted into the cavities becomes very small. Coupled with the reduction of vascularity, as shown by the deposition of calcium, it is not surprising that blood-borne drugs are less effective in the presence of obstruction and caseation.

The assertion that a closed and possibly calcified non-functioning kidney was a source of danger and should be removed (Hanley, 1952) still holds good in spite of the use of anti-tuberculous drugs.

Calcification developing during the course of treatment.—Scattered areas of calcification are now appearing in several of our drug-treated and quiescent kidneys. This indicates that multiple areas of ulceration have become walled off by fibrous tissue and that calcium

has been deposited in the resultant avascular tissue. It is hoped that these areas were sterilized by drugs before they became walled off—in which case we can hopefully accept the calcification as "evidence of healing". At the moment, I believe that while calcification which occurs before drug treatment is started may harbour living tubercle bacilli, and may therefore be dangerous, the calcification which develops during treatment may be sterile and safe. Only time will provide the correct answer.

Postural drainage.—A special problem arises when a patient has a bone or joint lesion combined with a renal lesion.

Immobilization of a patient by any type of apparatus which prevents his turning over in bed has a profound effect upon urinary drainage, even in young people. We have found that secondary urinary infection develops rapidly in these patients and they tend to have a deposit of mucus and phosphate in the base of the bladder.

The daily turning of a patient in a spinal frame is a great problem in these days of nursing shortage but it is a vital necessity in some cases. This problem was brought to our notice by the occurrence of a dirty urine and hæmaturia following the turning of several patients who had been lying on their backs for some weeks undisturbed.

We now try to turn them daily until the dirty urine and bleeding subsides, after which the strain on the staff can be eased.

Urinary obstruction and hypertension.—Finally we must refer to an alarming problem which has only just become evident to us (Table III). 36 of our 104 patients have had, or still have, radiological evidence of some obstruction at the pelvi-ureteric junction or at the uretero-vesical junction. 17 of these 36 patients are hypertensive. Of these 17, 13 are under 35 years of age, and they are all under 45.

15 of these 17 patients show unmistakable radiological evidence of obstruction to the outflow of one or both kidneys. The remaining 2 patients have had the obstructed kidney removed but remain hypertensive.

In this small series, 3 patients are in a state of malignant hypertension. They have had bilateral disease for more than five years and have each had a closed pyonephrosis removed.

Reference to Table III shows that 19 of the patients with urinary obstruction are not

TABLE III.—HYPERTENSION RELATED TO URINARY OBSTRUCTION

(Total series 104 patients)

36 patients have (or had) obstruction on one or both sides.
17 of these are hypertensive:
2 of these are still hypertensive after removal of an obstructed kidney.
3 are in a malignant state.

Hypertension = Pressures in excess of 140/95 mm.Hg.

hypertensive. However, to our certain knowledge, the obstructive element has been present for less than a year in half of them, and it could easily be that there has not been time as yet for hypertension to develop. We have watched the blood pressure rise in two cases over a period of six months. One young man developed a closed pyonephrosis, the removal of which restored his blood pressure to normal. The other, a most encouraging result, had his pressure reduced by an ileocystoplasty which markedly relieved a serious ureteric reflux.

Looking at these figures impartially, there are as many patients with obstruction and a normal blood pressure as there are patients who have obstruction and hypertension, but *all* of the hypertensive patients show signs of obstruction. One cannot help suspecting the obstructive or fibrotic element.

In any event, the incidence of hypertension in 17 of our 104 patients is alarmingly high, particularly if we remember that 13 of them were under 35 years of age. One can only hope that this is a coincidence which will not be repeated in a larger series. However, we are to-day undoubtedly preserving kidneys which a few years ago would have been removed on sight, and this problem will have to be studied very carefully.

At the present time we are in favour of nephrectomy for cases with obstruction in the presence of hypertension, but are prepared to wait and watch in the absence of hypertension. We are certainly most ardent supporters of conservatism, but would hesitate to exchange a healed tuberculous kidney for hypertension in a young person.

MEETING HELD AT THE WHITTINGTON HOSPITAL, LONDON

Spontaneous Gastro-jejunostomy.—W. W. DAVEY, M.D., F.R.C.S., F.R.C.S.I.

This case is presented because it is the first record of a spontaneous gastro-jejunostomy due to a gastric ulcer.

Past history.—Mrs. E. S., now aged 72, developed gastric symptoms in 1930 when at the menopause. There is little doubt that her symptoms were due to a gastric ulcer for she was admitted to University College Hospital in 1931 and again in 1933 for six weeks on each occasion, and from 1935 till 1939 she was under the care of Lord Horder at St. Bartholomew's Hospital, including six weeks as an in-patient. While in these hospitals she had three barium meals, all of which showed a low lesser-curve gastric ulcer. Only one fractional test meal was done; this showed free and combined acidity within normal limits. In 1941 she was investigated at the Royal Northern Hospital and considered to have rheumatoid arthritis.

Present history.—She first came to the Whittington Hospital in July 1950 and since then she has been an in-patient for long periods on six occasions.

She was first admitted on account of a right femoral vein thrombosis, but while in hospital she was found to have the blood picture of a macrocytic anæmia, possibly pernicious anæmia as suggested by blood counts, sternal marrow examination, repeated histamine-fast achlorhydria and her response to liver and vitamin B_{12}.

FIG. 1.—Barium meal (3.12.52) showing shortening and scarring of lesser curvature in region of angulus.

FIG. 2.—Barium meal (26.1.54) showing hour-glass spasm of the stomach with ulcer on the lesser curvature.

FIG. 3.—Barium meal (1.12.54) showing gastro-jejunal fistula.

Because of her dyspeptic symptoms and her previous gastric history a barium meal was carried out; it showed a low lesser-curve gastric ulcer. Barium meal studies were repeated at fairly frequent intervals because she was known to be achlorhydric; they all revealed deformity in the region of the angulus suggestive of a gastric ulcer, of which Figs. 1 and 2 are examples. Gastroscopy was performed on three occasions and this confirmed the "hour-glass" like deformity of the lower stomach with pouching out of the greater curve and scarring above the angulus on a shortened lesser curve. During many barium meals the radiologist (Dr. W. Stachurko) had commented on several occasions on the rapid passage of barium into the jejunum but not till December 1, 1954, did he venture to suggest that a gastro-jejunal fistula existed (Fig. 3).

RÉSUMÉ OF INVESTIGATIONS

Blood:
27.7.50: Hb 53%, reticulocytes 2%, R.B.C. 2,500,000, P.C.V. 22%. Marked anisocytosis and poikilocytosis. There was a reticulocyte response of 7·5% six days after starting vitamin B_{12}. (The dosage of vitamin B_{12} used was: 4.8.50, 80 mg.; 22.8.50, 80 mg.; 5.9.50, 100 mg. Cytamen every two weeks.) Before vitamin B_{12} was given the reticulocytes averaged between 1% and 2%.
23.11.50: Hb 82%, R.B.C. 3,800,000, P.C.V. 37·5%, on vitamin B_{12} and iron.
9.2.51: Hb 80%, R.B.C. 4,400,000. Film normal.
31.12.52: Hb 66%, R.B.C. 4,200,000, P.C.V. 33%.
25.3.53: Hb 70%, R.B.C. 3,500,000.
12.11.54: Hb 70%. Group B, Rh-positive.

Marrow:
20.9.50: Megaloblastic liver deficiency anæmia.
9.10.50: Normoblastic but hypercellular on vitamin B_{12}.
31.3.53: Hypoblastic iron deficiency and early stages of a deficiency of the liver factor.

Fractional test meals:
28.7.50: Achlorhydria.
8.12.52: Achlorhydria with histamine.
31.12.52: Achlorhydria with histamine.
26.11.54: Achlorhydria, Kay's augmented histamine.

Barium meals:
25.10.50: Suggests low lesser-curve ulcer. Rapid emptying and irregularity of incisura which is suspicious of malignancy.
21.11.50: No change.
9.2.51: Well-defined low lesser-curve ulcer. No malignancy.
2.12.52 and 9.2.53: Scarring of low lesser curve suggesting ulceration.
1.12.54: Chronic gastric ulcer with early hour-glass deformity. Barium seen to pass from stomach into jejunum.

Gastroscopy:
6.1.53: Stomach shows classical "tea-pot" deformity with great shortening and scarring of the lesser curve. No sign of malignancy. Pylorus not seen.
4.5.53: No change.
8.11.54: No change.

Operation (December 1954).—Following the discovery of a gastro-jejunal fistula surgery was considered necessary. Laparotomy revealed a perfectly performed, posterior, retrocolic, short-loop gastro-jejunostomy. There was no tumour, no enlarged lymph glands and no evidence of active ulceration. The lower stomach was deformed showing shortening of the lesser curve and scarring of the anterior wall of the stomach in the region of the angulus. The gastro-jejunostomy was dismantled, the jejunum repaired and a Billroth I gastrectomy performed (Fig. 4 A and B).

Follow-up.—In the two and a half years since operation she has had no gastric symptoms. A barium meal shows a normally functioning Billroth I gastrectomy. Her weight has been maintained at slightly below the pre-operative level. She has received no anti-pernicious-anæmia treatment and her blood picture has remained normal apart from a mild microcytic anæmia which one might expect with chronic rheumatoid arthritis. A test dose of radioactive vitamin B_{12} was normally absorbed and estimations of vitamin B_{12} in the serum were within normal limits. The diagnosis of pernicious anæmia cannot therefore be upheld.

RÉSUMÉ OF INVESTIGATIONS

Blood:
18.8.56: Hb 67%, R.B.C. 5,100,000, P.C.V. 36%. Film normal.
12.12.56: Serum vitamin B_{12} 350 $\mu\mu$g. per ml. (normal 120–900).
February 1957: Test dose of radioactive vitamin B_{12} normally absorbed.
Kay's augmented histamine test (26.2.57): Achlorhydria.
Barium meal (5.9.56): Normal Billroth I gastrectomy.
Gastroscopy (5.9.56): The entire pouch was seen and considered to be normal. Three biopsies were taken from high on the posterior wall using Wood's forceps.
Gastric biopsy (6.9.56): Inflammatory hyperplasia.

Morbid anatomy and histology.—The resected specimen is a sleeve of stomach. The serosa is smooth and shiny and there is a deficiency on the posterior wall (2·5×1·5 cm.) representing the stoma of the spontaneous gastro-jejunostomy (Figs. 5 and 6).

Microscopy (Dr. S. H. G. Robinson).—"Chronic inflammation and fibrosis of the wall of the stomach in the margin of a gastro-jejunal stoma and conspicuous adenomyosis with greatly dilated ducts in the remainder of the wall of the stomach."

No record of such a fistula can be traced in the literature. C. C. Gardner (1955, *Postgrad. med. J.*, **31**, 16) has described one resulting from a gastric neoplasm.

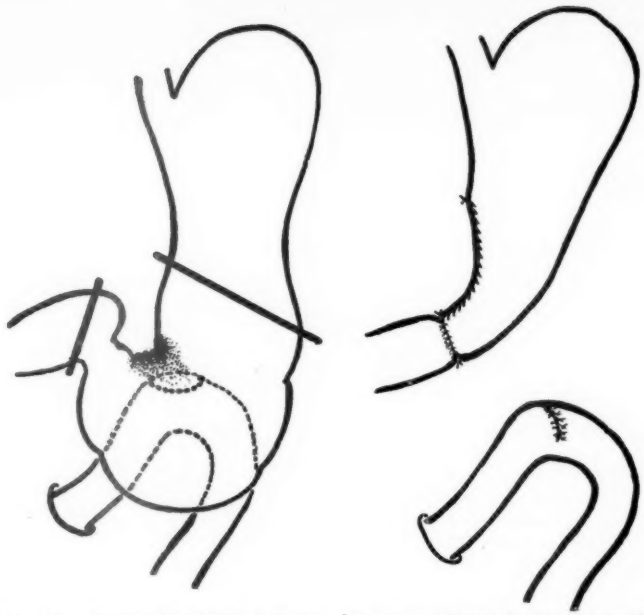

FIG. 4A.—Dismantling of spontaneous gastro-jejunostomy.

FIG. 4B.—Billroth I gastrectomy with repair of jejunum.

(Drawn by Mr. H. Collinson, F.R.C.S.)

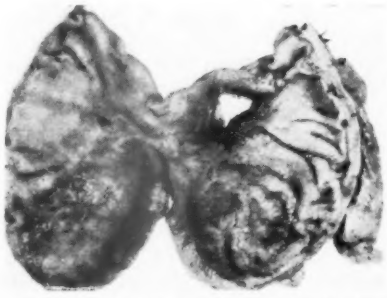

FIG. 5.—Operation specimen opened along the greater curvature showing scarring of the lesser curvature and the gastro-jejunal stoma on the posterior wall of the stomach.

FIG. 6.—Operation specimen viewed from behind showing gastro-jejunal stoma with fringe of jejunum attached to stomach.

Conclusion.—The original lesion was a chronic innocent gastric ulcer. Some time between 1950 and 1954 or perhaps earlier a spontaneous gastro-jejunostomy developed because the ulcer became adherent to and finally penetrated a high duodeno-jejunal flexure. A gastro-jejunostomy alone does not account for macrocytic anæmia, there must be some additional factor—in this case severe gastritis with adenomyosis of the stomach. Gastric surgeons are often blamed for causing anæmia by their operations; it is a pleasure therefore in this case to have cured one.

Acknowledgments.—I wish to thank Dr. A. L. Jacobs and Dr. K. C. Robinson, under whose medical care this patient has been.

Hepato-lenticular Degeneration.—MICHAEL ASHBY, B.M., M.R.C.P.

Girl, aged 13 years.

Her condition rapidly deteriorated to the point of grave incapacity. Treatment appeared to arrest the deterioration completely and to bring about a material improvement in mobility but much less so in speech.

History.—1953: The condition presented at the age of 13 with slowness of speech and movement and marked deterioration of school performance.

August 1953: Signs of Parkinsonism were found and she was started on stramonium. The condition slowly progressed.

February 1954: Right spontaneous pneumothorax. Admitted to hospital. No Kayser-Fleischer rings or hepatomegaly were noted. On discharge she was put on Artane, but took this somewhat erratically.

June 1954: Admitted for dental treatment.

September 1955: Gait now very slow and severe dysarthria. Examination showed Kayser-Fleischer rings, and she was readmitted to hospital.

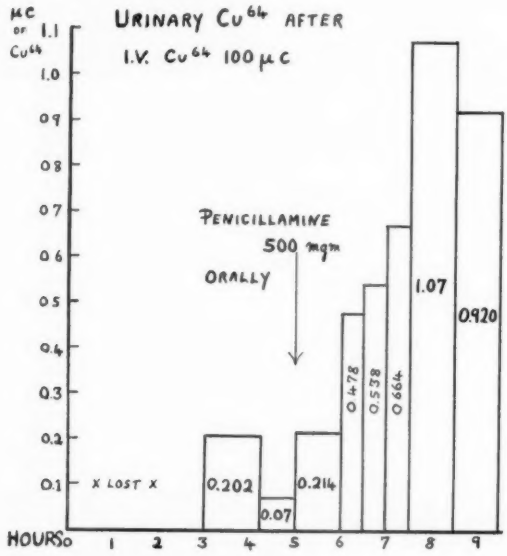

FIG. 1.—Chart of radioactive copper excretion showing greatly increased output in the urine following administration of oral penicillamine 500 mg.

Copper metabolism was investigated by Dr. J. N. Cumings of the National Hospital, Queen Square, and she was subsequently treated with B.A.L. and potassium sulphide.

	Serum copper	Oxidase activity
Normal	70–150 μg./100 ml.	120–180 μl. of oxygen/ml. per hour
Patient, before B.A.L.	59	Nil
after B.A.L.	43	11·6
Parents and 4 sisters ..	110–143	123–148

Considerable improvement in mobility and reduction in spasticity were noted after the three courses of B.A.L.

The patient was then transferred to the Medical Unit of University College Hospital where Dr. J. M. Walshe undertook further studies, including radioactive copper excretion (Fig. 1).

Greatly improved copper excretion was obtained after oral penicillamine, 500 mg.

A marked further improvement was obtained in the patient's mobility, and she again became able to hurry and even to run. Speech, however, has improved very little and dysarthria is still very severe.

Resuscitation of the Burned Child

By D. W. SHANNON, M.B., Ch.B., F.F.A.R.C.S., D.A.

Consultant Anæsthetist,
Royal Hospital for Sick Children, Edinburgh

BURNS are to-day a serious social problem ranking second only to motor vehicle accidents as a cause of death, or injury in children. Any minute, any hospital in the country may admit a seriously burnt child. As a member of the Surgical Team, the Anæsthetist must be prepared, therefore, to assist, or, if necessary, assume responsibility for the immediate care of a child in a state of oligæmic, or "burn", shock.

CLINICAL ASSESSMENT

When treating the burned child, a clinician has two problems on his hands, (1) the child, and (2) the burn. He must firstly protect the child from those inherent weaknesses, which, under the circumstances, may endanger his life, and secondly, from the pathology associated with the burn.

There is one point relevant to this discussion which I should like to emphasize, i.e. the child's tremendous thirst for oxygen, a 5-year-old child (the average child) requiring 5–6 c.c./kg. body-weight/minute compared with 3·9 c.c. in adults. Even at rest, the child's heart and lungs are working half as hard again as those of the adult. He has not, therefore, the tremendous respiratory and cardiovascular reserves that the adult has to fall back upon in times of stress.

This is the reason why a child's condition deteriorates rapidly following a serious injury. It is the reason why the assessment of such a case is based upon the functional efficiency of the respiratory and cardiovascular systems. Because of the rapidity with which the vital reserves are depleted, this assessment should be determined from clinical observations: the colour of the child, the feel of his pulse, the capillary filling time, the child's temperature, the dryness, or dampness of his skin, the rate and depth of his breathing, and his muscle tone. Such observations give an immediate and reliable indication of the efficiency of the child's vital systems. Special investigations and laboratory findings are delayed and may be misleading. It is against this background that the patho-physiology of a burn must be considered.

Cope (1951) has compared the burn wound to a leech, which sucks water, protein and electrolyte from the plasma circulating in its depths. The volume of fluid lost is proportional to the extent of body surface burned, and the leakage continues for forty-eight hours, the loss being greatest during the first eight of these hours. The result of this fluid loss is to lower the circulating plasma volume, interfere with the hæmodynamics of circulation and so reduce its efficiency. In deep burns, this efficiency may be still further impaired by red blood cell destruction.

The child's response will depend upon the volume of fluid lost. Following extensive burns, which, for my present purpose, I shall take as burns involving more than 10% body surface, the child is unable to accommodate the loss. The clinical picture during the hours immediately following injury is one of thirst, pallor, and restlessness. These signs indicate a mobilization of his fluid reserves and are a silent demand for fluid. If this demand is ignored, the child's fluid reserves will be drained and his cardiovascular system will no longer be able to carry out its normal physiological function. The child's condition will

deteriorate rapidly, his blood pressure will fall, his pulse-rate will rise, and he will become cyanosed, apathetic and later comatose. In such cases, fluid replacement is a matter of the utmost urgency and must be given intravenously.

The healthy child, with less extensive burns, has reserves which are capable of sustaining him during the early hours when fluid loss is greatest. Fluid replacement is, therefore, less urgent and his requirements may be given by mouth. These cases, however, are potentially dangerous because not all children are healthy. Many have a chronic illness (bronchitis, anæmia, malnutrition), which has already sapped their reserves. In such cases, the fluid loss occurring in a 6–10% surface burn may be sufficient to drain those reserves and precipitate oligæmic shock. Vomiting is the earliest sign of trouble in these borderline cases and an immediate indication to discontinue fluids by mouth and substitute intravenous replacement.

Intravenous Fluid Replacement Therapy

The literature has emphasized the danger of over-infusing children. This propaganda has encouraged clinicians to err on the safe side and give too little rather than too much. Yet the effect of under-infusing an extensively burnt child will be even more serious.

To effect a happy compromise between too much and too little, the nature and volume of the fluid and the rate at which it is given must be carefully assessed. Ideally, it should be similar to the nature, volume and rate of fluid loss. The assessment is based upon certain specific information:

(1) The time which has elapsed since injury and the treatment that has already been given.

(2) The weight of the child.

(3) The depth and extent of the burn, the extent being estimated from a simple diagram based on Berkow's tables (Fig. 1).

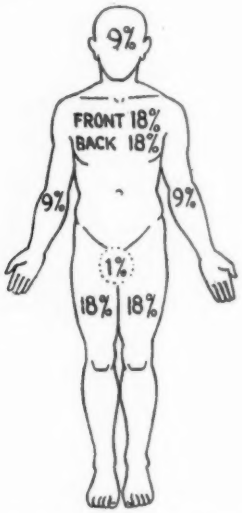

Fig. 1.—"Rule of Nine" for estimating area of burn.

The *nature* of the replacement fluid depends upon the depth of the burn. A superficial burn is given reconstituted plasma, a fluid which is similar to the burns exudate. A deep burn, however, must be given whole blood in addition to plasma in order to replace the red cells destroyed, or damaged, in the depths and at the periphery of the wound. The hæmoconcentration, which occurs in the hours immediately following a burn, is not a contra-indication to the giving of blood. Indeed, its administration at this time is necessary to delay and to limit the characteristic anæmia, which will later complicate the stage of healing.

Many formulæ have been devised to assist the clinician in assessing the *volume* of fluid required to replace that lost into the burn wound during the forty-eight hours immediately following injury. In Edinburgh, the formula used is based upon the extent of the burn

and the child's weight, 3 c.c. colloid fluid being given/1% surface area burned/kg. body-weight (e.g. a child weighing 20 kg. with a 20% burn would require 1,200 c.c. fluid).

The *rate* at which it is given is indicated by the extent of the burn and the time that has elapsed since injury. Following a burn of less than 30%, one-third of the estimated total replacement volume is given in the first four to six hours following injury, this period being calculated from the time of injury and not from the time of admission to hospital. A second one-third is given during the next twelve to sixteen hours, and the final one-third during the remainder of the forty-eight-hour period. These figures are a guide to therapy. The object in treatment is to get the child out of shock as quickly as possible to protect him from the harmful effects of prolonged tissue anoxia. The rate, therefore, will ultimately depend upon the clinical response of the child.

Following more extensive burns, or when intravenous therapy has been delayed, it may be necessary to give as much as two-thirds of the total replacement volume in the first few hours following injury to prevent early death due to shock, or, if this be averted, hepatic and renal failure due to prolonged anoxia. The total volume given, however, remains the same; only the rate is altered.

Following a deep burn, a part of the estimated replacement volume has to be given as whole blood. The volume given depends upon the red blood cell loss, which may amount to 20–40% of the red blood cell volume, depending upon the extent of the burn, e.g. a child with a blood volume of 1,600 c.c. and, therefore, a red blood cell volume of 720 c.c. would, following a 30% deep burn, have to be given 140 c.c. of red blood cells, i.e. 300 c.c. of whole blood as part of the estimated total fluid replacement volume.

Assessment of Progress

The efficiency of treatment is assessed by:

(1) The clinical response of the child, his colour, warmth of skin, lessening of thirst and diminishing restlessness.

(2) The hourly urine output. This is obtained by means of an indwelling catheter and is the most important single guide to the patient's response.

Throughout the period of oligæmic shock, the urine output is reduced through the action of anti-diuretic hormone (A.D.H.), which is released as a part of the child's response to injury. A reasonable output, therefore, for a 1-year-old would be 8–10 c.c., for a 5-year-old 12–15 c.c., and for a 10-year-old 18–20 c.c. It is the changes in the hourly output that are important, however, rather than the absolute volume. A steady output in the region of those figures I have mentioned or a rising output, which becomes stabilized after a few hours, indicates a satisfactory response; whereas an output which continues to increase from hour to hour or which, after increasing and stabilizing begins to fall, indicates in the first instance that too much fluid is being given and in the second too little.

Following a deep burn, anuria may occur as a result of the hæmoglobin released by red cell destruction. Normal healthy kidneys are capable of dealing with large quantities of hæmoglobin. The kidneys of a severely burned child, however, are not functioning normally. Renal anoxia, an associate of oligæmic shock, together with the increased reabsorption of fluid following the release of A.D.H. concentrates hæmoglobin in the distal tubules and may precipitate lower nephron nephrosis, and a renal shut down. This danger may be anticipated by identifying hæmoglobin in a scanty urine, and averted by:

(1) The prompt and effective treatment of oligæmic shock.

(2) The intravenous infusion of mannitol.

This high molecular substance reverses the effects of A.D.H. and by retaining water lowers the concentration of urinary solutes, including hæmoglobin, in the tubules.

Metabolic Fluid Requirement

Fluid replacement therapy takes no account of the metabolic fluid requirements—of the daily loss of water through the lungs, kidneys, skin and bowel. Water must, therefore, be given in addition to blood and plasma. It must be noted that because of the oliguria and skin destruction associated with a burn there is a reduction in water loss. The water intake during the first few days must, therefore, be reduced correspondingly and indeed in certain cases it may be necessary to reduce the normal metabolic fluid requirements by half. These requirements are satisfied by small hourly drinks, which should be given after the child has been brought out of shock and the danger of vomiting has passed. Serum sodium estimations indicate the accuracy of the assessment. Normal serum sodium is 140 mEq./litre. This level should be maintained. A fall indicates that too much water is being given and forewarns water intoxication.

Following burns of less than 10%, fluid replacement is less urgent and the child's requirements may be satisfied by drinks of half-normal crystalloid, 6 c.c. of sweetened half-normal saline/kg. body-weight/1% burn being given in small hourly fractions. The metabolic fluid requirement must be added to this volume, less restriction of water being necessary in these cases because the effect of A.D.H. is less marked.

Supportive Measures

Though fluid loss is the cause of oligæmic shock and fluid replacement, therefore, urgent and imperative, it must be remembered that the effect of shock is anoxia and it is tissue anoxia, which changes it from a reversible process into an irreversible state. Besides restoring the circulating blood volume, every effort should be made to ensure that the other systems concerned with tissue oxidation are functioning adequately.

Serious respiratory embarrassment is readily recognized and commands immediate attention. Minor incidents may, however, pass unnoticed, yet, if allowed to persist, they will exaggerate the anoxia of oligæmia and possibly endanger the child's life.

The oxygen supply may be interfered with in a variety of ways:

(1) The respiratory centre may be depressed by the indiscreet use of sedatives, or stimulated by anxiety or fear to produce a rapid, shallow breathing, which is exhausting and inefficient.

(2) The respiratory muscles may be damaged, or their action interfered with following burns of the chest and abdomen.

(3) The respiratory passages may be obstructed by: (*a*) laryngeal and pulmonary œdema following the inhalation of noxious gases. (*b*) Pressure upon the trachea due to œdematous fluid accumulating deep to the inelastic eschar of a circumferential burn of the neck. (*c*) Crusting of secretions within the vestibules of the nose. This is a common occurrence following burns of the face. It results in mouth breathing with all its harmful effects and in the accumulation of thick viscid post-nasal secretions, which ooze down into the laryngeal region causing exhausting bouts of coughing, and respiratory embarrassment.

The child's weakness is his thirst for oxygen. As long as his supply and its transport is restricted, therefore, every effort must be made to cut down as far as possible his tissue demands for oxygen.

Handling should be reduced to a minimum, only essential diagnostic and therapeutic measures being permitted.

Restlessness must be controlled by adequate fluid therapy and the control of pain and anxiety by the careful use of opiates.

Acknowledgment.—I wish to thank Mr. A. D. R. Batchelor and Mr. A. B. Wallace for their encouragement and help in the preparation of this paper.

Anæsthesia for Burned Children

By Harry Middleton, F.F.A. R.C.S.

Consultant Anæsthetist, Welsh Regional Burns Unit, St. Lawrence Hospital, Chepstow

The present tendency to admit burns chiefly to special centres has resulted in burned children becoming the province of a relatively small number of anæsthetists. This paper is based on experiences with 500 burned children admitted consecutively to the Welsh Regional Burns Unit, Chepstow, of whom 21 died. 199 of these children required no surgery, but the remaining 301 underwent 502 procedures under general anæsthesia. 10% suffered from infectious diseases on or after admission, and many had other complications such as are found in overcrowded and poor living conditions which themselves increase the risk of being burned (Tempest, 1956).

Adequate resuscitation is essential; for this, the chart of Lund and Browder (1944) simplifies the assessment of the burn, and a guide to the chances of death in each case may be obtained from the probit analysis of Bull and Fisher (1954).

Personal contact with these children is the first essential for success. They arrive in hospital having suffered the most terrifying experience of their lives, they may be gravely ill, and they are going to be submitted to the ordeal of resuscitation and in many cases to multiple operations. Everyone in the unit must be a friend—the anæsthetist among them.

It is therefore preferable that the latter's visits should be frequent and made in his theatre clothing. The anæsthetist is going to be glad of all the co-operation he can get, and familiarity may obviate the need for heavy sedation which he will be unwise to use.

Breathing exercises are instituted by the physiotherapists from the day of admission, and the use of a detergent aerosol to loosen mucus has been found of value. Some chest complications, however, are very intractable though they must not be allowed to delay operation once the time is ripe for surgery. A very few are undoubtedly due to the inhalation of smoke and hot gases and these patients must be checked for carbon monoxide poisoning, but Wakeley in 1941 and Wyatt and Khoo in 1950 described the presence of fat embolus in fatal burns and it is very probable that some of the cases which we describe as "chesty" pre- or post-operatively are suffering from this condition. This problem is undergoing investigation at the moment. It is possible that if fat embolus is implicated, one of the intravenous emulsifying agents may be found to be of use. The anæsthetist, then, is faced with complications which in most other branches of surgery would cause him to advise postponement, but this should be avoided in the treatment of a burn. Even though the patient's condition may appear critical, any delay will lead to deterioration and the anæsthetist's acceptance of the risk may be life-saving.

As it is seldom practicable to weigh a severely burned child, the pre-anæsthetic sedatives must be chosen on a basis of assumed weight, with due allowance for toxæmia, pyrexia and depressed renal function. (The urinary chlorides should be estimated frequently by the Fantus test (Prendiville, 1954).)

I prefer to give papaveretum by intramuscular injection about an hour before operation, in the dosage recommended by Anderson (1951); the infants have pentobarbitone sodium by mouth up to 0·7 grain per stone (7 mg. per kg.).

Atropine complicates the regulation of temperature and therefore the dose should be minimal.

The severely burned child is largely deprived of her most important heat-regulating organ—the skin, by loss as burn and by loss as donor site. She is first of all rendered hypothermic by exposure under anæsthesia and by cold transfusions and then rendered potentially hyperpyrexial by bulky dressings which prevent normal heat loss. In hot weather, especially when humidity is high, these children must be supervised most carefully. An indwelling rectal thermometer with a remote dial will be found useful.

The premedication ordered at the initial pre-operative examination may be the first of many and moreover it will err, if at all, on the safe side. In the course of the last six years I have developed a cumulative anæsthetic record system. This has proved of great value, not only in burns, but also in all the other multiple anæsthetics of pædiatric and plastic surgery.

The object of this system is to ensure that experience of an individual response to premedication, anæsthesia and recovery is carried forward for the benefit of future procedures after making allowance for discrepancies due to mistiming of the premedication or to altered age or circumstances.

The choice of the anæsthetic to be used in the surgery of the severe burn should be governed principally by experience in the use of an agent rather than by the agent itself. Edwards and his associates (1956) in their report on a thousand anæsthetic deaths note the serious implications of departure from accepted practice and I would suggest that the severely burned child is not a subject for the use of unfamiliar drugs or techniques.

In this series we have used a variety of drugs and methods, but the majority of infants, and the more severely burned of the older children, have been induced with cyclopropane and oxygen and maintained with methyl n-propyl ether, oxygen and nitrous oxide. Most of the remaining children have had thiopentone, gallamine and nitrous oxide.

I have followed Hewer's (1955) plan and have had the anæsthetic room ceiling decorated with an attractive washable wallpaper with coloured tropical fish. This provides excellent diversion for the child who is not asleep.

Cyclopropane has a vapour density of 21 compared with 14·3 for air. It may therefore be "poured" over the child's face from a tube concealed within the hand and the child will have no suspicion that it is being anæsthetized (Middleton and Picken, 1954).

A mask is substituted as soon as consciousness is lost and oxygen is added to the cyclopropane.

Anæsthesia deepens very rapidly and usually in a very few breaths the jaw will relax and intubation is performed immediately. I cannot recommend that those who are not

accustomed to the intubation of children should practise this technique of intubation under cyclopropane, as the relaxation wears off in a few seconds and leaves no time to spare. I advocate intubation most strongly and of the 502 anæsthetics given to these children 497 have been by the endotracheal route. Admittedly complications can occur, but they are far outweighed by the advantage of absolute control. With Prendiville I reported 4 cases (Prendiville and Middleton, 1954), none of them fatal, of a condition similar to acute laryngo-tracheo-bronchitis occurring in burned children and Rook (1953) reported three similar. There were no other serious sequelæ and only an occasional transient stridor.

Some burns around the neck and shoulders produce a surprising degree of œdema of the glottis which may embarrass the airway and on occasion we have had to intubate these children for the performance of elective tracheotomy.

Methyl n-propyl ether with oxygen and with nitrous oxide to make up an adequate flow rate is introduced as soon as intubation has been performed and is my choice for the maintenance of anæsthesia, in all infants, and in children who are severely burned. I use a home-made version of the Cardiff connector described by Picken (1950) for the infants, and a Magill or Westminster assembly for the others.

Anæsthesia is kept very light indeed and methyl n-propyl ether has the advantage of flexibility, enabling anæsthesia to be deepened very quickly if need be. Rapid recovery is the rule, and is particularly desirable because a child requires between 60 and 100 ml. of fluid by mouth every waking hour. Pre-operative starvation, and the recovery period, must be cut to a minimum to avoid dehydration.

It is essential that the transfusion be set up as soon as the anæsthesia has been settled and surgery must not start until the drip is going well. Under anæsthesia, veins will appear which were invisible before and it should be a matter of anæsthetic morality not to take an easy vein if a difficult one will do. The external jugular vein is easily needled with a Guest cannula by turning the head to one side and by stretching the vein between the back of the forefinger and the thumb. A breath of strong diethyl ether at the critical moment will cause straining which will dilate the vein and facilitate the procedure. Once the cannula is in, it is sutured in position.

The rate of transfusion should always be kept level with the blood loss, which can be estimated with reasonable accuracy by the use of standard swabs. After use these are counterbalanced by clean swabs from the same batch and the weight in grams used to balance gives the blood loss directly in millilitres.

When replacing lost blood, it must be remembered that a standard bottle of 540 ml. of blood contains 120 ml. of anticoagulant and that deterioration takes place at the rate of 1% per day for the first ten days and more rapidly thereafter. A bottle of blood near expiry therefore has a value of only about 300 ml. and the amount of useless fluid in a late dated bottle must be taken into consideration to avoid overloading.

If at any time it appears that blood loss is overtaking replacement and that shock may occur, the operation must be stopped and the child rested by covering up the wound and by lowering the head of the table. The operation must not re-start until the child is again in reasonably good condition.

The curettage of granulating surfaces to produce a good base for the reception of a skin graft is a procedure which seems to produce shock out of all proportion to the area involved. It is important to anticipate this, to rest the child from the operation at the earliest sign of trouble and to have adequate blood available for rapid transfusion if need be.

I have used elective hypotension on a few children having burns excised, using a drip 1 in 1,000 or 1 in 500 trimetaphan (Middleton and Kunz, 1956). This has produced a substantial reduction in hæmorrhage and has shortened the operating time. The children have been notably unshocked. This technique causes a big saving to the blood transfusion service and avoids replacement by citrated blood. The acid citrate dextrose used to store blood is metabolized rapidly by the liver and is unlikely to influence clotting in quantities which do not produce cardiac arrest, but the transfusion of large quantities of stored blood may delay clotting due to a deficiency of platelets (Stefanini, 1954). The citration of blood also causes a deviation to the left of the oxygen dissociation curve which lasts for several hours (Valtis and Kennedy, 1954). Transfusion of such blood may cause an appreciable diminution of the child's oxygen-carrying capacity and may influence us to give a high oxygen percentage during anæsthesia and in the immediate post-operative period.

Perhaps the worst part of the operation in any surgical treatment of burns is the application of dressings. The burned patient, even without anæsthesia, is singularly susceptible to blood pressure response to changes in posture and even the most careful application of

dressings may cause collapse after an uneventful operation. Treatment is the adoption of the head-low position and if necessary an infusion of l-noradrenaline.

I find that, in practice, the severely burned are best transferred to bed in the theatre before withdrawal of the anæsthetic. I then set up an oxygen tent but continue to administer oxygen through the anæsthetic circuit until the tent oxygen concentration is high enough.

An oxygen tent, newly erected, increases its oxygen content at a rate of roughly 1% per minute at a five litre per minute flow, so it is important not to be lulled into a false sense of security by its presence. A concentration of 50% should be obtained before the supply delivered directly to the child is disconnected.

In order to hasten the increase, a secondary oxygen supply is introduced into the tent (Middleton, 1955), as it is not possible to introduce a high flow through the normal inlet, in most tents in use in this country.

All our patients undergoing surgery return to recovery wards in which oxygen and suction are piped to each bed. We have had six and a half years' experience of these wards and we are convinced that they are essential for really efficient management of post-operative patients.

21 deaths occurred in this consecutive series of 500 children. Many of these had no hope of survival and others did not undergo surgery before they died. Of concern to the anæsthetist are the 6 who died following surgery:

I. *Christine*, aged 7, arrived moribund with a 60% full-thickness burn. She was resuscitated, but by the ninth day she was so toxic that it was decided to excise dead tissue. 39% of the body surface was removed in stages over two hours and twenty-five minutes using 150 mg. of thiopentone with nitrous oxide, oxygen, gallamine and pethidine. She was awake and talking at the end of the operation, but she died forty-five hours later from toxæmia and septicæmia.

II. *Carol*, aged 4/12, sustained full-thickness burns of most of her face. She developed enteritis, but was successfully anæsthetized on two occasions for tarsorrhaphy and grafting. She died on the twenty-third day, five days after her last operation as a result of enteritis.

III. *Yvonne*, aged 6, had 70% full-thickness burns. On the fifteenth day the burns on the anterior half of her body were excised. Induction was by cyclopropane and maintenance by methyl n-propyl ether, oxygen and nitrous oxide. Two days later she developed ileus and died on the third post-operative day.

IV. *Christine*, aged 5, had 55% burns, 48% full-thickness. She was in very poor condition, but her sloughs were stripped on the nineteenth day under a similar anæsthetic to the last case. She remained toxic and died forty-eight hours later.

V. *Sheila*, aged 8, had a 54% burn, most of it of full-thickness and circumferential of the chest. She survived four operations with the same anæsthetic sequence, cyclopropane, methyl n-propyl ether, oxygen and nitrous oxide within the first sixty-one days, but on the seventy-first day she succumbed to a sudden respiratory infection.

VI. *Iris*, aged 6, had 45% burns, almost all of them of full-thickness. She had a stripping of sloughs and application of electric dermatome grafts on the twentieth day, anæsthesia being as in Case V. She was in good condition post-operatively, but died with multiple pulmonary infarcts three days later.

These 6 deaths, occurring as they did after 502 operations in 301 children, do not give the impression that surgery or anæsthesia in itself causes any increase in the mortality of burns in children—probably the reverse; and in none of these patients could death be attributed to anæsthesia. The implication is, in fact, that the anæsthetist undertaking the care of a burned child is faced with a patient whose life may be in jeopardy, but by failing to undertake a hazardous anæsthetic he may turn a likely mortality into a certainty.

The essentials of anæsthesia for burned children may be summarized as follows:

1) The personal approach.
2) The acceptance of the very bad risk.
3) The careful choice of premedication.
4) The use of a thoroughly familiar anæsthetic sequence.
5) The complete control of resuscitation during operation.
6) The prolongation of anæsthetic care into the recovery period.

My thanks are due to Mr. Emlyn Lewis and to Mr. Leonard Schofield under whose care these children had been admitted, and to the several anæsthetists, notably Dr. John Greatrex and Dr. Jean Horton who have given those anæsthetics in this series which I have not given myself.

Mr. Emlyn Lewis regarded the anæsthetist as the physiologist of the Burns Surgical Team, and stressed the importance of close liaison between the surgeon and the anæsthetist in the treatment of the burned patient.

He stressed the magnitude of the problem in view of the massive excisions of full-thickness burns; the importance of blood replacement during such excisions and, also, the value of hypotensive drugs during such excisions.

He also expressed the opinion that, within the not too distant future, surgeons would be carrying out excision of massive full-thickness burns within the first few hours of infliction.

He emphasized that it was not the custom at Chepstow to give repeated anæsthetics for dressing purposes and, in fact, he strongly deprecated such procedures.

Dr. Patrick Shackleton was interested in Mr. Emlyn Lewis' suggestion that it might be of advantage to tackle these children within the first hours after they had been burned. He had worked for some years in a burns unit and had the feeling that there was a brief period within the first few hours of the accident when it might be possible to do surgical excision or other procedures before the onset of hæmo-concentration and shock. He asked whether there was a safe, if short, interval where surgical intervention would be practicable.

Mr. Douglas Jackson: Since the concept of early excision of extensive burns has been raised, I think it is worth mentioning our experience with it.

For the last ten years at the Birmingham Burns Unit it has been our practice to excise and graft small deep burns, such as those produced by molten metal, on the day of injury (Ross, 1950; London, 1953). Since 1954, however, we have extended this to a trial of early excision and grafting in burns large enough to require intravenous colloid resuscitation. The largest area excised and grafted in this way has been 25% of the body surface, and this has been done in patients with burns up to 55% total area, excluding erythema. About 25 cases have now been treated in this way.

The operation is planned to close the wound or at least make it smaller at the earliest moment, and if possible before it has become contaminated, with the aim of lowering mortality, shortening healing time and lessening infection and discomfort.

The operation is a big one, but not technically difficult. It has been carried out in selected cases about six to eight hours after injury as it has usually taken us this time to resuscitate the patient and be sure that the blood volume is restored. An amount of blood is lost which is possibly a little greater than that following delayed grafting at two to three weeks if granulations are removed: it may amount to 1–1½ blood volumes of blood in a child. Swab weighing and controlled blood replacement are required during operation, and pre- and post-operative red cell volume estimations are necessary with burns of more than 20–30% total area to make the procedure safe. These investigations have been done by Dr. E. Topley using radioactive phosphorus or chromium techniques. With burns of more than 40% total area, post-operative blood volume estimations are particularly necessary since an amount up to 50% of the patient's red cells may be destroyed in the body during the first forty-eight hours after burning without visible evidence and in addition to the operation loss measured by swab weighing.

It is early days still to assess results but the procedure is certainly possible, and it appears to be safe *provided that* swab weighing and red cell volume estimations are used. It should be emphasized that this is not an operation upon a shocked patient but on a resuscitated one with a normal blood volume, during what is usually regarded as the "shock period" of the first forty-eight hours after burning.

BOOK REVIEWS

Text-Book of Orthopædic Medicine. Vol. 1. Diagnosis of Soft Tissue Lesions. By James Cyriax, M.D.Cantab., M.R.C.P.Lond. 3rd edit. (Pp. xiv + 711; illustrated. 45s.) London: Cassell & Co. Ltd. 1957.

It is Dr. Cyriax's thesis that orthodox methods of diagnosis in painful conditions of the locomotor system are slovenly and unsatisfactory. As a corollary of this, many of the treatments which are commonly prescribed are illogical or harmful. It is his laudable objective to remedy this state of affairs by teaching clinical methods of examination which are simple, logical and accurate and which require very few adventitious aids—such as X-rays—to be effective.

Although there appear to be extremely few changes in this edition as compared to the last, the fact that this book has required three editions within ten years suggests that the need for new thought on these problems is widely accepted, and in critically evaluating Dr. Cyriax's provocative contributions one must be quite clear whether one is applying empirical or strictly scientific criteria.

As judged empirically there is much to be said for the use of "shock tactics" and dogmatic statements as a method of impressing points upon the reader, especially if the teaching is aimed at postgraduate students who already have a basic knowledge of the subjects under discussion. It is less certain if it is a legitimate approach in training undergraduates.

For example it is a refreshing challenge to one's accepted beliefs to be told on page 81 that osteo-arthritis of the knee-joint is a symptomless condition except in very advanced cases, and that when symptoms do occur they are caused by the impaction of cartilaginous loose bodies within the joint. However, one must challenge the statement on the same page that osteo-arthritis is a purely degenerative process, since it is well recognized that an inflammatory infiltration of the synovial membrane is usually found if osteo-arthritic joints are biopsied in the acute or subacute stages. On page 365 one is arrested by the bald statement that the conception of a "postural backache" is a figment of the clinician's imagination and again on page 488 that the treatment of backache by postural exercises is actually harmful to the patient.

For each part of the skeleton a comprehensive and systematic method of clinical examination is described, and although it is difficult to accept all the interpretations which the author suggests (for example that there are 6 distinguishable varieties of subdeltoid bursitis, p. 248—or three separate types of tennis elbow, p. 278) this is probably the most important message in Dr. Cyriax's teachings. A systematized approach is undoubtedly useful in examining problem cases, it also trains the clinician's powers of observation to examine cases routinely according to a set pattern.

It is not possible to comment on the unorthodox approaches to treatment which are recommended since, except in broad outline, these are relegated to a separate volume. It seems rather a pity to separate two such interwoven themes. It would seem preferable, if two volumes were necessary, to divide them on a topographical basis rather than to leave the reader frustrated by the desire to learn how to cure the patient he has learned to diagnose so accurately! A list of references at the end of each chapter quoting the authority for some of the more startling statements is another improvement which might well be incorporated into future editions.

This book is well presented and thoroughly stimulating. As such it should certainly be studied by those who are interested in this group of common yet ill-understood conditions. As for the validity of Dr. Cyriax's concepts one is forced to reserve judgment until the results of properly controlled clinical trials are available to prove beyond dispute that his methods are a significant improvement over those which he so abhors.

Atlas of the Commoner Skin Diseases. By Henry C. G. Semon, M.A., D.M.Oxon., F.R.C.P.Lond. Colour photography originally directed by the late Arnold Moritz, B.A., M.B., B.C.Cantab. Revised with the collaboration of Harold T. H. Wilson, M.A., M.D.Cantab., M.R.C.P., D.T.M. 5th edit. (Pp. viii + 375; 153 colour plates. 105s.) Bristol: John Wright & Sons Ltd. 1957.

The fact that this atlas has had five editions is a sure sign of its value. It contains 131 plates illustrating the "commoner" skin disorders and 22 plates of "some less common" dermatoses. Accompanying each plate is a fairly brief text usually describing the disease illustrated and its diagnosis and treatment but sometimes giving a brief account of the

patient photographed. The value of the plates is variable; most of them are excellent but some are rather too crimson. They are mostly well chosen, though in one, the diagnosis given, varicose ulcer, seems improbable. It is a pity that dermatologists should use the ridiculous name varicose eczema. Apart from this the text has been brought up to date satisfactorily. The book is very well produced and has a good index. The value of an atlas of clinical dermatology is a matter of opinion but this is a good one. It can be warmly recommended for those who find such a work useful. Considering the cost of good colour photography the price is most reasonable.

Textbook of Physiology and Biochemistry. By George H. Bell, B.Sc., M.D.Glasg., F.R.F.P.S.G., F.R.S.E., J. Norman Davidson, M.D., D.Sc.Edin., F.R.F.P.S.G., F.R.I.C., F.R.S.E., and Harold Scarborough, M.B., Ph.D.Edin., F.R.C.P.E., M.R.C.P. 3rd edit. (Pp. xii + 1068; illustrated. 60s.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

This textbook has now attained the dignity of a third edition within seven years, an indication of its usefulness. The authors apologize unnecessarily for the slight expansion since the last edition—the amount of information supplied could hardly be shortened further. The medical student who masters its contents will be well armed for his future clinical studies. Despite the tripartite authorship there is a considerable unity of structure, the text is well abreast of present-day physiological and biochemical thinking, the gaps in our knowledge are indicated clearly and adequate references are given to enable the student to get rapidly *au fait* with such detail as he may require and by far the greater number of the references are in English which is fully justified in a textbook of this type. Sufficient of the history of the subject is included for the modern advances to be seen in their proper perspective. There has been no sparing of illustrations, a number of which are in colour. The diagrams are clear and to the point. Many of the figures are from classical papers, a useful feature. The combination of biochemistry and physiology in one volume has much to recommend it from the student's angle and has been very successful although on occasion this has necessitated a certain degree of over-simplification but this is perhaps a criticism in detail. The format is clear—the proof reading has been excellent and the result is a very satisfactory, readable modern introduction to what can still be described as the "Institutes of Medicine" and which will also be useful to the postgraduate needing a rapid survey of the present beliefs and practices in these subjects. It is to be hoped that the authors will not flinch from their voluntary martyrdom and continue to keep it up to date and within controllable limits.

Hypotensive Drugs. Proceedings of a Symposium on Hypotensive Drugs and the Control of Vascular Tone in Hypertension, held in London on April 5 and 6, 1956, at the Wellcome Foundation. Edited by M. Harington, M.B., M.R.C.P. (Pp. x + 222; illustrated. 50s.) London and New York: Pergamon Press. 1956.

This symposium held at the instigation of the Biological Council brought together a very representative group of chemists and biochemists, pharmacologists and clinicians, to discuss certain aspects of a common problem, hypertension.

Starting with a series of papers on the chemistry and biochemistry of drugs lowering the blood pressure, it ranged through to their pharmacology and clinical application and concluded with a discussion on the control of vascular tone in hypertension. Such combined discussions lead to a clearer picture of the real status of the pharmacology and therapy of the disease. The earlier papers indicated the wide range of substances available and showed up the wide diversity of their biochemical modes of action both centrally and peripherally. Structure and activity relations showed up clearly within various series. In the general discussions on the pharmacology of these drugs, considerable attention was devoted to Reserpine, the β-haloalkylamines, the veratrum alkaloids and tolerance to ganglion blocking substance. All the more important types of drug used were discussed including some of the most recent whose clinical status is still under discussion. The amount of pharmacological information now available is surprisingly large but the difficulties of its direct application were clearly demonstrated when the clinical and pathological aspects came under discussion. Until clearer ideas of the pathology or pathologies of the hypertensive state are available the therapeutic attack has to be to a certain extent empirical, but it is yielding results and these results were well dealt with by the subsequent speakers. The symposium, international as it was in character, performed a useful function in that it made those interested better acquainted with the lines of thought underlying the efforts of the various disciplines and gave them a greater appreciation of the difficulties involved and the editor is to be congratulated on the rapidity with which the whole has reached publication to give an up-to-date summary of how matters stand.

Operative Surgery. Editors: Charles Rob, M.C., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. In 8 volumes and index. (Volume 3 Rectum and Anus. Thorax; illustrated. £5 10s. per vol., Index £2.) London: Butterworth & Co. Publishers Ltd. 1957.

We have already given a warm welcome to Volumes 1 and 2 of this work (*Proceedings*, 1957, **50**, 114). The subjects of the present volume form an interesting contrast in that the first part deals with well-standardized operations on the rectum and anus, and the second with the surgery of the thorax, including such recently developed operations as the closure of atrial septal defects. In the section on the surgery of the rectum and anus, it will be a source of pleasure and confidence to readers that the St. Mark's school is so strongly represented in Lloyd-Davies, Goligher, and Lockhart-Mummery. There is little calling for critical comment, but perhaps proctoscopy is too banal a procedure for inclusion in a work of this kind, and we would have been personally happier if exteriorization rather than excision of pilonidal sinus had been described. The excision operation is responsible for much unnecessary morbidity in the form of prolonged and uncertain healing. In the section on fistula-in-ano, we welcome the use of the much more logical term of ischio-rectal fistula instead of ano-rectal fistula. In the treatment of rectal prolapse we wonder whether the editorial policy of getting the contributor to describe fully merely the operation he thinks the best is not an undue simplification of a very difficult problem.

In the section on the thorax, we are glad to see among the contributors the names of such British pioneers as Holmes Sellors and Franklin. We are sorry, however, not to see Sir Russell Brock's name, though in compensation his junior colleagues of the Guy's school are well represented. It is interesting to see how quickly operations have become standardized which only a few years ago were breath-taking advances. The operation of mitral valvotomy so admirably described by Belcher is an outstanding example. A similar criticism to that made above on the treatment of prolapse of the rectum might perhaps also be made about the chapter on the treatment of reflux œsophagitis. We wonder, too, whether the section on methods of obtaining ideal conditions for open heart surgery is not as yet a little too premature for dogmatic description in an operative surgery textbook. These are, however, relatively minor criticisms, and the main impression left by this third volume is that it has fully satisfied the high expectations aroused by the first two volumes.

Lymphatics, Lymph and Lymphoid Tissue. By Joseph Mendel Yoffey, D.Sc., M.D.Manch., F.R.C.S.Eng., and Frederick Colin Courtice, M.A., D.Phil.Oxon., D.Sc.Sydney, F.R.A.C.S.Hon. 2nd edition. (Pp. vii + 510; illustrated. 60s. 0d.) London: Edward Arnold (Publishers) Ltd. 1956.

This very readable book covers a wide field of physiological and experimental medicine, a field which is largely neglected in the average student's education. The examination of many of the beliefs which appear in the average textbook on the functions of the lymphatics and lymph nodes shows that in many cases experimental evidence of their incorrectness has been available for several decades without apparently penetrating very far into the main body of opinion.

Some of the problems discussed in this book are complicated by the variation between species and what is true for the cat is not necessarily true for the human lymph system. The arrangement follows the orderly system of an initial general survey of the anatomy and geography of the lymphatic system. The next chapter is on the formation of lymph and this inevitably entails consideration of the extracellular body fluid and its distribution in the body. The first real step forward in the understanding of the production of lymph followed Starling's paper in 1896 and his original concepts have stood the test of time. One point which is well brought out is the universal presence of protein in the fluid filtered through the capillaries and experiments are quoted showing how the quantity of this protein in the normal dog may vary from 200 mg. to nearly 800 mg. per 100 ml. in varying states of activity. Using the modern electrophoretic techniques, it is shown that this protein corresponds closely to the plasma proteins. When the volume of the extracellular fluid is considered, it becomes obvious that a very large protein pool exists outside the vascular system and, in fact, the amount of protein in the pool is usually greater than the amount in the blood. The return of the protein to the circulation occurs via the various lymph ducts which drain into the vascular system, of which the thoracic duct is best known. Practically the whole of the protein circulating in the vascular system filters through the capillaries and returns through lymph ducts about once every day. The factors affecting the rate of filtration of lymph through the capillaries are discussed, and in particular, oxygen lack.

In the next chapter, the lymphatic systems of the body, alimentary tract, liver, skin, kidney, bones, &c., and the manner of their function in disease is described. The following chapter deals with the rate of flow, the pressure, and the composition of lymph, and useful tables are given of the quantities of the various electrolytes and non-electrolytes found in lymph.

Chapter V discusses the biological significance of lymphoid tissue and its efficiency and it opens with an important section on the effect of irradiation on the lymph tissues of the body. Interesting experiments on the relationship between the amount of lymphoid tissue and bacterial infection are given and it is shown that an animal brought up in a completely aseptic way had only approximately a quarter of the amount of lymphoid tissue present, however such animals were, without exception, malnourished and usually died. The exact position of the lymphoid tissue in the defence mechanism is discussed at some length and considerable doubt is thrown on many theories. In particular, it has been shown that the "barrier" theory is only partially true. It is certain that production of lymphocytes is one of the main functions of lymphoid tissue.

The following chapter is a study of the lymphocyte itself, its development and its function and here there is considerable conflict of opinion, particularly as regards the relationship between the small and the large lymphocytes, plasma cells and monocytes, &c. In the final chapter, practical considerations concerning the relationship between the lymphatic system and disease, such as œdema, inflammation and malignancy are considered.

In this book the literature has been well and thoroughly reviewed. It is, however, more than a mere compendium of other people's research work. Both authors have contributed much themselves and they are not afraid to give their own opinions clearly, even if these are in opposition to some accepted ideas. The book is well produced with good illustrations and only a few misprints.

Cancer of the Lung—Pathology, Diagnosis and Treatment. By Milton B. Rosenblatt, M.D., and James R. Lisa, M.D. (Pp. xiii + 330; illustrated. 120s. 0d.) New York: Oxford University Press. London: Cumberlege. 1956.

This monograph, to which ten authors have contributed, is based upon a study of material derived from the wards of the New York City Hospital and from private practice. It has as its central theme the early diagnosis of carcinoma of bronchus at a stage at which surgical treatment can offer reasonable hope of cure. The necessity for earlier diagnosis is illustrated by the fact that in only 5% of the patients was operation undertaken before the growth had spread beyond the lung of origin to the regional lymph nodes, or metastasized more distantly. With this aim in view the chapters concerned with physical examination and modes of presentation of the disease contain considerable detail and are fully illustrated by case reports and X-ray photographs. Onset with neuropathy is an unexpected omission, but this is the only major criticism of this aspect of the subject. Bronchoscopy, cytological examination of the sputum, and the adenoma are all accorded separate chapters.

In other respects, however, the book falls short of the stature of a monograph. Such predisposing factors as smoking and atmospheric pollution are dismissed more cursorily than their current importance warrants. Medical and surgical palliative treatment, together with the "psychotherapy" of the cancer patient, have all been included with radiotherapy and suffer relative neglect. The bibliography bears no precise relationship to the text.

Biological Aspects of the Transmission of Disease. Edited by C. Horton-Smith (Pp. viii + 184. 21s.) Published for the Institute of Biology. Edinburgh and London: Oliver and Boyd. 1957.

In this age of increasing specialization in the many different aspects of biological research it is gratifying to see an attempt made to gather together some of the experts in their particular fields and, to quote the editor of this book, " . . . to break down . . . the specialist barriers that have hitherto hindered the dissemination of knowledge and exchanges of view. . ."

The book is a collection of papers presented at a recent symposium of the Institute of Biology on the transmission of disease. It includes 22 of the major papers read and these cover such widely different fields as mycology, bacteriology, protozoology, helminthology and virology, in respect of human, animal and plant disease.

In spite of the apparent sectional nature of the book there is, nevertheless, an overall continuity which is derived from the accent that has been placed on the modes of transmission of pathogenic organisms in general rather than on the organisms themselves. Thus the great importance of the soil as a reservoir for pathogenic organisms among the bacteria, parasitic Protozoa (e.g. coccidia), helminths (e.g. hookworms), &c., is increasingly apparent with each paper read. At the same time one is reassured by the vast range of biological and non-biological factors which govern the dispersal, survival and transmission of these organisms: the growing need of much work on such factors is continually stressed.

The book is a mine of information and will doubtless stimulate many readers to take advantage of the large list of references to more advanced reading matter. There is an interesting chapter devoted to the questions raised at the termination of the symposium. Unfortunately the rather monumental task of correlating the mass of problems and obser-

vations discussed by the speakers has not been attempted: the reader is presumably left to his own conclusions which, on the first reading, will probably be that he knows very little about a great deal.

Textbook of Medicine. Editors: Sir John Conybeare, K.B.E., M.C., D.M.Oxon., F.R.C.P., and W. N. Mann, M.D.Lond., F.R.C.P. 12th edit. (Pp. xvi+861; illustrated. 42s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

This medium-sized textbook, now in its twelfth edition, is remarkably successful, and is excellent value at its very moderate price. The whole has been revised, much has been rewritten, and students and general practitioners will find here succinct and readable descriptions which cover the wide field of medicine. The index is not up to this high standard. Whenever a student hears, on a ward round or in a lecture, an unfamiliar phrase, e.g. promin dressings (page 101), anchovy sauce sputum (page 144), axonotmesis (page 696), he ought to be able, on coming home, to look it up in the index of his textbook and so learn more about it. This index is not only incomplete; it is inaccurate, e.g. Queckenstedt's test is *not* mentioned on page 693, and the sedimentation rate is *not* mentioned on page 271. It is to be hoped that before the next edition the index will be expanded and most carefully correlated with the text. Incidentally, the authors might look again at the alleged hexameter on page 611. Try as he will your reviewer is quite unable to scan it.

Pulmonary Complications of Abdominal Surgery. By Anthony R. Anscombe, M.S.Lond., F.R.C.S.Eng. (Pp. x + 121; illustrated. 20s. 0d.) London: Lloyd-Luke (Medical Books) Ltd. 1957.

In this present small volume the author has recorded the work which gained him the Moynihan Prize of the Association of Surgeons, and the M.S. degree. One of the characteristics of present-day clinical research, in both its main subdivisions of physic and surgery, is the use of the tools of biochemistry and physiology. In the past, the physician has made greater use of these tools than the surgeon, the latter having been perhaps too exclusively preoccupied with the morbid anatomical. But the balance is being rapidly redressed, and in the volume under review a surgeon has attempted to throw light on the chest complications of operations by quantitative physiological investigations of the mechanical effects of operation on lung function.

After a brief historical introduction in which the modern era is rightly noted as beginning with William Pasteur's classical article of 1908 on massive collapse of the lung, the author describes his own investigations. He has used modern spirometric methods, and relied chiefly on determinations of the vital capacity and the maximum expiratory and inspiratory rates. Charts are given of the effects on these measurements of a wide variety of factors such as various types of abdominal incision, peritonitis, pain, drugs, dressings, distension and posture.

The degree to which the findings can be applied to post-operative chest complications depends on the degree to which the investigations can be regarded as an index of pulmonary function, and the author rightly recognizes that they are incomplete and imperfect indices. But some of the discussion is unduly simplified. Thus, he tends to equate hypoxia with hypoventilation when there may be many other factors in its causation. The author deserves credit for his energy and initiative, and the work can be accepted as a useful introduction to the problem, but it might perhaps have been better contracted into an article in a surgical journal rather than expanded into a monograph.

Dextran and Its Use in Colloidal Infusion Solutions. Anders Grönwall, M.D. (Pp. 156; illustrated. 20s.) Stockholm: Almqvist and Wiksell. New York: Academic Press Inc. Oxford: Blackwell Scientific Publications. 1957.

This monograph, by one of the group which introduced dextran into medicine, is a comprehensive study of the principles involved in its use as a plasma volume expander and the research aspects involved in its clinical use and manufacture. The last war re-emphasized the need for a solution capable of replacing blood. On the Allied side this was largely solved by the use of the blood-bank and freeze-dried plasma. On the German side high molecular polymers such as Periston (polyvinylpyrrolidone) were used. This latter to a certain extent suffers the disadvantage of the older Bayliss gum saline by remaining unmetabolized in the body too long. While the Allied method was the more logical and more satisfactory, under disaster conditions such a type of treatment would be very difficult to keep going. Dextran has the advantage of not requiring exacting conditions of storage and it can be stock-piled if necessary. It comes intermediate between the non-metabolized polymers and the blood and serum preparations in being completely metabolized, and further is free from the danger of

carrying any latent virus infection. The first chapter discusses in detail the advantages and disadvantages of the various types of replacement solution so far employed and makes the point that blood *per se* is not always necessary in cases of shock. It gives a rational basis on which the best choice of solution may be determined. The succeeding seven chapters deal with the chemistry of the dextrans undegraded and degraded, the adaption of molecular size towards the desired therapeutic effect, the fate of dextran given intravenously, the serology, the therapeutic effect and clinical studies of the use of dextran solutions. In addition, there is a postscript dealing with the most recent references at the time of going to press, a mute comment on the ever-accelerating rate of research. The main medical uses of dextran in the last decade are more than adequately covered, the whole field is thoroughly dealt with, the settled facts indicated, difficulties are not minimized, the gaps in our knowledge are shown and the reader is given ample evidence on which to base his own opinions.

The Swedish Dextran Team have every reason to be satisfied with the work initiated. The translation is adequate and the print and general format very satisfactory and the price for such a specialized publication is very reasonable.

The Principles of Therapeutics. By J. Harold Burn, M.A., M.D., F.R.S. (Pp. ix+278; illustrated. 27s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

This book consists of the lectures given by Professor Burn to Oxford medical students. Apparently this is their only formal instruction in therapeutics. However, the lectures are a useful bridge from the laboratory to the clinic. The information given is condensed but clear, and will repay careful reading. As befits its title, therapeutic dosages are seldom mentioned. These are best learned when actually dealing with the diseases. The senseless rote of lists of doses that plagued the medical student of earlier generations did not add to the interest of pharmacology or materia medica as it then was called. The author's enthusiasm is infectious and he demonstrates in an interesting fashion the facts which form the basis of present-day drug therapy. Working during the most active and successful period of the development of pharmacology, he has been able to indicate in broad outline the rapid increase in the efficiency of drug therapy, the transition from therapeutic nihilism to an almost calm expectancy that few problems are too difficult given time and application. In a short work of this nature a great deal of selection of items of study is to be expected and a degree of individual preference inevitable. This is perhaps the case in the field of the local hormones which Professor Burn has studied and enriched over many years. Pharmacologically, however, this is justifiable as it is an essential feature of so much of drug activity. The principles of biological standardization are described sufficiently, and the last lecture is on biological variation and clinical trials. The tone of the book is essentially practical—the author's views on the use of hypnotics are very down-to-earth—it is interesting to find the virtues of the open air invoked as an adjuvant to the treatment of insomnia. He also stresses very early in the course the necessity of good clinical understanding to inspire confidence in the patient. Altogether the book will serve as a useful substructure for rational therapeutics and will hold the interest of the student wherever he may be. The general layout of the book is good and the price, for these days, reasonable. An interesting book, not only for undergraduates.

Mathematics and Statistics for Use in Pharmacy, Biology and Chemistry. By L. Saunders and R. Fleming. (Pp. x+257; illustrated. 27s. 6d.) London: The Pharmaceutical Press. 1957.

This monograph has been published by direction of the Council of the Pharmaceutical Society of Great Britain "to meet the need of those who practise and study pharmacy for a book which is comprehensive but which will not require for its study an unduly high proportion of their time". The first half of the volume is devoted to a rapid survey of various aspects of mathematics at a standard that corresponds roughly to the advanced level of the General Certificate of Education. Many of these chapters are short, and although they are clearly expressed, it seems doubtful—in spite of the authors' assurances—whether many readers will derive much benefit from them unless they have had a good grounding in the subject beforehand. The second part is devoted to statistical concepts and to their employment in various aspects of biological and biochemical assay.

The book contains many examples that are largely illustrative of problems that arise in medical and pharmaceutical work, and these, together with the set questions and answers at the end of each chapter, will prove of much help to the serious reader anxious to ground himself thoroughly in the principles discussed. But in general the standard of the text is pitched high, and it may be doubted how useful the book will be to anyone who does not combine the advantages of a good school background in mathematics with a taste for the subject itself.

In all directions...

Since the introduction of chlorpromazine, clinical studies have continued to reveal many new aspects of treatment with this drug. The therapeutic applications of 'Largactil' extend in many directions, and its use in general medicine has become well established.

Included in the indications for which 'Largactil' is of value in general practice are: the control of intractable nausea and vomiting; the enhancement of the action of analgesics and hypnotics in the relief of intractable pain; the relief of pruritus; the alleviation of anxiety and tension states; the home management of behaviour disorders in children; in the management of senility, particularly confusional states; and in the treatment of psychoneuroses.

PRESENTATIONS

Tablets — 10, 25 and 100 mgm.

Syrup — containing 25 mgm. per 3.6 c.c. (approx. 1 teaspoonful).

Solutions for Injection — 1% solution in 5 c.c. ampoules, 2.5% solution in 1 c.c. and 2 c.c. ampoules.

Suppositories — containing 100 mgm. base.

DISCUSSION ON THE CHANGING VALUES IN ELECTROENCEPHALOGRAPHY

Dr. Denis Hill (Institute of Psychiatry, Maudsley Hospital, London):

The title of this discussion suggests that there have been some significant and radical changes in the theory or practice of electroencephalography. This, I think, has not yet occurred, but I believe we are now in a position to take another look at our subject and to make an attempt at re-appraisal of its techniques and of its usefulness. The history of electroencephalography indicates that in its clinical application it has been necessary always to use an empirical approach. We still have no fundamental knowledge of how the EEG phenomena are produced by neurones, and we have little knowledge of how these phenomena are altered by disease processes. We still do not know with any certainty what physiological functions, if any, these spontaneous electrical rhythms reflect. Interpretation of the EEG record for meaningful clinical purposes has rested therefore upon a basis of approximate correlations. There is little or no physiological logic or meaningfulness in this process, which has been empirical at the lowest level—i.e. a process of correlating EEG patterns with clinical facts without, as a consequence, the development of any theory which can be tested by experiment to account for the associations which have appeared. The lack of a general theory of cerebral functions to take account at once of both the normal and the abnormal EEG is still the greatest defect in the subject. The patterns of electro-cortical activity seen in the experimental animal subjected to lesions in, and stimulation of, different subcortical areas bear striking resemblances in many instances to the abnormal patterns encountered in the human EEG. It has proved very tempting to interpret the phenomena of the abnormal human EEG in terms of the results obtained on the experimental animal. The recognition of the influence which subcortical systems have upon the patterns of the cortical EEG has been the outstanding advance in knowledge of the last ten years.

Nevertheless we must admit that the empirical approach to the subject has failed, since by this method the accuracy of diagnosis—the capacity to answer the clinical problem—has not significantly increased. Rather the reverse has occurred, since with increasing knowledge and experience, the apparent correlations have become less certain. In this respect we can compare the situation of clinical electroencephalography with other empirical techniques in medicine which have proved successful. Generally speaking, most of the measurements of chemical or physiological variables and the single observations of an anatomical or of a structural nature which we can make on man have reasonably hard and fast and therefore predictable associations. It is upon such things that the validity of laboratory techniques rests in clinical medicine. The empirical approach to electroencephalography has failed by comparison. The early work relating simple EEG observations to obvious clinical events has not proved a solid foundation upon which further measurements could be made which, in turn, increased knowledge of cerebral function or led to greater accuracy in topographic diagnosis or understanding of disease process. I would say that, as a result of a single EEG examination and without any clinical information it is rarely possible to predict what is likely to be wrong with a patient. The most useful knowledge the electroencephalographer can possess is clinical information about the patient; indeed, the electroencephalographer must interpret his data in the light of the clinical symptoms. Complete ignorance of the clinical state or an inability to understand the clinical problem which the patient presents, leads to the wildest errors, even in the hands of the most experienced physiologists.

Some of the difficulties which have arisen may have been due to common errors of thinking such as:

(1) First there has been preoccupation with areas of the brain as if they were autonomous units when, in fact, every area is part of a system or systems, disturbance in any part of which may disturb the functions of the area under observation.

(2) As a corollary of this there has been the idea that the disturbance caused by a lesion is necessarily at the site of the lesion.

(3) Thirdly there has been the erroneous idea that there exist electrophysiological or "electropathological" entities having constant clinical associations and a common causation. An example of this is the idea that bilaterally synchronous spike and wave activity is a func-

tional entity with epilepsy as the clinical association and a constitutional or genetic causation.

(4) Then there is the common error of treating the data recorded on the moving paper as if it was a "thing", when in fact what are recorded are only changes of excitability during the period of time under observation. From this another error follows, that there is "an amount of abnormality". We commonly say, for example, that "there is a considerable *amount* of 2–3 c/s activity in the right frontal areas", or there is a "large *amount* of bilaterally synchronous spike and wave activity", suggesting that the greater the "amount" of abnormality, the more pathogenic the lesion, or the more certain it is that a lesion exists, or, by implication, the more serious the prognosis.

In place, therefore, of a spatial anatomical concept of local areas of the cerebral cortex as autonomous units, the electrical functions of which reflect the state of health or disease in them, there is a functional non-spatial and physiological concept of neuronal systems, involving cortico-cortical, intracortical, and subcortical-cortical connexions. Every area of the cortex is involved in all such systems, and the character of the spontaneous electrical activity in any cortical area may be affected by excitability changes in any part of any of the systems in which it is involved, and of which it forms a part. The EEG pattern is therefore sensitive to a large number of different physico-chemical changes but also to structural lesions of all kinds and in many anatomical sites remote from the area under observation. The functional or clinical correlates of changed excitability in these neuronal systems are *not* with motor behaviour or sensory experience, i.e. *not* in altered functions as detected by the methods of classical neurology. Rather it seems that the probable distinctive correlates will prove to be with adaptive psychological functions at a high level, such as learning abilities or conditioning processes. If this proves true we cannot therefore expect to find, and in fact we do not find, hard and fast correlations between EEG phenomena and sensorimotor functions of the C.N.S. In this respect there is a clear contrast with the data of morbid anatomy. Very numerous different clinico-pathological entities may result in the same EEG pattern, and many types of EEG pattern can occur in one disease.

I would like to illustrate this theme by reference to three commonly encountered abnormal phenomena of the EEG. The first of these is concerned with the alpha rhythm and can be described as—*changes of amplitude and occurrence of the alpha rhythm, lateralized to one hemisphere or confined to one area of the head.*

Selective loss of the alpha rhythm on one side of the head is encountered in gross hemiatrophy and is seen, for example, in patients with infantile hemiplegia. In these cases it is assumed that the cortex producing alpha waves is absent. One can, in fact, map out maximal areas of atrophy with some precision by this means and recording the EEG under barbiturate narcosis facilitates the process since the fast rhythm which then develops in normal cortex is absent in atrophic areas. But if many records are taken in such cases it will be seen that the amount of rhythm in the damaged cortex varies from time to time. It is never safe to assume atrophic cortex on the basis of a depressed or absent alpha rhythm in one record. Indeed absent rhythm may mean that a mass of inert tissue, such as a hæmatoma or meningioma, intervenes between the recording electrodes and the brain. But there are often equally important and more commonly encountered cases than this. Reduction or absence of the alpha rhythm may follow a cerebral thrombosis, a contusional blow, a focal epileptic seizure, a surgical procedure and sometimes when there is a space-occupying lesion, either intracerebral or extracerebral, anterior in the head on the same side. In all these cases the actual cortex from which the alpha rhythm is absent is itself normal from the structural point of view. As Williams and Reynell (1945) were the first to point out in the case of traumatic contusion, the site of disease or injury is generally anterior to the areas of depressed alpha rhythm. In these instances we are obviously observing the changed excitability in cortico-cortical systems.

A similar but sudden reduction of alpha rhythm is often witnessed when an epileptic focus starts to fire on the surface of the cortex. This active "suppression" of normal rhythm often precedes the discharge phenomena of the epileptic seizure and no doubt the same cortico-cortical neuronal systems are involved.

The focal abnormality.—The second commonly encountered phenomenon of the EEG is the focus of abnormal activity, and here I shall discuss only the slow wave focus and the focus of spike potentials. *The slow wave focus* is regarded as evidence of abnormal cortical function in the neighbourhood of the electrode from which it is recorded. Walter (1936) was the first to point out the difference between the focus of slow waves having *irregular form* (i.e. varying frequency, amplitude and harmonic content) which is strongly suggestive of local structural disease, and the regular sinusoidal type of slow wave focus not necessarily found in association with organic disease but often found in epileptics. The *organic type* irregular wave form focus is indeed one of the few distinctive, valuable and predictive signs in the EEG, being associated very frequently with structural lesions in the neighbourhood. But again the phenomenon can occur in the absence of such structural disease and

it is most unwise to predict this on the evidence of a single EEG, particularly if the patient suffers from epileptic seizures. A focus of this type of abnormal activity can persist for some days after the seizure in the area from which a focal seizure has started. Serial EEGs spaced over some days are necessary to establish the constancy of the finding. In both types of case, the postictal focus and the tumour focus, depression of the alpha rhythm may be evident as well on the same hemisphere.

In the sinusoidal regular rhythmic slow wave foci, reported first in epileptics, the situation is more complex. These foci occur in normal cortex distant from structural lesions, and for this reason I think the term "physiological foci" is justifiable. They occur in a very large number of disease processes, as well as in epilepsy and in many cases in which there is no known cerebral disease. In the latter these foci are often found in the posterior temporal areas. Yet in other cases where known local lesions of the brain exist, the physiological focus may be also in the posterior temporal areas, when the lesion is elsewhere, perhaps in the other hemisphere. Indeed the physiological focus is always at a distance from the lesion if one is present, e.g. frontal in an occipital lesion, parietal in a frontal lesion, posterior temporal with a lesion in the homologous areas of the opposite hemisphere. Here again one must assume the altered excitability in cortico-cortical neuronal systems. These "physiological foci" are often very sensitive to arousal stimuli, more so than the alpha rhythm, and in this respect contrast with the slow waves in the neighbourhood of lesions.

The spike focus.—The repeated random appearance of spike potentials from one area of the head has not itself any clinical correlations. Brazier (1955) has suggested that these spikes have the same origin as strychnine spikes, namely, that they represent the synchronized discharges of the apical dendrites of large cortical cells, without necessarily any discharge of the cells themselves. The focal spike discharge has been generally accepted as the best evidence we have of a local epileptogenic lesion, be it scar, atrophic gyrus, neoplasm, or vascular anomaly. The spike foci are encountered, it is realized, in the marginal cortex adjacent to the diseased area; the spikes therefore are thought to have localizing value and indeed a wide clinical experience with the EEG gives good support for this view. Electrocorticographic studies have confirmed that the spikes are found in normal cortex around the lesion and moreover that such spikes are often at a considerable physical distance from the lesion. Indeed in many cases of infantile hemiplegia and in some of temporal lobe epilepsy in which focal macroscopic lesions are later found, spike foci have been obtained not only on the atrophic cortex and in the anterior temporal areas near to the lesions, but also *on the opposite hemisphere.* Moreover the firing of the spike discharges on the normal hemisphere is not in any way triggered by those on the diseased side, but is quite independent of them; nor are the spikes on the normal hemisphere necessarily in areas homologous to those on the diseased side from which spikes can be recorded. If one takes a series of EEG records over a few weeks in a cerebral hemiatrophy case or in a temporal lobe epileptic, one is likely to be confused by the fact that the sites of spike foci are not constant, nor is the intensity of their firing constant, from one occasion to another. The ubiquitous but inconstant character of spike foci is baffling to the electroencephalographer who from this data alone is hard put to it to determine which spike focus, out of a possible 4 or 5, is the important one with localizing value. To put the matter in another way, if the patient has epileptic seizures, from which area or areas do the seizures start? Which are the functionally operative area or areas and which are the unimportant ones? There can be no doubt that this is the proper question, for in hemiatrophy cases in which spikes are found on *both* hemispheres, they disappear from the normal hemisphere after hemispherectomy of the atrophic side. The answer to this question at present is, I think, that from spike foci alone the electroencephalographer cannot make a decision; he needs other data. This data may be available in the EEG record—for example, a constantly reduced alpha rhythm in an atrophic area seen over a period of days or in repeated examinations; or may be clinical—the constant aura or focal character of the seizure pattern; or may come from radiology, or from the physical signs. But considered in isolation the single EEG examination may be frankly misleading. In fact, in those cases in which the presenting symptoms are epileptic seizures having a focal character, what elucidation can the single EEG provide? It may show that epileptic spike discharges can certainly be recorded from the expected area. This is satisfactory because on clinical grounds it was suspected, but if one is already confident on clinical grounds that focal epilepsy is occurring, it is merely irritating and solves nothing if the EEG is normal. However, an epileptic discharge may be recorded not only in the suspected area but also in one or more other areas as well. The decision of which is the operative epileptogenic area, the choice between spike foci, can only be made on a concordance between EEG and clinical evidence—the aura—focal character of the fit. In yet other cases it is necessary to activate the brain with a convulsant and to watch the focal abnormalities in order to determine from which of them the seizure starts.

Intravenous metrazol, Megimide, chlorpromazine and other drugs are currently used for this purpose.

Subcortical type epileptic activity.—The third commonly encountered abnormality in the EEG is subcortical type epileptic activity. This phenomenon, the bilaterally synchronous episodes of spikes, spike and waves in different associations, has a number of forms. In its 3 c/s spike and wave form it was formerly regarded as the best EEG evidence of idiopathic epilepsy. Occasionally, however, this can develop after brain damage causing epilepsy and a cortical spike focus may also be present.

In the less characteristic forms of fast and slow spike and wave complexes, the subcortical type discharges are found in association with a very large number of diffuse pathological processes and the clinical associations are equally varied and do not necessarily include epilepsy (Hill, 1956). It seems very probable that these discharges reflect changed excitability in subcortical-cortical systems and in themselves have no pathological or diagnostic significance. They are observed in the EEGs of patients with many and varied neurological disorders, in epileptics, in catatonic schizophrenics, and in behaviour problem patients; there is no single symptom or grouping of symptoms that can be related to the phenomenon.

The EEGs of the two following patients illustrate disturbances in cortico-cortical and subcortical-cortical systems brought about in one patient by a meningioma—itself not localizable directly by the EEG, and in the other patient by a vascular disorder, a carotid artery thrombosis, whose effect might be expected to disturb the functions of one hemisphere predominantly.

Case I.—This woman aged 59, under the care of Mr. Murray Falconer, was found to have a large tentorial meningioma growing from the dura in the region of the anterior part of the right lateral sinus. The tumour had bulged up and invaginated the inferior part of the temporal lobe at the temporo-occipital junction. For seven years she had suffered from temporal lobe seizures with tinnitus and flashing red lights as an aura. On one occasion she had had an olfactory hallucination. There were no signs or symptoms of raised intracranial pressure. The EEGs showed: (1) An alpha rhythm which was *larger on the right side;* (2) rhythmic 2–3 c/s activity in the right frontal areas; (3) a focus of low voltage 6 c/s activity in the right central areas in the transverse electrode line; (4) very poor photic responses in the right parietal areas compared with those on the left; (5) gross reduction of barbiturate-induced fast rhythm in all areas, including the sphenoidal area, on the right side. After removal of the meningioma, *reduction* of the alpha rhythm was seen on the right side.

Case II.—This man of 47, under the care of Dr. Denis Leigh, was found to have partial occlusion of the right internal carotid artery from an atheromatous plaque. He had suffered three small "strokes" causing left-sided weakness, from which he recovered rapidly on the first two occasions. The third occasion resulted in coma and during recovery from this a left-sided Jacksonian fit occurred. He showed a left hemiparesis and left-sided astereognosis and autotopagnosia. This patient subsequently had an operation for removal of the atheromatous plaque and artery repair carried out by Professor C. G. Rob at St. Mary's Hospital. A series of EEGs showed the following characters:

(1) A reduction in the alpha amplitude on the right side together with poor responses to photic stimulation on this side (Fig. 1).

(2) Focus of rhythmic high voltage 2 c/s activity in the right frontal areas and low voltage 6 c/s activity in the right temporal areas (Figs. 2 and 3).

(3) Bursts of subcortical type epileptic activity, i.e. bilateral, mainly frontal grouped spikes and slow waves (Fig. 2).

(4) Under I.V. Pentothal narcosis, barbiturate fast rhythm showed gross reduction throughout *all* areas on the right side (Fig. 3).

(5) A focus of "sharp" waves at the right sphenoidal electrode, which persisted under Pentothal narcosis (Fig. 4).

Three months after operation the Pentothal pattern and the focus at the right sphenoidal electrode were still evident.

Discussion.—Any general statement about the diagnostic value of the EEG must include the recognition that the single routine EEG has a very limited value. At most it can provide an indication that something is wrong and perhaps roughly where it is wrong, but precisely what is wrong it cannot predict. In many patients the single routine EEG is normal, but if repeated studies are made in which the brain is subjected to activating measures and to a changed physio-chemical milieu, new information often becomes available which can throw light on the disturbed cerebral functions of the patient. For lack of a general theory we can again only use this information in an empirical way. It seems likely therefore that the use of the EEG as a single standardized test will be superseded in time by a series of detailed special investigations, planned in advance to answer certain quite specific questions about the cerebral functioning of the patient. Clinical diagnosis in terms of the anatomico-pathological concepts of disease, is, I suggest, at one remove from the data of the EEG. Hitherto we have not known precisely what questions to ask. If we knew them we might find that the answers to them are of an importance equal to those we get from other sources and by other methods.

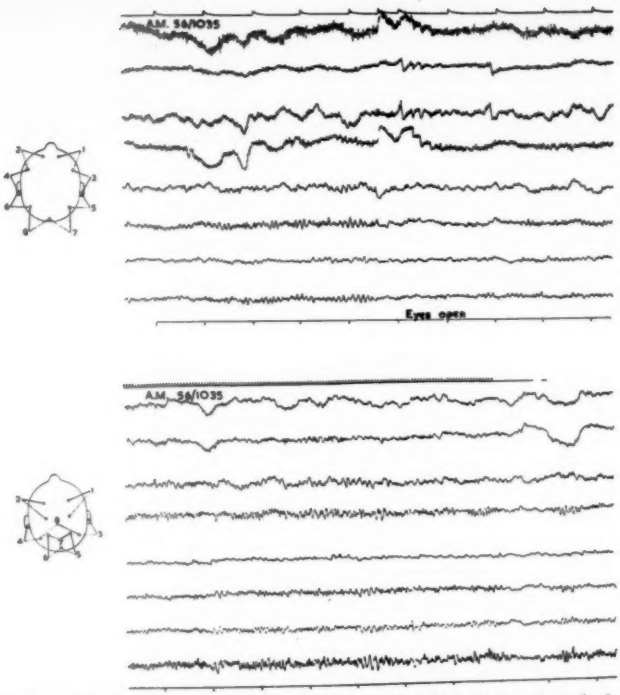

FIG. 1.—*Above:* Reduction in the alpha rhythm on the right side in channels 5 and 7 compared with the alpha rhythm on the left side in channels 6 and 8. *Below:* Reduction in the responses to photic stimulation seen on the right side in channels 3 and 5 compared with those on the left in channels 4 and 6.

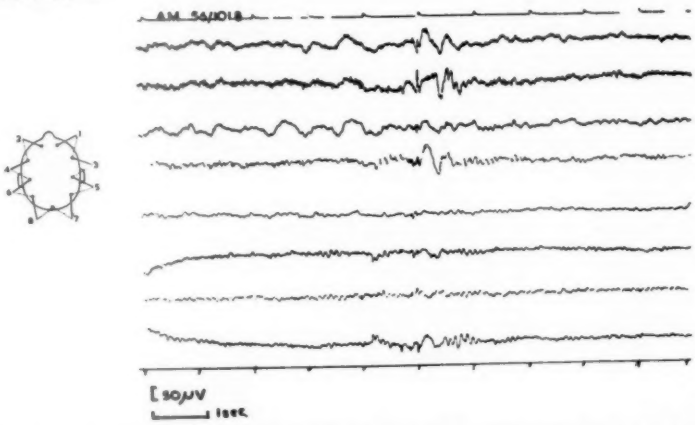

FIG. 2.—A burst of subcortical type epileptic activity: spikes and slow waves seen in the frontal areas maximally (channels 1–4) but also in all areas as spike discharges.

The new approach to the subject calls for some new attitudes and for significant changes in the practice of the subject. Comparatively few patients would be examined, but these would be examined repeatedly under a variety of conditions. This would call for a much closer working relationship between clinician and laboratory worker, both of whom must understand the clinical problem and the range of questions to which the EEG can provide

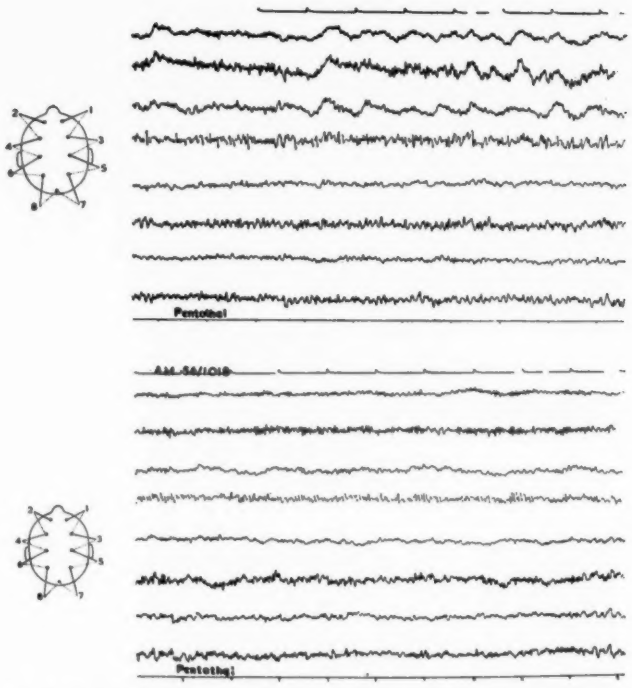

FIG. 3.—Records taken under intravenous Pentothal, showing reduction of barbiturate induced fast rhythm in all areas on the right side (channels 1, 3, 5 and 7).

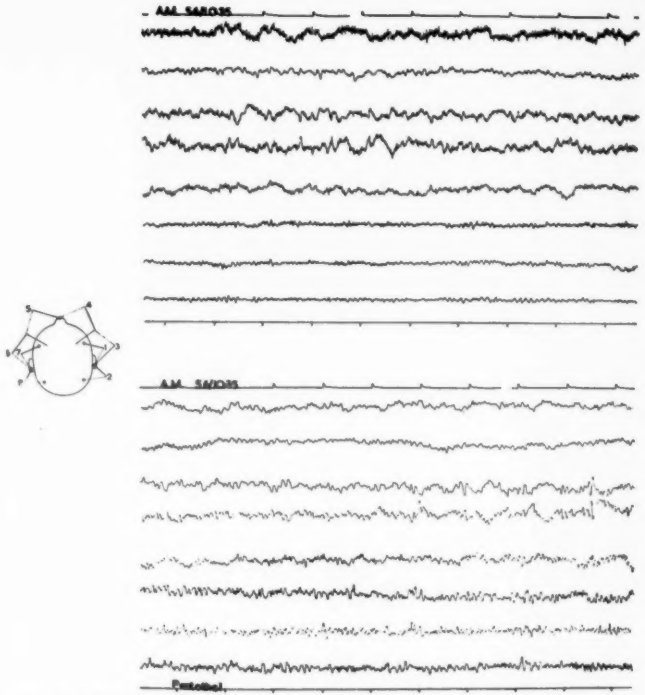

FIG. 4.—Records taken using sphenoidal electrodes showing (above) a focus of sharp waves at the right sphenoidal electrode (channels 3–4) with patient awake, persisting (below) under Pentothal narcosis.

any sort of answer. The isolation of the EEG laboratory and the lack of communication of ideas between clinicians and EEG workers in this country contrasts most vividly with the position in other countries. On the other hand there has been our failure to interest neurophysiologists in our problems. This again contrasts to our disfavour with other countries where we witness clinicians, physiologists and clinical EEG workers actively in communication and working together on clinical problems. Clinical electroencephalography may not yet have much importance in the whole field of the brain sciences. Yet in a sense the health and vitality of this small subject in any place, is a good indicator of one thing—the extent to which neurological thinking is based upon neurophysiological ideas and knowledge.

ACKNOWLEDGMENTS

I wish to thank Mr. Murray Falconer, Mr. Peter Schurr and Dr. Denis Leigh for their collaboration and for permission to report upon their cases. I am indebted particularly to Mr. Falconer for his interest and help in the planning of the EEG investigations and to Dr. W. A. Kennedy for his valuable assistance in carrying them out.

Dr. Gerald Parsons-Smith (West End Hospital for Neurology and West London Hospital):

An entirely fresh dimension in neurology has been opened up by the use of serial EEG records instead of placing reliance upon single tracings. Records taken at regular intervals have proved of prognostic value in cases of head injury, epilepsy and in cerebral infections. They have a diagnostic value in differentiating between an improving vascular episode and a worsening neoplastic process. They have disclosed new facts; thus Cobb and Hill (1950) described the development of unique and diagnostic changes in subacute progressive encephalitis, whilst Gibbs and Gibbs (1947) found in other forms of encephalitis that children, unlike adults, develop 3 c/s spike and wave complexes in the course of the illness. In *cerebral lipidosis*, Cobb *et al.* (1952) found a remarkable diagnostic and persistent EEG pattern in children, but which does not occur in adults.

Although the EEG can be expected to give exact localization in about 70% of the gliomata and lateralization in 90%, it should not be employed to demarcate the anatomical limits of a *cerebral tumour* since this can be achieved so accurately by various radiological methods. Its value lies in the selection of cases for investigation and once they have been diagnosed to reinforce the clinical evidence of their progress. Indeed, in the course of such cases, the EEG tracings may show deterioration well before there is any clinical evidence of this. Differential tumour pathology is impossible on EEG grounds alone except when there are multiple focal abnormalities such as are seen with metastatic deposits. If the clinical and radiological appearances of the tumour suggest that it is a *meningioma* a persistently normal EEG indicates that it is avascular whilst it can be inferred from a severe focal abnormality that the tumour has developed a fringe of blood vessels from the internal carotid tree and will be extremely vascular at operation.

In *epilepsy* the pattern of the migration of foci in children was found after study of serial recordings. The work by Gibbs *et al.* (1954) throws most light on these changes. During the first year of life, generalized continuous epileptic discharges are frequently encountered in a pattern which they term hypsarrhythmia. This appears to be the most malignant form of epilepsy. Afterwards until about the age of 5, the picture is commonly one of impure epileptic complexes, mixtures of slow spikes and slow waves. From then until about the age of 12 generalized 3 c/s spike and wave discharges occurring in bursts are common and indicate a relatively benign form of epilepsy. Although these epileptic features are more or less specific for their age groups, they do not tend to be transformed from one to another with increasing age. During adolescence, generalized seizure activity becomes rare and anterior temporal discharges are more likely to be encountered. Focal epilepsy is seen, however, in young children when the occipital lobes are generally involved. If these cases are kept under observation, the epilepsy will either clear up completely or the foci will move forwards into the mid-temporal area. Around adolescence these, too, clear up or migrate into the anterior parts of the temporal lobes. They later migrate to deeper structures. In a series of children nearly half (48%) with occipital foci had become quite normal by the age of 9, whilst similar improvement later was found in those with mid-temporal lobe epilepsy, 50% having become normal by the age of 15.

Epileptic spike and wave activity is now known to occur in a number of different *biochemical disturbances*, though there may well be an underlying linkage between them

These rhythms have followed the prescription of one of the *hydrazides* which can induce a temporary epileptic state in animals and have been used to produce therapeutic convulsions. The most effective is thiocarbohydrazide, an oral dose of from 100 to 200 mg., producing a spontaneous seizure after one to three hours. EEG studies indicate that the seizures originate subcortically and 3 c/s spike and wave bursts have been recorded (Pfeiffer *et al.*, 1956). The epileptic response to these hydrazides is thought to be due to acute pyridoxine (vitamin B_6) deficiency, the most convincing reason being that when given by mouth it acts as a complete antidote to the temporary epileptic state.

Following experimental work on animals on synthetic diet and particularly Swank and Jasper's (1942) finding that epileptic paroxysms occurred in the EEGs of pigeons on a thiamine-deficient diet, Fox and Tulledge (1946) treated eight schoolboys of 14 and 15 years of age suffering from epilepsy with pyridoxine without the slightest change in the incidence of their fits. A similar clinical experiment was carried out by Livingston *et al.* (1955) who were not able to control epileptic seizures in any one of 31 patients treated with this substance. All these patients were over 6 months of age.

Experience with infants under the age of 6 months is, however, quite different. An outbreak of convulsive seizures occurred all over the U.S.A. and was reported by Coursin (1954) and Molony and Parmelee (1954). The common factor to these infants was the very pure dried milk preparation which was shown to be deficient in vitamin B_6. 54 of Coursin's cases responded immediately to treatment with pyridoxine as did Bickford's case (1954) whose EEG had shown hypsarrhythmia. Williams' case (1954) was controlled with this substance, but the fits recurred whenever it was deprived of it. 2–3 c/s spike and wave epileptic discharges occurred in the infant studied by Hunt *et al.* (1954) and these were abolished in the EEG fifteen minutes after the prescription of 6 mg. of pyridoxine. The infant's mother, in this latter case, had been given large doses of pyridoxine during pregnancy to control hyperemesis and it seems possible that in susceptible cases the fœtus develops an active enzyme system which is capable of accelerating the breakdown of pyridoxine. Following delivery, this metabolic anomaly could be manifested as a state of pyridoxine dependency in the infant.

It is interesting to compare this work with the changes described by Walton *et al.* (1954) in *pernicious anæmia* and vitamin B_{12} deficiency.

A high incidence of seizure activity of the *petit mal* type has been described in cases of *phenylpyruvic oligophrenia*, the 3 c/s spike and wave activity appearing particularly in sleep. The clinical picture of intellectual defect, muscular hypertonicity and occasional fits results from an inability to oxidize phenylalanine to tyrosine—and has been considered to be due to phenylalanine poisoning. The urine contains phenylpyruvic acid, phenylalanine and phenylacetic acid. No consistent pathological findings have been reported though in one case described by Corsellis (1953) one occipital lobe was demyelinated. Clinical improvement has been reported from several centres with phenylalanine-free diet but symptoms returned when a normal diet was substituted. In two of three typically fair-haired children so treated by Woolf *et al.* (1955) the *petit mal* ceased as did the spike and wave activity, the EEG becoming normal in one.

A new inborn error of metabolism has recently been described by Baron *et al.* (1956) and termed "*H*" *disease*. A defect in tryptophane metabolism to nicotinic acid has been postulated as the cause. They describe a family many of whom had a unique amino-aciduria.

Two of the children affected were subjected to serial EEG studies. The elder, a boy of 12, was mentally backward and developed in 1951 a pellagra-like illness with ataxia. He was admitted to the Middlesex Hospital under Dr. Edward Hart because these symptoms had not responded to vitamin-B therapy which had benefited his elder sister fourteen years earlier when she was similarly affected. Clinical examination disclosed a variable cerebellar syndrome together with some pyramidal involvement. The urine contained a variable amount of amino-nitrogen, from 600 mg. to 1,130 mg. per twenty-four hours, the normal figure being 41 mg. Paper chromatography disclosed a gross amino-aciduria. The urine contained at least twelve amino acids including analine, phenylalanine and tryptophane. A pyruvate-metabolism test was normal.

The disease was in an active phase during the period of EEG study. He was not drowsy. A feature of the tracings was the appearance of migrating 3 c/s focal abnormalities appearing over one or other of the temporal lobes. Thus, on 8.6.51 (Fig. 1) a severe 3 c/s abnormality was present in the left temporal lobe with a phase reversal. On 2.7.51 the dominant frequency was at 3 c/s and this occurred in all areas. A similar record was obtained three days later, but on 9.7.51 (Fig. 2) a 4 c/s focal abnormality was seen over the posterior part of the right temporal lobe, again with phase reversal. Three days later, this focal change disappeared. On 16.7.51 (Fig. 3) the 3 c/s focal change had reappeared over the left temporal lobe whilst three days later (Fig. 4) the focus had reappeared over the right temporal lobe. In the following month, there was a phase reversal over the right temporal lobe. In January 1952 the records were quite normal.

No further EEG examinations have been recorded, but he later developed violent outbursts of temper and developed choreiform movements. The symptoms continued to vary and one relapse

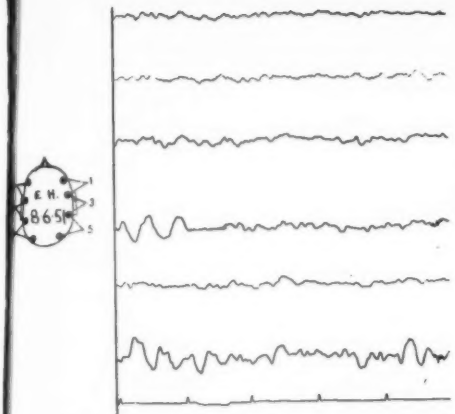

FIG. 1.—3 c/s focal abnormality over posterior part of the left temporal lobe.

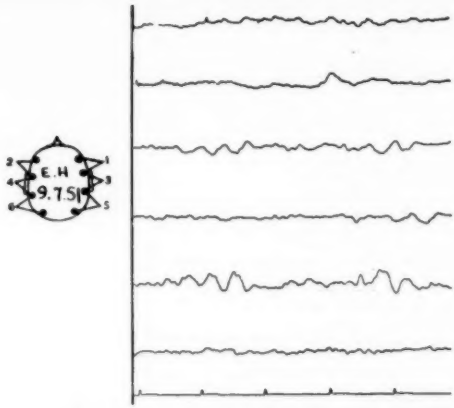

FIG. 2.—4 c/s focal abnormality over posterior part of right temporal lobe.

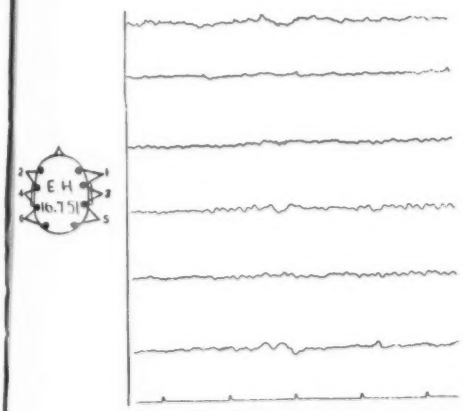

FIG. 3.—3 c/s focal abnormality over left temporal lobe.

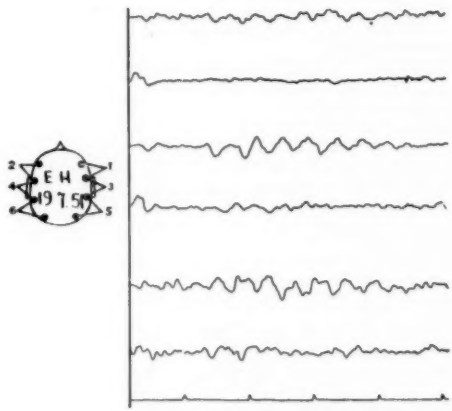

FIG. 4.—Focal abnormality over posterior part of right temporal lobe.

in 1955 was improved with chlortetracycline and nicotinamide. One of the patient's younger brothers also suffered from the amino-aciduria and rash, and was of low intelligence. His EEGs were similar to those of his brother, and in one a severe 3 c/s focal abnormality with a phase reversal was found over the right temporal lobe. His condition later deteriorated. In 3 other siblings normal EEGs were obtained. In 2 of these, the urine was quite normal, but the third, aged 6, showed the characteristic amino-aciduria though nothing clinically was amiss.

Reversible EEG changes dependent upon a disorder of protein metabolism are encountered in *portal systemic encephalopathy*. This condition is generally subsequent upon cirrhosis of the liver and the subsequent development of a portal collateral circulation. As a result, toxic nitrogenous material from protein breakdown in the gut avoids deamination, is deflected into the systemic circulation and adversely affects the brain, producing a picture of mixed pyramidal and extra-pyramidal disease which sometimes superficially resembles Parkinson's disease. The patients exhibit a flapping tremor together with changes in personality, confusional attacks, epileptic fits and sometimes even progress to psychotic states including mania and paranoia. These symptoms are always aggravated by increased nitrogen intake and coma may ensue. (Sherlock *et al.*, 1956.)

EEG studies have been carried out on 75 patients under the care of Drs. S. Sherlock, W. H. J. Summerskill and A. M. Dawson.

The results have been striking. The EEG tracings were placed into Grades 1 to 5, whilst the clinical condition was assessed in one of four grades. In the EEG, Grades 1 and 2 consisted of mild non-specific changes. In Grade 3, an alpha rhythm still appeared, but was disturbed by long runs of 5–6 c/s waves, whilst in Grade 4 no normal activity was seen, the dominant frequency being at 5–6 c/s in all areas. In Grade 5, this 5–6 c/s activity was disturbed by frontally-preponderant bursts of 2 c/s rhythms. The clinical grades were Grade 1, in which the changes were very mild, and Grade 2 when the flapping tremor was seen and there were early mental changes. In Grade 3, there was gross mental disorder with disorientation, whilst the patients in Grade 4 were stuporous. A close correlation was shown between the clinical state and the severity of the EEG abnormalities. The degree of the EEG abnormality was correlated with the level of ammonium concentration in the arterial blood, the peripheral vein blood and the C.S.F. Although the findings in most cases were striking, some discrepancies occurred which are being studied.

It has proved possible to reverse the EEG abnormalities by employing the specific treatment devised by Sherlock and her co-workers. If protein and nitrogen-containing drugs are completely withdrawn, whilst purges and chlortetracycline are given by mouth to diminish the small gut flora which act on the breakdown of protein and so assist in reducing the absorption of toxic nitrogen products, a quite normal EEG tracing may be produced coincidentally with the patient's clinical improvement.

ACKNOWLEDGMENT

I am indebted to the Dan Mason Research Foundation, West London Hospital Medical School, for a grant towards expenses incurred in some of the work carried out at that hospital.

Dr. J. A. V. Bates (Neurological Research Unit (M.R.C.), National Hospital, Queen Square, London):

A single EEG will occasionally localize intracerebral disease when no clues to the localization are provided by thorough clinical examination and X-ray study. Usually this is known in retrospect when the disease has progressed to give other signs of its presence. But these cases emphasize the need to make the electrical evidence of intracerebral disease as firm and unequivocal as a quadrantic field defect, a yellow C.S.F., or a shift of the ventricular system. Alongside these cases of successful prediction by the EEG one could place many failures, for there are a number of pitfalls in the interpretation of abnormal electrical patterns obtained from a single routine scalp record. For example, it is now clear that localized

electrical abnormality may arise from histologically and functionally normal cortex which is being influenced only by nervous conduction from a remote area—in other words, that false localizing signs occur in the EEG just as they do in clinical neurology; that a record normal to-day may be abnormal to-morrow or with one type of abnormality to-day there may be a different type to-morrow; that an abnormality in a resting record may disappear during a fit, or alternatively during a fit may shift to a distant area; that clinical improvement is not necessarily related to electrical improvement and vice versa; and that as experience increases, inspection of an EEG record makes one less and less definite about inferring the state of consciousness of the patient, for considerable changes may occur in the level of consciousness with no corresponding changes in the scalp record and vice versa.

I think it is fair to say that the general trend of work on the exposed brain with large and small electrodes is to increase our wonder that the scalp record is of any use under any circumstances at all, for this work repeatedly reminds us of the highly localized nature of many types of electrical change and we must conclude that much electrical activity of clinical significance finds no representation at all in the scalp record. Nevertheless it is possible sometimes not only to obtain a localization of electrical abnormality on the scalp, but to get from the EEG presumptive evidence of local disease strong enough to justify a craniotomy when the patient is sufficiently disabled. This is illustrated by the following two cases.

Case I.—As a boy of 11 the patient was taken to hospital because for one month he had been having frequent short spells in which he lost consciousness but did not fall. An EEG showed a left temporal slow wave but there was nothing clinically to support the idea of local disease, X-rays were negative and the boy was given Tridione. This *petit mal* type of attack without any warning became more frequent and an occasional *grand mal* attack was added. He became surly and violent at times, drugs were changed, schooling became impossible, and he was sent to a colony. In the colony his behaviour was deplorable, his fits frequent and he was discharged at the age of 15 to a most unsatisfactory home. He first came to Mr. I. McCaul at the Whittington Hospital at the age of 19. He was a miserable specimen, sour and aggressive in between his fits, quite unemployable, in trouble with police and neighbours. He had no lateralizing aura to his fits, but he had a feeling that the ceiling was descending on him before he lost consciousness. He had no physical signs and A.E.G. and angiography were normal. In the EEG there was a well-localized left temporal sharp and slow wave abnormality, but a bilateral abnormality was frequently present also. We decided not to operate on his left temporal lobe because the EEG localization was not supported by any clinical or radiological evidence, and in view of his general personality and bilateral EEG disturbance we thought him a bad bet. His response to this decision was to attempt suicide by swallowing a large collection of tablets. His life was saved by a lucky chance, but he told us on recovery that he would do it again and not fail if he could not have the operation. Faced with this unusual predicament his left temporal lobe was explored with electrocorticography under local anæsthetic. The cortex looked normal but beneath the electrical focus a cyst 1 cm. in diameter surrounded by extensive gliosis was found and removed. Since the operation two years ago he has been entirely free from fits, though he has had an occasional "feeling" which does not develop further. There has been a striking change for the better in his general morale and behaviour and he is now at work for the first time in his life.

Case II.—A boy of 14 came under the care of Dr. Denis Williams. He was a normal child in a good home until at the age of 7 he had a series of major attacks. Anticonvulsants were given but the attacks continued without any localizing features and there was a sudden onset of severe aggressive behaviour associated with his attacks. He was investigated a year later. There was nothing to find clinically or on lumbar encephalography, but a single routine EEG reported on by Dr. W. Cobb showed a left frontotemporal slow spike and wave. This was suggestive of an acquired lesion but there was nothing to support it, operation was deferred and the boy was lost sight of. He, in fact, went from bad to worse, a colony could not keep him because of his severe behaviour disturbance and at the age of only 12 he was sent to an adult mental institution. Here he developed a left foot-drop and now, aged 14, was sent again to the National Hospital. Here he would have outbursts of extreme, aggressive behaviour terminating in a *grand mal* attack. The reason for his foot-drop was a mystery, but there was nothing to suggest an intracerebral lesion; a lumbar encephalogram was again normal. The most conspicuous feature of his very abnormal resting EEG was frequent bilateral outbursts of complex and irregular spike and wave episodes. They were most prominent in the frontal leads and showed a slight difference on the two sides of the head—the spikes were sharper and greater in amplitude on the right side and the slow components occasionally more marked on the left. It was suggested that there might be a left frontal lesion giving rise to secondary bilateral synchrony, but a left carotid arteriogram was reported on as normal. In spite of this further EEG explorations were done, for a significant piece of past history was now discovered, namely that after one series of attacks several years before he had had a dysphasia and right-sided weakness of a few hours' duration. In the further EEG tests there were several recordings from additional scalp electrodes, while intravenous barbiturates were given, and finally extradural electrodes were placed over each frontal lobe through frontal burr holes. These additional tests greatly strengthened the electrical evidence for a left frontal lesion and when a flap was turned by Mr. W. McKissock a large lesion was at once apparent. The operation notes read "the surface of the cortex shows an oval area of old haemorrhage, 5 cm. in diameter, greenish-yellow in colour and to me exactly the sort of lesion that one sees from intracranial hæmorrhage due to a cortical angioma. The area of abnormal tissue

extended down to the base of the anterior fossa and on to the undersurface of the frontal lobe extending as far backward as 1 cm. short of the lesser wing of the sphenoid". The electrical abnormality was even more widespread on electrocorticography and an extensive amputation of the left frontal lobe was performed. The pathologist reported that "sectioning was difficult owing to calcification but the specimen contained a cyst and locules of altered blood bounded by dense white connective tissue suggestive of an angiomatous malformation". The boy has been entirely free from fits since the day of operation over two and a half years ago and attends a normal school and is a socially satisfactory person.

Discussion.—These two cases bring out a number of significant points. First that in their fully-developed state both cases satisfy all the criteria on which "idiopathic epilepsy" is diagnosed: no localizing features in the character of the fit, no physical signs, special X-rays normal, generalized bilateral EEG disturbances; and they remind us that *grand mal* and a type of minor attack without lateralizing aura are common symptoms of local disease in a cerebral hemisphere. This point needs stressing because there is a tendency to look on fits of these types as evidence of a primary disorder of a "centrencephalic" system and *ipso facto* untreatable save by drugs. No EEG record should, in my opinion, ever be used to support a diagnosis of "idiopathic" or "essential" or "centrencephalic" epilepsy. These terms are, at the moment, required to cover our ignorance, and I would suggest that the EEG is being over-interpreted if it is used to make these terms scientifically respectable.

A second and more fundamental point which these cases illustrate is well known to electroencephalographers, namely the questionable value of a single routine scalp record. If it gives some supporting evidence, however weak, to a clinical impression, it may be appreciated, but if a localization is suggested for which there is no other support, the single routine scalp record will be ignored (and in my opinion rightly) because the evidence it provides is insufficiently definite.

It would seem that cases like the above two in which this occurs should be admitted to hospital for a thorough investigation of cerebral function with a series of electrical tests appropriate to the case planned by a clinician with special training in EEG methods and with neurosurgical assistance at hand. He will have a number of questions to consider: Shall medication be withdrawn? Shall a fit be provoked with an intravenous drug during a recording? Shall intravenous barbiturates be used? Shall sphenoidal electrodes be used, or shall electrodes be inserted through burr holes in the scalp? Is electrocorticography necessary? And so on.

As the variety of procedures and tests is multiplied and evidence of cerebral damage becomes consistent throughout different types of test, the EEG evidence has a chance of acquiring the necessary firmness, and only then will action be taken on it. There are good grounds for suspecting that the single routine EEG as at present conceived is strangling the proper development of the art. For the few trained people are occupied in the provision of a large volume of reports, many of which must be too indefinite to be helpful to the clinician, and, at worst, may be definitely misleading to him.

DISCUSSION: RECENT ADVANCES IN THE USE OF TISSUE CULTURE METHODS IN VIRUS RESEARCH

Dr. F. Kingsley Sanders:

Virus Titration in Cell Suspension Cultures

The behaviour of viruses within their host cells can best be studied under conditions where a known number of uniformly susceptible cells is exposed simultaneously to a known number of infectious virus particles, and the resulting yields of new virus accurately measured. This is most easily done when both cells and virus can be kept continuously in suspension, and is, in fact, standard practice in work with bacteriophages. Cell suspension cultures, however, have been little used in animal virology so far. Sanders (1953) described the multiplication of mouse encephalomyelitis virus in suspensions of mouse ascites tumour cells; later, Pereira (1954), and Dulbecco and Vogt (1954), studied the multiplication of fowl plague and Western equine encephalomyelitis virus in suspensions of cells prepared by the trypsinization of chick embryos. In all 3 cases the cell suspensions were used only as a primary growth system for the virus. Estimates of virus content were made separately by other techniques such as hæmagglutination titrations, infectivity end-point estimations in tube cultures, or by plaque counting on monolayer tissue cultures.

The present paper describes a technique whereby the progress of infection in a cell suspension culture can be followed directly, and includes a method for estimating directly the quantity of virus present in such a culture.

Theoretical considerations.—If a suspension of free, separate, cells at a concentration of C cells/ml. is mixed with a virus suspension and adsorbs V virus particles/ml. from that suspension, the average multiplicity of infection m, is given by the expression:

$$m = \frac{V}{C} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

whence

$$V = m \times C \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Moreover, the proportion of cells infected by 0, 1, 2, ...n virus particles will be given by the successive terms of the Poisson series. The first term of this series is:

$$P(O) = e^{-m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Thus, if we can determine P (O)—i.e. the proportion of uninfected cells in such a suspension, m can be read off directly from a table of exponential functions. Then, if the total concentration of susceptible cells is also known, the virus content can be determined from the expression (2) above. C may be found by directly counting the number of cells present per ml. of suspension. To determine m it is necessary to find some way of distinguishing infected and uninfected cells in the suspension.

A method of titration based upon these principles has been used to study the multiplication of encephalomyocarditis (EMC) virus, in suspensions of mouse ascites tumour cells (Krebs 2 carcinoma). A description of this method is presented in the hope that a similar technique may be useful to other workers, in particular those who are investigating systems in which the multiplication and the release of virus may not be accompanied by any clear cytopathic effect. Ascites tumours consist of a large population ($1–2 \times 10^8$ cells/ml. of exudate) of separate similar cells floating free in fluid in the mouse peritoneum and can easily be recovered, washed and suspended in suitable media. Hoskins and Sanders (1957) have shown that such cells, maintained as a sheet of cells adherent to the wall of the culture vessel, are able to support multiplication of encephalomyocarditis (EMC) virus with high virus yields, and the production of cytopathic change.

Cell suspension cultures.—Mice with well-developed ascites are killed, and the tumour cell containing exudate aspirated from the peritoneal cavity, and the cells washed free of ascitic fluid by centrifuging with phosphate buffered saline (PBS, Dulbecco and Vogt, 1954). Such cells can be maintained in suspension by the methods described by Earle *et al.* (1955) in a simple mixture of saline and glucose. The culture vessels used are 150 ml. Pyrex, flat-bottomed boiling flasks containing 10 ml. cell suspension. The cells are maintained in suspension by shaking on a Brunswick type shaker at a rotation speed of 1 r.p.s. at 37° C. When such cultures are set up at a concentration of up to 3×10^7 cells/ml. of culture fluid there is no significant loss of cells during seventy-two hours of incubation; on the other hand, no significant cell multiplication occurs during this time.

Detection of infected cells.—In the past, a number of *in vitro* methods have been used to distinguish between "viable" and "non-viable" cells in a given preparation of tumour cells. Among these is the method suggested by Schrek (1936), who showed that when a tumour cell suspension is treated with 0·05% aqueous eosin under controlled conditions, differential staining occurs, which is correlated with cell viability; only "dead" or injured cells are presumed to stain.

When freshly washed suspensions of Krebs-2 carcinoma cells are treated in this way less than 5% of the cells take up the stain (Hoskins *et al.*, 1956). This is so both for cells freshly removed from mice with ascites, and for cells which have been maintained in agitated fluid cultures for up to thirty-six hours. However, when cultures infected twenty-four hours previously with a large amount of EMC virus were similarly tested, over 95% of the cells stained with eosin. It was therefore suspected that the cell staining of infected cultures might be correlated with the growth and release of virus from infected cells. Fig. 1 shows

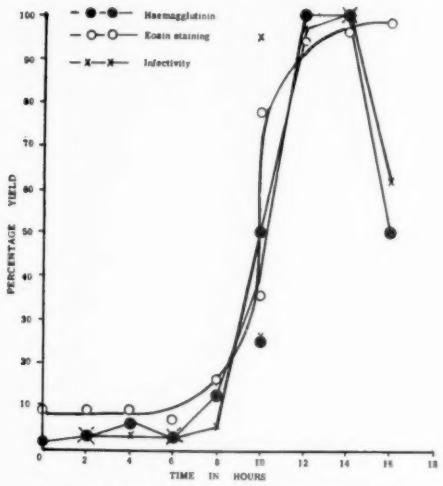

FIG. 1.—Coincidence between the time of release of EMC virus hæmagglutinin and the staining of infected cells.

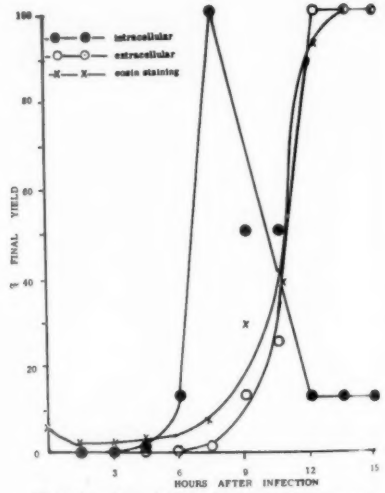

FIG. 2.—Correlation between the quantity of EMC virus released and the staining of the primary culture.

the percentage of cells taking up eosin in samples withdrawn from a suspension of tumour cells, at intervals after the addition of EMC virus in high multiplicity. It will be seen that there is a very close correspondence in time between the appearance of cell staining, and the virus content of the supernatant fluid of the culture. The figure also shows that the time before the release of new virus begins is of the order of eight hours, and that release of virus is virtually complete by fourteen hours. When suspensions of cells are infected at lower multiplicities, a smaller total number of the cells becomes stained. It is thus suggested that the staining reaction with eosin can be used to mark which cells in a given suspension have become infected. In each case a total cell count, together with a differential cell count of the cells remaining *unstained* by eosin (i.e. uninfected cells) provides all the information necessary to calculate the amount of virus adsorbed by the cells according to the principles given above. The basis of the test is to infect a suspension of cells with virus and after a time sufficient for one cycle of multiplication to take place (i.e. ten to fourteen

hours), to stain the cells with eosin, and count both the total number of cells and the proportion which remains unstained. From these figures the virus content of the suspension can be calculated. Fig. 2 shows the curve of virus release, when the virus content of the different suspensions is measured by this method, correlated with the results of hæmagglutination titrations of the same material, and with the appearance of eosin staining in the primary culture. It is seen that there is a very close agreement between the values obtained and the hæmagglutinin development curve. Such a method of titration has an accuracy close to that given by plaque counts, and about ten times the accuracy of end-point titrations in either tissue cultures or mice. For example: of two typical virus preparations, consisting of the supernatant fluid from infected suspension cultures, the first (K 9) has a titre of $1{\cdot}02 \pm 0{\cdot}08 \times 10^9$ cell-killing units/ml. (SE of the mean of 12 observations), the second (K 8) contained $1{\cdot}83 \pm 0{\cdot}08 \times 10^8$ cell-killing units/ml. (SE of mean of 11 observations).

In practice the time at which samples from the cultures are stained is critical. In experiments with multiplicities of less than 1·0, in which the course of the growth cycle was followed by means of the eosin staining reaction, clear evidence of a "second step" in the growth curve was found as early as fifteen hours after inoculation. To be certain that the proportion of stained cells found relates to only one cycle of growth, at least two successive samples should be counted between twelve and fourteen hours after inoculation; both should show roughly the same proportion of staining. Alternatively, sufficient encephalomyocarditis (EMC) antiserum to prevent the second cycle can be added to the culture one hour after infection. In this case it is advisable to use antiserum which has been adsorbed with cells to remove Krebs cell agglutination, otherwise clumping of cells in the culture may distort the results of the counts.

As a test of the validity of the method for measuring virus concentration a number of experiments were made in which virus and cells were mixed at different multiplicities and the proportion of unstained cells counted at eleven to fourteen hours after inoculation. The results are shown in Fig. 3.

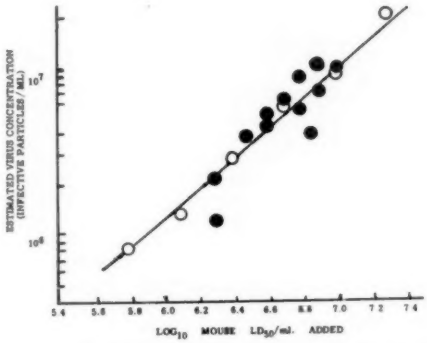

FIG. 3.—Comparison of virus titres obtained by the "cell-killing" method with those obtained in mice; explanation in text.

In the first experiment (shown by open circles in Fig. 3), a set of virus-cell mixtures were made in which twofold dilutions of virus were added to twofold dilutions of cells, the dilutions being chosen in each case to give an approximate multiplicity of 1·0 on the basis of the infectivity for mice of the virus suspension used. In the second experiment (shown by the black circles in Fig. 3) a constant cell concentration of 1×10^7 cells/ml. was infected with virus diluted so as to give multiplicities varying between 1 and 0·3. The amount of virus added, calculated from the known titres in mice of the virus suspension used, was then plotted against the apparent titre measured according to the principles described. The straight line is the calculated regression line for the whole data. This had a slope of 0·98 which was found not to differ significantly from the value of 1, which would be expected on theoretical grounds. It can, therefore, be concluded that the method, as used, provides a valid way of estimating the virus content of a suspension.

The method used at present for the performance of these titrations is as follows: Unknown virus suspensions are first titrated *in vitro* for their hæmagglutinin content. Once this is known the infective virus content of the suspension may be roughly estimated as

HA units/ml. $\times 10^6$. On this basis a cell suspension and virus suspension are prepared at such dilutions that when mixed they will give a theoretical multiplicity of between 0·1 and 1. The reason for the choice of this range is that at a multiplicity of one the suspension may be expected to contain about 37% of uninfected cells. At a higher multiplicity a smaller proportion of uninfected cells may be obscured by the presence of a small number of cells which are naturally resistant for some reason or other, i.e. although infected by virus they do not release new virus and thus do not stain. The preliminary hæmagglutinin titration is used merely as a guide to the correct virus and cell dilutions to choose for the actual titration itself.

At the lower end of the scale the method is not yet suitable for the measurement of small quantities of virus. The cells do not survive well at a concentration of less than 10^6/ml. and the proportion of stained cells at multiplicities of infection at below 0·1 are too small for accuracy in counting. Dilute normal uninfected tumour cell suspensions incubated for the same time as infected cultures may contain up to 10% of stained cells. Cells like this, which die a "normal" death, are likely to distort the results of cell staining titrations carried out with multiplicities of less than 0·1. Thus, the method as a whole cannot be expected to give reliable results when virus concentrations in the culture itself are less than 10^5/ml.

Comparison between the results of the cell-suspension and plaque titration methods.—A plaque method of titration for the system EMC virus/Krebs-2 carcinoma cells has recently become available and will be reported elsewhere. Fig. 4 shows the type of plaques obtained

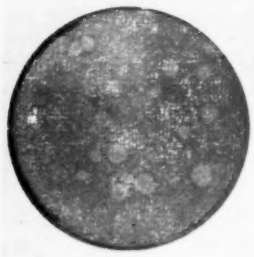

FIG. 4.—Plaques given by EMC virus (K 2 strain) on a layer of Krebs-2 carcinoma cells, stained with Neutral Red.

with this virus and the Krebs-2 carcinoma cells. When selected virus suspensions are titrated simultaneously by both methods the results obtained do not always closely correspond. Any differences observed can, however, be related to the nature of the virus suspension itself and not to the errors of the methods. For example, "fresh" virus—i.e. virus harvested and titrated immediately upon its release from infected cells—or "intracellular" virus—i.e. virus released artificially from infected cells by shaking with glass beads at the peak of the multiplication cycle—give the same virus content whether measured by plaque titration or by eosin staining in cell suspension cultures. However, virus which has been frozen and thawed in the absence of protective protein, or heated for more than one hour at 37° C. shows a much lower infectivity titre by plaque count than by the staining method. Similarly, fresh virus released from cells at very high multiplicities of infection also has a lower virus content when measured by the plaque method than by cell staining. In this connexion it must be remembered that a plaque forming particle represents a virus unit which is able to infect cells and multiply within them to form new virus which can then initiate further cycles of infection in other cells; and this process must go on long enough to produce a visible plaque. The cell staining procedure, on the other hand, measures virus which is able to adsorb to cells and initiate changes within them so that the infected cells are killed after a time equivalent to one growth cycle; no virus able to infect other cells need be released. It is obvious, therefore, that the cell staining and plaque methods of titration do not necessarily measure the same virus property. For this reason we now express the content of virus suspensions titrated by the cell staining method in cell-killing particles (CKPs) per ml., to distinguish this property from the plaque-forming particle (PFP) content of such suspensions. There is preliminary evidence that the CKP can appear as a degraded form of the PFP, and also that infection of cells at very high multiplicities can perhaps produce progeny virus where a great excess of CKPs are present. Generally speaking, the hæmagglutinin content of EMC virus suspensions follows its CKP and not its PFP content.

Further applications.—As with other titration methods the method can also be used to measure the antibody content of sera. In this way, incubated serum virus mixtures can

be added to a larger volume of cell suspension and the number of uninfected cells estimated. With appropriate experimental design the rate constant of neutralization (K) can be measured with fair accuracy.

General principles.—In order that similar methods can be applied to other cell virus systems the following conditions must be fulfilled:

(1) The cells used should be separate, identical, and capable of surviving in free suspension for the period of observation necessary without significant mortality.

(2) A high and constant proportion of the infecting virus present must rapidly adsorb to the cells and subsequently undergo "multiplication".

(3) A method must be available for distinguishing unequivocally between infected and uninfected cells, for measurement of the proportion of uninfected cells must be carried out after an interval sufficient for one growth cycle, and no more.

Mr. R. F. Sellers:

Some Observations on the Plaque Technique

Since Dulbecco (1952) introduced the plaque technique, it has been successfully applied to a number of viruses (*see* Isaacs, 1957). Two methods are used. In one a cell monolayer grown on glass is infected with virus and covered with an agar or plasma overlay (Dulbecco, 1952; Noyes, 1953); in the other a suspension of cells is infected with virus, melted agar added, and the mixture poured on to a preset agar plate (Cooper, 1955). In both methods after a period of incubation the necrotic areas caused by the virus (the plaques) are brought into prominence by an intravital dye. The plaques can then be counted, measured or isolated as a pure virus clone.

In 1955 I found that the virus of foot-and-mouth disease multiplied on pig and calf kidney-cell monolayers and that plaques could be produced on pig kidney-cell monolayers (Sellers, 1955). Since then we have used these monolayers extensively. Cell suspensions obtained by trypsinization from the kidney cortex are grown in glass containers in a medium consisting of Earle's saline, lactalbumin hydrolysate 0·5%, yeast extract 0·01% and 7·5–10% ox serum. The cultures are incubated at 37° C. in an atmosphere of 4% CO_2 in humidified air. After six days' growth the monolayers formed are transferred to Petri dishes using a minimum cell concentration of 4×10^5 cells/ml. and incubated under the conditions described before. Complete monolayers are formed in two days, and are then infected with a suitable virus dilution and after an adsorption period of 30 minutes covered with an agar overlay. The agar overlay consists of 1·2 ml. 3% Difco washed agar in distilled water, 0·1 ml. neutral red in distilled water, 1·3 ml. twofold Earle's saline, 0·2 ml. ox serum and 0·9 ml. of Earle's saline, lactalbumin hydrolysate, yeast extract solution. The plaques may be seen and counted from two days onwards.

It is an essential requirement of the technique that the virus should destroy the cells, but several factors affect the cytopathic action, the virus yield and the number and morphology of the plaques formed. A monolayer culture normally susceptible to virus action may become resistant due to changed culture conditions. This resistance may be due to the presence or overgrowth of the susceptible cells by a resistant cell population or to a physiological change in the susceptible cells. In a study of the action of the virus of foot-and-mouth disease on calf kidney-cell monolayers, my colleagues Mrs. Burt and Miss Cumming (Burt, Cumming and Sellers, 1957) have found that by continued culture and infection in the presence of ox serum the cytopathic action of the virus on the epithelial type cells is masked by the overgrowth of a resistant fibroblastic type of cell. By reduction of the ox serum concentration and addition of pig serum, the rate of growth of the fibroblastic cells appears to be hindered, and in many instances plaques can be produced, which although smaller give a similar titre to those obtained on pig kidney-cell monolayers. Wesslén and Dinter (1956) have found a similar effect on calf kidney cells, when they used bovine amniotic fluid in the medium. My colleague Pay (1957) describes two types of cells encountered in monolayer cultures of adult cattle tongue epithelium, both of which produce virus but only one shows the cytopathic changes. Resistant fibroblastic-type cells are present to a certain extent in pig kidney cultures, but here culture conditions affect the

physiological state of the cells (Sellers, 1957). When the monolayers are grown in a medium, where Hank's saline is substituted for Earle's, among strains of the virus of foot-and-mouth disease forming large plaques the plaques are smaller and fewer and the cytopathic effect is reduced. When Earle's saline is used and excess carbon dioxide allowed to act on the cells for a short time, there may be a reduction of thirtyfold or more in the number of plaques formed on a plate, the plaques are smaller and in the case of strains forming small plaques may be absent altogether. Presumably it is the effect of pH on the cell metabolism which causes this; a high bicarbonate content buffered by a regular concentration of carbon dioxide being preferable. Gifford *et al.* (1956) found a decreased virus yield of polio virus from HeLa cells due to an increase in acidity, and Barron and Karzon (1957) described a pH effect on the cytopathogenicity of orphan viruses on monkey kidney tissue cultures. Sabin (1956) found a delayed cytopathogenic action and reduced yield of non-neuropathogenic strains of poliomyelitis virus in monkey kidney cultures under acid conditions.

Another factor affecting the culture is the state of the kidney from which the original cell suspensions are obtained. Under similar conditions we have noticed that cells from some kidneys grow faster and better than from others, and my colleague Sharpe (1957, personal communication) has recently demonstrated a difference in size and number of plaques formed by the virus of foot-and-mouth disease on monolayer cultures obtained from different pig kidneys. Dulbecco and Vogt (1954) found that slow growing testis cultures were less sensitive than the fast growing ones for the formation of plaques with poliomyelitis virus.

An essential requirement is that the monolayer be complete, and we have found that transferred monolayers are more satisfactory in this respect. A cell inoculum of minimum concentration of 4×10^5 cells/ml. is essential. In incomplete monolayers some of the virus may come into contact with glass and the rate of spread from the cell initially affected is reduced; in the complete monolayer cells closely packed survive better under the agar overlay.

The composition of the overlay has been found to affect the type and size of plaque. Dulbecco and Vogt (1955) have described a virus line, which produces large plaques under an overlay containing either embryo extract or monkey serum, whereas the wild type produces large plaques under the monkey serum overlay but small plaques under the embryo extract overlay. They have also found that certain mutants (d type) take longer to appear under an acid overlay than under a normal overlay, and that these mutants are non-pathogenic for the nervous system of monkeys (Dulbecco, 1957; Sabin, 1956). Rappaport (1956) has found that the number of plaques is increased when an amino-acid mixture is substituted for calf serum in a calf serum-Earle's saline overlay; and Dubes (1956) has found that plaque development is retarded when cystine is omitted from Eagle's maintenance medium in the overlay. Hsiung and Melnick (1957) have also described the effect of the overlay composition on the appearance of plaques. So far we have not investigated the effects of overlay of different composition on the formation of plaques by the virus of foot-and-mouth disease, and our overlay composition resembles that used in the growth of the cells. For the formation of plaques on calf kidney-cell monolayers a reduction of ox serum and addition of pig serum is beneficial (Burt, Cumming and Sellers, 1957).

It is clear that there are optimum culture conditions for each virus-host cell system, and departure from the optimum may lead to loss of sensitivity and reproducibility. The need for optimum cultural conditions is perhaps more necessary for kidney cultures, where the cells are cultivated *in vitro* for eight to fourteen days, than in chick embryo monolayers, where a monolayer is formed in twenty-four to forty-eight hours and the virus infection and plaque count completed in another three days. Pure cell lines derived from single cells (Puck, Marcus and Ciecura, 1956) which are adapted to *in vitro* conditions would be more suitable, but optimum conditions for them would still have to be determined.

Under the culture conditions described before most strains of the virus of foot-and-mouth disease examined show a linear relationship between virus dilution and number of plaques indicating that plaques are initiated from single virus particles.

Table I shows a good relationship in the case of strain M.11 pig kidney virus. With strain Ven. 1 derived from bovine tongue epithelial tissue cultures the relationship is not good. This strain produces small plaques on pig kidney-cell monolayers and titres of the same material in mice are higher. However when trypsinized bovine tongue cell suspensions (Cartwright, Pay and Henderson, 1957) are infected with virus, washed free of unadsorbed virus and tested on pig kidney-cell monolayers, then the relationship holds good and titres in mice are the same.

In a previous paper (Sellers, 1955) I said that the titres obtained by mouse inoculation and plaque count were in fair agreement. Further comparative titrations have been carried out and Tables II, III and IV show the results of such titrations. In some cases the mouse titre is higher, in some the same and in others lower than that obtained by plaque count. Titrations by other methods are included for comparison.

TABLE I.—RELATIONSHIP BETWEEN NUMBER OF PLAQUES AND CONCENTRATION OF VIRUS

	Relative concentration of virus	No. of plaques on each plate	Expected mean	Observed mean
Strain M.11	1	39, 42, 50	38	44

The numbers in Tables II, III and IV represent the log. titre in infectious units per ml. assuming 1 ID50 = 0·7 I.U.

Differences between titres perhaps reflect the degree of adaptation to the host of the virus strain used. Important are the physiological state of the cells (as mentioned before) and deriving from this the physiological state of the small or large animal used for titration. Important too are the degree of adsorption and the extent to which the virus remains at the site of inoculation. When the monolayer plates are overlaid after the adsorption period, the fluid containing the unadsorbed virus is mixed with the overlay, and consequently the virus is subject to heat inactivation and other adverse conditions. With the virus of foot-and-mouth disease, washing the cells after varying periods of adsorption has shown that 60% of the final count has been subjected to this influence, so that the actual titre may be higher. When a three dimensional system such as the cell suspension method is used, a greater efficiency should be obtained, and Cooper (1955) has shown with the virus of vesicular stomatitis that in the cell suspension method 30–50% more plaques are obtained than by the monolayer method. My colleague Miss A. Cumming (1957, personal communication) with the virus of foot-and-mouth disease has found a higher titre using suspensions of calf kidney cells than with pig or calf kidney-cell monolayers. With strain Ven. 1 mentioned before the better relationship with the cell suspensions may be a result of better adsorption on to tongue epithelial cells due to the adaptation of the virus to them and to the fact that it is a three dimensional system.

Under the culture conditions described before use has been made of another advantage of the plaque technique, namely the isolation of pure virus clones and the use of plaque morphology as a genetic marker. With the virus of foot-and-mouth disease differences in plaque size and shape have been seen between and within strains. Large, medium and small plaques with well-defined or irregular edges have been observed (Sellers, 1957). In Fig. 1 can be seen large and medium plaques obtained with strain KEN/3/57 Type S.A.T.2, and in Fig. 2 smaller and irregular plaques with strain KEN/121/56 Type S.A.T.2. M.11 pig kidney strain produces large and medium regular plaques on pig kidney-cell monolayers,

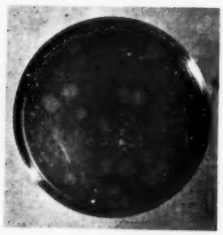

FIG. 1.—Plaques of the virus of foot-and-mouth disease strain KEN/3/57 on pig kidney monolayers forty-eight hours after infection.

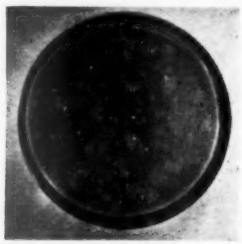

FIG. 2.—Plaques of the virus of foot-and-mouth disease strain KEN/121/56 on pig kidney monolayers forty-eight hours after infection.

while M.11 cattle strain produces small irregular plaques with an occasional larger one. Subculture from single plaques has been carried out with success.

The plaque technique is essentially a macroscopic study of virus-cell interaction. The information that can be obtained from each plate on which there are plaques is extensive. There is an accurate estimate of virus titre, a knowledge of plaque morphology, the possibility of isolating virus clones and indications of cell metabolism. The effects of culture conditions on cytopathogenicity, plaque titre and plaque morphology are important from the point of view of detection of infective virus in inactivated vaccines; this and the problem of adsorption might be overcome by incubating the virus with high concentrations of cells from different hosts and tissues before inoculation of the tissue culture or animal. By using different cell strains under different conditions it is possible to use the plaque technique as a means of differential diagnosis; by the same methods it may be possible to define the conditions necessary for growth, detection and isolation of virus mutants and variants non-pathogenic for the animal host; and these could be used as a live vaccine, as is being done with polio virus. (Dulbecco, 1957; Sabin, 1956). Conversely by the same methods virus strains may be isolated which are highly pathogenic and antigenic and which would be suitable for preparation as inactivated vaccines. With the plaque technique problems of cell physiology might be studied using a standard virus clone as a plaque marker and defining the conditions of the cells which produce variations in plaque size. The difference in titre by the different methods of virus assay raises the question of the ability of virus to adsorb on to cells, to penetrate cells, to multiply and produce characteristic changes in the host cell or organism. Again by varying cell strains and conditions, by varying virus types and strains it may be possible to obtain some knowledge of this problem, which could be applied at the organism level.

I should like to thank my colleagues at Pirbright for helpful discussion and the provision of unpublished results. I am grateful to Miss P. Tremayne-Smith for able technical assistance.

Mr. T. W. F. Pay:

The Propagation of the Virus of Foot-and-Mouth Disease in Monolayer Cultures of Adult Bovine Tongue Epithelium

A survey of the literature has so far revealed few references to the growth on glass of monolayer tissue cultures prepared from trypsin dispersed cell suspensions of normal adult stratified squamous epithelium. This has been probably due very largely to the difficulty in obtaining a suitable source of such tissue in a sterile condition, and without admixture of other structures such as hair, glandular tissue, connective tissue, etc. The adult bovine tongue, however, does provide such a source of epithelium, and monolayer cultures can be grown from it without difficulty. Attempts to produce cultures of this type were first made principally to obtain a system more suitable than cell-suspension cultures of tongue epithelium (Cartwright *et al.*, 1957) for the study of certain aspects of virus multiplication. It was soon found, however, that the interpretation of results of "growth curve" experiments so obtained was complicated by the occurrence of two quite distinct types of cell growth, which behaved very differently following infection with foot-and-mouth disease virus.

Methods of preparation of tissue cultures.—Cattle tongues were obtained fresh from the abattoir. After washing, the superficial keratinized layer of the mucosa was removed by the traction method described by Frenkel (1947). The deeper layers of the stratum malpighii were then collected by slicing off with a sterile razor blade. This tissue was minced with scissors and placed into a sterile solution of 0·5% trypsin (Difco 1:250) in a calcium and magnesium free modified Tyrode solution (Rinaldini, 1954). It was then incubated at 37° C. for half to one hour, during which time it was agitated to assist separation of cells. The resulting cell suspension was filtered through a coarse mesh stainless steel gauze to remove large fragments of undigested tissue, and then allowed to stand for several minutes to sediment out the denser clumps of tissue, mainly the basal portions of filiform papillæ, which had passed through the filter. The decanted supernatant was centrifuged at 1,000 r.p.m. for 2 to 3 minutes, and the cell deposit resuspended in culture medium without washing. Several media have been employed, including bovine amniotic fluid + 10% bovine serum (BAF + BS); 0·5% lactalbumin hydrolysate in Tyrode solution + 10% bovine serum (LH + T + BS) and Tyrode solution + 10% bovine serum (T + BS).

Cytology of cultures.—Cell suspensions prepared in this way consisted of a mixture of single cells and cell clusters of varying sizes. Filtration and sedimentation procedures were directed towards including cell clusters only up to the order of 1 mm. diameter. Histological examination of sections made from centrifuged deposits of the suspensions showed that the majority of the clusters were bounded on one or more sides by basal layer cells, and hence probably were derived from fragments of the epidermal rete ridges.

When BAF + BS or LH + T + BS were employed as culture media, two distinct types of cell growth developed. Within twenty-four hours the cell clumps and single cells had adhered to the glass of the culture vessel, and usually after forty-eight hours evidence of cell growth was apparent. Around the cell clumps a zone of cells developed which formed an almost intact "membrane-like" sheet, whereas on those parts of the glass where only single cells were adherent, a growth of discrete polygonal-shaped cells developed.

The "membrane" type of cell growth was seen only in association with cell clusters. In living cultures, it was characterized by a somewhat refractile continuous sheet of cells in which some nuclei could be seen, but cell boundaries were difficult to recognize. Phase contrast microscopy, or a silver impregnation method of staining revealed the cell boundaries and demonstrated a typical mosaic "pavement-epithelium" type of arrangement (Fig. 1). Near to the cell clumps, the cells were often more than one layer deep and overlaid one another in an irregular fashion. So far it has not been possible to passage serially cells of this type.

The "polygonal" type of cell growth consisted of irregular polygonal-shaped cells with long cytoplasmic processes. Morphologically, they resembled HeLa or kidney cells in monolayer cultures, and even when cells had become tightly packed together it was always possible to recognize the discrete nature of the cells (Fig. 2). Cells of this type have been

successfully propagated in serial cultures and have been maintained in the original culture vessels for periods of at least six months.

When the cell suspensions were cultivated in T + BS it was found that only the "membrane" type of cell sheet developed. The single cells persisted on the glass without undergoing division. Table I shows the results of an experiment where duplicate "flying coverslip" preparations were incubated for four days in either LH + T + BS or in T + BS. Some were then left in the original media and some from each group, after washing, were transferred to either LH + T + BS + M/20,000 colchicine or to T + BS + M/20,000 colchicine, and incubated for a further eighteen hours. The coverslips were then fixed and stained. Table I indicates the relative amounts of growth and the mitotic index of each type of cell growth found in the various groups. These results suggested that T + BS would not support mitosis in either type of cell growth, whereas the addition of 0·5% w/v lactalbumin hydrolysate was sufficient to stimulate mitosis in either type of cell growth, the mitotic index for the "polygonal" cells being about twice that of the "membrane" cells. After four or five days' incubation in T + BS the cell sheets of the "membrane" type were almost as extensive as those produced in the more complete growth medium. Hence it appeared that this type of growth originated mainly by migration of cells from the original cell clusters.

TABLE I.—COMPARISON OF AMOUNT OF GROWTH AND MITOTIC ACTIVITY IN CELLS OF THE "MEMBRANE" AND "POLYGONAL" TYPES AFTER INCUBATION IN EITHER LH + T + BS or T + BS

Culture Medium		Membrane Cells Develop around cell clusters only		Polygonal Cells Develop from single cells	
4 days +	18 hours	Growth	Mitosis	Growth	Mitosis
LH + T + BS	LH + T + BS	+ + +	6/1000	+ + +	11/1000
LH + T + BS	LH + T + BS + colchicine	—	—	+ + +	60/1000
	T + BS + colchicine	+ + +	0/1000	+ + +	4/1000
T + BS	T + BS	+ +	0/1000	±	No mitosis
T + BS	LH + T + BS + colchicine	+ + +	22/1000	±	50/1000
	T + BS + colchicine	+ +	0/1000	±	No mitosis

Cytopathogenic effects.—Following infection with the virus of foot-and-mouth disease, the two types of cell growth responded in quite different ways. Both appeared to support the multiplication of virus. In the case of cells of the "membrane" type, this was accompanied by cytopathogenic effects leading to cell death; whereas young cultures of the "polygonal" type of cell showed little or no evidence of cytopathogenic effects. To make interpretation of the time sequence of the various stages of cell degeneration easier, experiments were made in which cultures were infected with large inocula of seed virus to produce initial infection of all susceptible cells. These cultures were then examined either in the living state by phase contrast microscopy and cine-photomicrography, or by microscopy of fixed and stained coverslip preparations. No significant differences in the nature of the cytopathogenic response, other than the time sequence, were observed in cultures infected with limiting dilutions of virus.

As early as three to four hours after infection, the membrane cell sheets began to retract and become fenestrated in appearance, and by four to five hours many cells had begun to produce large cytoplasmic protrusions (Fig. 3). These were usually radially arranged, starting as small hemispherical blebs and proceeding to long club-shaped or filamentous structures. They were never observed to burst or to become detached from the cell, but they appeared to coalesce gradually until they enveloped the cell. Thus by eighteen hours most of the cells took the form of large, clear spherical cells, which would seem to bear some resemblance to the cells showing hydropic degeneration found in the developing vesicle on the tongue or foot of an infected animal (Fig. 4). At this stage, the nuclei were completely pyknotic and by usual histological criteria the cells would have been presumed to be dead. However it was found that the majority of such cells were still impermeable to eosin, which readily stains dead cells. This is in keeping with the probable continued function of the cell membrane suggested by the swollen nature of the cells. Wesslén and Dinter (1956) have described similar cytopathogenic changes in plasma clot cultures of bovine embryonic tongue and skin epithelium infected with the virus of foot-and-mouth disease. Damaging the cells by heat or by exposure to hypotonic solutions produced cytoplasmic protrusions in cells of the "membrane" type. However, these protrusions remained hemispherical, usually numbered only 2 or 3 per cell, and never gave rise to the picture produced by virus infection.

Cultures consisting predominantly of the "membrane cell" type of growth have been

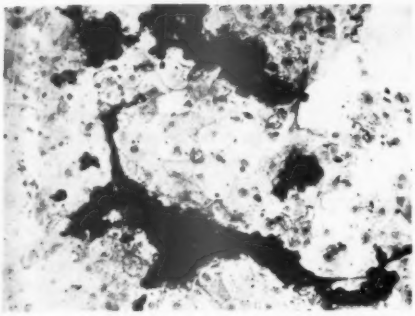

FIG. 1.—Cell clusters with "membrane" cells stained by silver impregnation to demonstrate cell boundaries. Three days' growth in T + BS. × 92.

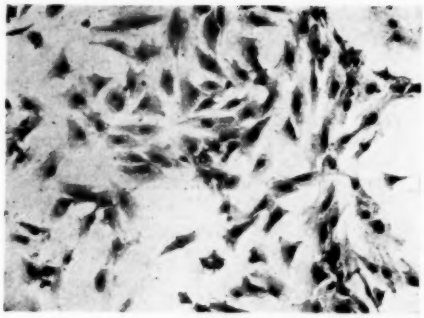

FIG. 2.—"Polygonal" cells. Five days' growth LH + T + BS. × 92.

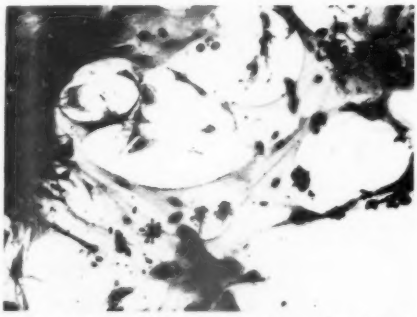

FIG. 3.—"Membrane" cell sheet, five hours after infection with large inoculum of foot-and-mouth disease virus, showing fenestration and cells with cytoplasmic protrusions. × 92.

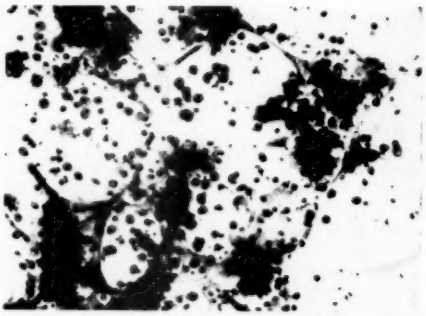

FIG. 4.—"Membrane" cell sheet, eighteen hours after infection with large inoculum of foot-and-mouth disease virus, showing almost complete destruction of cell sheet and swollen, spherical cells with pyknotic nuclei. × 92.

successfully used as a titration method, 50% end-points being calculated from numbers of cultures showing cytopathogenic changes after inoculation with dilutions of virus. Results obtained in this way have given close agreement to those obtained from the inoculation of unweaned mice or from plaque counts and limiting dilution methods in pig kidney-cell monolayer cultures.

Recently the observation has been made that a number of strains of foot-and-mouth disease virus that have been serially passaged in mice or in embryonated eggs, and have reached a stage of failing to produce vesicular lesions when inoculated into the tongues of susceptible cattle, also fail to produce cytopathogenic changes in cultures of tongue epithelium containing the susceptible "membrane" cell type growth. One of these strains has been shown to multiply in such cultures and to give virus yields comparable to those given by strains pathogenic for cattle.

Hence, to summarize the present position regarding the cytopathogenicity of strains of foot-and-mouth disease virus for tongue epithelial cell cultures, it appears that unadapted virus strains multiply in both "membrane" and "polygonal" type cells and produce cytopathogenic changes in the former only, some attenuated strains multiply in both types of cell and fail to produce cytopathogenic effects in either, and some other attenuated strains may fail to multiply at all in tongue epithelial cell cultures.

The results of a few experiments have so far suggested that the *Indiana C.* strain of vesicular stomatitis produces cytopathogenic effects in the "membrane" cell type of growth only, but probably multiplies in cells of both types.

Virus multiplication.—It will not be possible here to give any detailed account of the results of virus multiplication studies using tongue epithelium monolayer cultures. However, some interesting facts have emerged while carrying out experiments of this kind.

In some experiments, cultures, which had been infected with high multiplicities of virus and in which all recognizable growth of the "membrane" type of cell had been destroyed twenty-four hours after infection, continued to produce virus at a gradually decreasing rate until by seventy-two or ninety-six hours after infection they had usually become non-infective. When such cultures, which by then appeared to consist entirely of "polygonal" cells, were reinfected with large seed virus inocula of either the homologous or the heterologous type, they once again produced virus in quantities not significantly different from control cultures infected for the first time, allowance being made for the slightly higher titres obtained in cultures containing growth of the "membrane" type. Fig. 5 shows the result

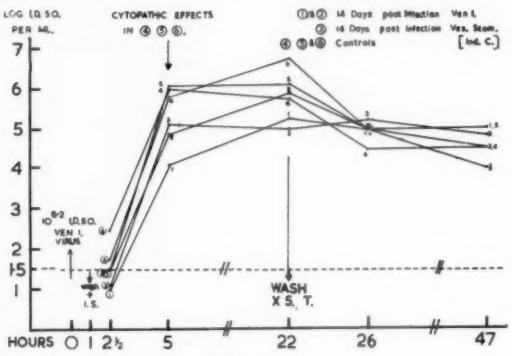

FIG. 5.

of an experiment in which two cultures 1 and 2 had been infected with the Ven. 1 strain (Type 0 foot-and-mouth disease virus) fourteen days previously, and one culture 3 had been infected with the *Indiana C.* strain (vesicular stomatitis virus) fourteen days previously. The cultures were checked for non-infectivity of the media and then they were reinfected with a large inoculum of Ven. 1 strain virus together with three duplicate control cultures not previously infected. After incubation for one hour, the unutilized seed virus was removed by repeated washing including the use of specific immune serum. At six hours the titre of the controls was about tenfold higher than the others, but this was associated with cytopathogenic changes in the "membrane" type cells present in the control cultures. By twenty-four hours, the titres of both groups were very similar and the "membrane" type cell growth had been destroyed in the controls. The cultures were then thoroughly washed, fresh media added and incubated for a further four hours. The two sets of cultures, which were then more or less identical by microscopic examination, gave the same yields of virus by twenty-six hours and by forty-eight hours after infection.

Similar experiments have been made in which cultures shown to have become non-infective, have been reinfected on the seventh day after primary infection and have subsequently produced as much virus as control cultures. Identical results have also been obtained when such cultures have been maintained in growth media containing sufficient colchicine to inhibit mitosis and to prevent the production of new cells after the culture had become non-infective. Thus it would seem that under some circumstances cultures containing the original cell population of "polygonal" type cells can be reinfected as soon as three days after the cultures had become non-infective.

The picture has been made rather more complicated recently, however, by the observation that when a group of duplicate primary cultures are infected with virus and handled in an identical manner with frequent washing and media changing, some of the cultures may become non-infective within seven days or so, whereas others continue to produce virus at a constant low level for more than thirty days.

The factors controlling the loss of infectivity associated with an ability to be reinfected found in some cultures, and the production of chronic infection in others, remain to be identified.

[*May* 10, 1957]

MEETING AT THE ROYAL BERKSHIRE HOSPITAL, READING

Cardiospasm and Epithelioma of Œsophagus Treated by Œsophagectomy.—G. L. BOHN, F.R.C.S.

Mr. F. B., aged 47.

Cardiospasm was diagnosed in 1942. Treatment was by mercury bougie, but this has not been necessary in recent years.

In December 1956 he vomited blood and experienced epigastric pain. There was no increase in his dysphagia and no loss of weight.

Investigations.—Barium meal showed a tumour in the œsophagus, cardiospasm and a duodenal ulcer. Œsophagoscopy revealed a large epitheliomatous ulcer in the mid-œsophagus. Histology: Squamous cell carcinoma.

Treatment.—February 1957: Œsophagectomy with œsophago-gastric anastomosis.

He made a satisfactory recovery but in May 1957 had three epileptiform attacks which are under investigation but are considered to be probably due to cerebral metastases.

October 1957: He remains well. The presence of cerebral metastases has not been confirmed.

In the English and American literature there have been reports of 18 cases of carcinoma arising in association with cardiospasm and this case underlines the points already brought out by previous writers: There is a very long interval between the onset of the cardiospasm and the subsequent epithelioma, usually between fifteen and twenty years. The carcinoma, when it develops, is initially silent and diagnosis therefore tends to be late, so that in only 2 of the cases previously recorded was resection possible. The carcinoma is not infrequently missed on radiological examination and also on œsophagoscopy. A relationship between the two conditions based on chronic irritation sounds feasible but the statistical evidence is somewhat conflicting.

Hypertension Due to Unilateral Renal Lesion.—C. LATTO, F.R.C.S.

Mrs. A. H., aged 38.

History.—2.2.54: For two years has been complaining of headaches, lassitude, breathlessness on exertion, and slight swelling of her ankles in the evenings.

Past history.—Scarlet fever at the age of 13 years followed by probable rheumatic fever (in bed three months). Three normal pregnancies.

Family history.—Father well, aged 75. Mother well, aged 66.

On examination.—Blood pressure 270/150. C.V.S.: Cardiac enlargement, apex beat (thrusting) being palpable in 5th space 5 in. from mid-line. Aortic 2nd sound accentuated. Apical presystolic triple rhythm. Femoral pulses synchronous with radials. Eyes: Grade 3 changes in fundi.

Investigations.—Chest X-ray: Transverse cardiac enlargement and uncoiling of aorta. E.C.G.: Left ventricular hypertrophy and gross strain. Urine: Albumin and pus cells with a few Gram-negative bacilli. Blood urea 35 mg./100 c.c. Maximum clearance test: 44%. I.V.P.: Dye excreted by right kidney which appeared normal. No dye seen on left. Retrograde pyelogram: Urine seen coming from left kidney. X-ray shows small, hydronephrotic left kidney. Ureteric catheter specimen: Right normal; left blood-stained.

Treatment and progress.—As the blood pressure was persistently raised in the region of 270/150 to 240/140 removal of the abnormal left kidney was considered imperative.

Operation (9.3.54).—Left nephrectomy: small atrophied kidney removed.

Pathological report.—"The kidney measures 5 × 3 × 1 cm. The cross section is that of a hydronephrosis in a small kidney."

Post-operative follow-up.—There was an immediate fall in blood pressure to 140/80 with a gradual rise over the next few days and a subsequent fall to the region of 170/90–105. This improvement has now been maintained *for three years* and she has become and remained symptom free.

2.4.57: Blood pressure 170/100. No shortness of breath. No headaches. Eye fields: No hæmorrhage or exudates, residual arterial attenuation.

Discussion.—If we accept the criteria of a successful result laid down at the meeting of

the Section of Urology in 1952 on this subject (*Proceedings*, **45**, 729), that is, a fall in diastolic pressure to 100 mm.Hg or less for at least one year, then this case cannot be included as her diastolic pressure has varied from 90–105 mm.Hg. Nevertheless the fall, from 270/150 to 170/100, has been maintained for three years. This is surely a very successful result.

Langley and Platt (1947) could find only 47 successful cases in the literature and at the Section of Urology discussion in 1952 only 59 cases were recorded as having a good result after nephrectomy.

Apart from the surgical treatment of a phæochromocytoma, a cortical adrenal tumour and coarctation of the aorta, nephrectomy is one of the very rare cures for the disease.

Braasch estimated that 15,000,000 people in the U.S.A. suffer from hypertension and about 30,000 would benefit from nephrectomy. This indicates that we should all keep up the search.

Dextro-inversio Cordis.—ALASTAIR ANDERSON, F.R.C.P.

E. D., male, aged 19½. A known case of dextrocardia referred for opinion regarding fitness for National Service. He denied any symptoms.

On examination.—Dextrocardia. Apex beat (heaving) palpable in 6th space right anterior axillary line. Insignificant grade 1 basal systolic murmur. Blood pressure 160/80. Femoral pulses synchronous with radials. No situs inversus. Moderate "crater" chest.

Fluoroscopy.—Dextrocardia. Cardiac enlargement. Left aortic arch and descent. No situs inversus.

Cardiogram.—No "mirror image" dextrocardia. Left ventricular hypertrophy and strain pattern in standard and unipolar limbs leads. "Systemic" ventricular leads across chest from V 5 R to V 5 with hypertrophy and "strain" in right chest leads (Fig. 1).

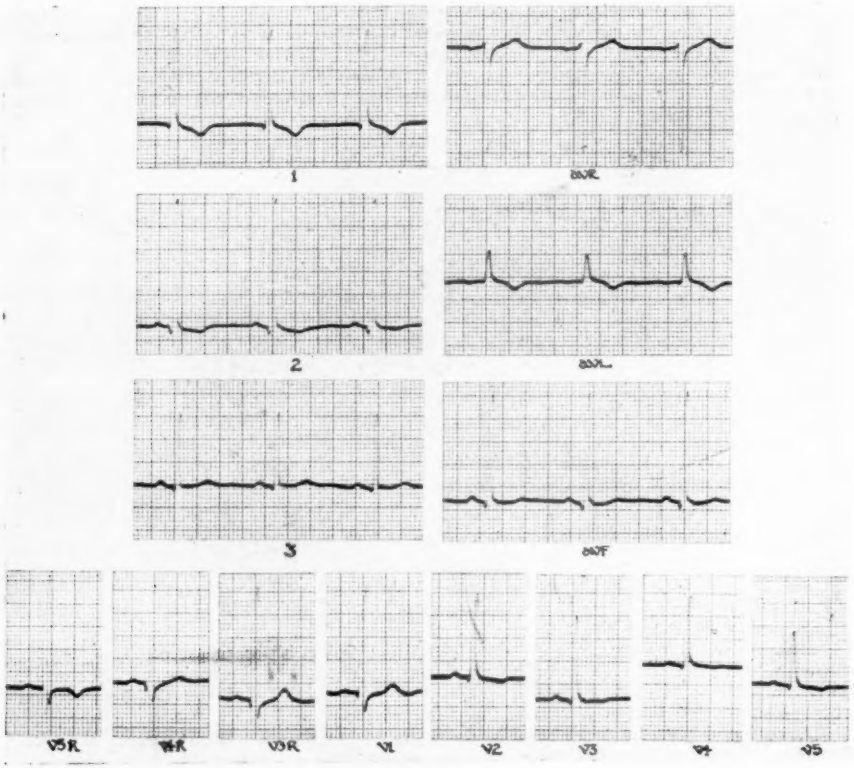

FIG. 1.

Dextrocardia may be classified as: (*a*) Mirror image. (*b*) Dextro-inversio cordis (pivotal). (*c*) Mixed (Fig. 2).

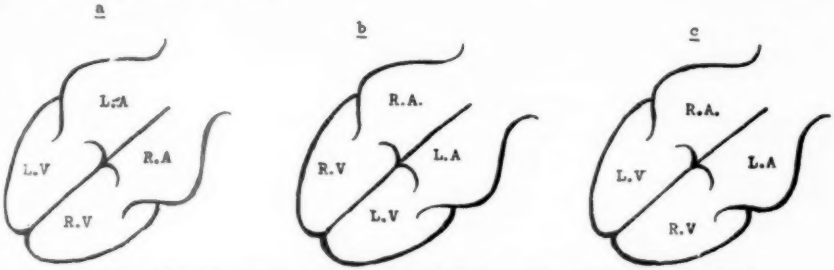

FIG. 2.—After Maurice Lev, M.D., Dept. Pathology, Mount Sinai Hosp., Miami. (1954) *Lab. Invest.*, **3**, 71.

Mirror image.—When "mirror image" dextrocardia is accompanied by situs inversus other congenital cardiac abnormalities do not ordinarily occur. When situs inversus is not present—isolated "mirror image" dextrocardia—other congenital cardiac anomalies are almost invariable and commonly of severe degree.

Dextro-inversio cordis.—Here the position of the chambers is such as would obtain if the heart in lævocardia was simply rotated in a horizontal plane till the apex lies on the right. The morphological left ventricle comes to lie in front and the morphological right ventricle lies behind. This type of dextrocardia is not associated with situs inversus. There is a left aortic arch, and other congenital cardiac defects are almost invariably present and usually gross.

Mixed.—In "mixed" dextrocardia the morphological ventricles are inverted in relation to the atria. Thus the atria lie in a pivotal position, but the morphological ventricles in a "mirror image" position.

I think that this is the state of affairs in this patient: basically pivotal dextrocardia but with inversion of the ventricles so that the anterior and functionally left ventricle is morphologically a right ventricle. This may explain the enlargement of this ventricle. When a morphological right ventricle has to operate against systemic arterial pressure, as for instance in a truncus arteriosus, it enlarges. I suggest it has done so in this case for the same reason.

Multiple Kidney Operations for Cystine Calculi.—G. L. BOHN, F.R.C.S.

Mrs. M. M., aged 39.

1924 (aged 6): Bilateral nephrolithotomy.

1928: Left nephrolithotomy.

1940: Right nephrolithotomy.

1942: Left nephrolithotomy.

In 1951 she was found to have large hydronephroses and multiple calculi in both kidneys. The urine was heavily infected and the blood urea was raised (50 mg./100 c.c.).

The treatment was: (1) To clear both kidneys completely. (This required three more operations, bringing the total to eight.) (2) To eliminate infection with the new antibiotics. (3) To maintain an alkaline urine by means of a vegetarian diet.

Since then the patient has remained well, free of stones and free of urinary infection. Her blood urea was normal in 1956.

Until the 1940 operation, the stones were pure cystine; after that they were a mixture of cystine with calcium phosphate.

Two Cases of Carcinoma of the Ampulla of Vater Treated by Local Excision.—R. G. REID, F.R.C.S.

I.—Mr. F. B., aged 65, was first seen in July 1954 with intermittent jaundice since March 1954. He was deeply jaundiced with urine loaded with bile and the stools clay-coloured. There was a suggestion of a mass in his right hypochondrium. He was obese and appeared unfit for a major operation. Just prior to admission he had a fairly severe melæna for which he was given two pints of blood. The abdomen was explored on August 5, 1954, when the jaundice was found to be due to a small mobile tumour at the ampulla of Vater. The duodenum was incised, the tumour resected locally with diathermy, and the common bile duct re-anastomosed to the duodenum. Section of the tumour showed it to be an adenocarcinoma.

Now, two years and eight months later, he has no symptoms referable to his growth.

II.—Mr. T. P., aged 79, was referred in October 1954 by the skin physician, to whom he had been sent because of four months' intense irritation. He was not very jaundiced, but biliary obstruction was complete and his stools were clay-coloured.

The abdomen was explored on November 8, 1954. The common bile duct and pancreatic duct were both obstructed by a soft mobile tumour of the ampulla of Vater. Although initially, in view of his age and general condition, a short circuit alone was contemplated, after this was done the tumour was again examined and it was seen to be so mobile that a local excision of it was considered worth while, if only to unblock the pancreatic duct. It was, therefore, removed with diathermy. Section showed it to be a well-differentiated carcinoma.

His recovery was interrupted by the development of prostatic obstruction for which he had to have a prostatectomy. He has remained well ever since, and now, two years and six months after the operation, has no symptoms referable to his original complaint.

Discussion.—In showing these cases of tumours of the ampulla of Vater, I wish to stress two things: firstly, the characteristic low malignancy and slow growth of such tumours in which they differ so markedly from carcinoma of the head of the pancreas, and secondly, that surgery carries with it so small an immediate mortality that a local resection may well be worth while if the patient is not fit for a radical operation.

The growth is generally a papillary adenocarcinoma which grows slowly and metastasizes late. It thus differs from carcinoma of the head of the pancreas which with any line of treatment has a poor prognosis. Patients with ampullary growths may live for many years and Morley (1947) records a patient who apparently had a spontaneous cure, for the tumour for which he performed a cholecystenterostomy preparatory to a radical removal was found to have disappeared at the second operation, and a near-by gland which was removed was filled with spheroidal cell carcinoma. The patient lived for another twenty years, dying eventually of a coronary thrombosis.

The first surgical excision of such a tumour was performed by Halstead (1899) in 1898. The approach was through the duodenum and the patient lived for nine months. Many subsequent attempts were made to deal with this condition by limited resections, with a fairly high mortality, until 1935 when Whipple *et al.* (1935) devised a radical two-stage operation. In 1912 admittedly Kausch performed a radical excision anticipating in some respects Whipple's operation, but the operation was considered too severe by most surgeons. The paper by Whipple *et al.* (1935) gave a new impetus to radical operations in this region, and carcinoma limited to the ampulla was treated from then on in this way, if the condition of the patient permitted. The best results are perhaps those of Cattell and Pyrtek (1949) who had one death in 20 resections with a 50% three-year survival. In 1954 Moore and Younghusband (1954) in this country published a series of 8 cases treated by radical excision, one of which died as the result of the operation. At the time of publication it was too early to draw conclusions regarding survival. A study of the specimens obtained shows that the growth was in 50% of cases limited to the ampulla, which suggests that local excision might well have produced a cure.

At this hospital, since 1948, we have had 4 cases of ampullary carcinoma. The first patient, a woman aged 63, died three years and three months after a duodeno-pancreatectomy, from secondary deposits. The other 3, all men, aged 65, 65, and 79 years are alive. They all had a local resection of their tumour two years and nine months, two years and six months, and one year ago, respectively.

The very much better results from surgery for ampullary carcinoma as compared with carcinoma of the head of the pancreas are probably related as much to the early onset of the jaundice, which brings the patient more quickly for treatment, as to the proved lower malignancy of the growth.

An Outbreak of Infantile Gastro-enteritis (*E. coli O. 128*) in a Small Hospital Maternity Unit

By R. M. MAYON-WHITE, M.D., Ph.D., M.R.C.P., D.C.H.

Introduction.—The outbreak described here occurred in the maternity unit nursery at the West Suffolk General Hospital in the summer of 1955. The main features of the outbreak are indicated by means of an epidemic diagram (Fig. 1) of the type made familiar by Rogers and Keogler (1951).

The outbreak.—The month of June clearly preceded the outbreak. In July there were 2 cases of gastro-enteritis on the children's ward; they appeared to be sporadic cases, neither was particularly ill. In the following eight weeks 14 infants on the maternity ward developed gastro-enteritis, of whom 6 died. 60 other newborn infants at risk escaped infection. On August 16 a meeting of the Control of Infection Committee was called, the help of the Public Health Laboratory Service was obtained for epidemiological bacteriology, and it was decided that all sick infants should be transferred from the maternity unit to the children's ward. A meeting of an enlarged *ad hoc* infection committee was called for the following day.

On August 18 the maternity ward was closed, all mothers and infants were sent home except 2 who were transferred to a private ward temporarily used as an emergency maternity ward; 1 of these infants, and 8 of the 15 infants at risk in the maternity ward on August 18 subsequently developed gastro-enteritis. After cleaning, fumigation and standing empty for two weeks, the maternity unit was reopened on September 1; no recrudescence of gastro-enteritis occurred. In the meantime emergency maternity admissions were diverted to other hospitals in neighbouring towns (15 and 28 miles away).

Bacteriology.—The O. 128 B.12 strain of *E. coli* was obtained from all affected infants born in hospital and from two adult contacts: a maternity ward staff nurse on August 18, and, at a later date, from the children's ward Sister. The organism was not found in the stools of any mothers of affected infants. The same organism was also obtained after discharge from one of the two children's ward cases (Case 1), though not from the other.

Source of infection.—Attempts to trace the primary source were unsuccessful. There is obviously a possibility that infection was conveyed from the children's ward to the infant population of the maternity unit. Supposing that the infection originated either in Case 1 or Case 2, it is possible (*see* Fig. 1) to trace successive waves of new cases separated by an incubation period of seven to ten days. Thus, if Case 2 in the children's ward started the outbreak on about July 15, this infection might have been transmitted by some means to the maternity ward to affect Case 3 about July 24. The third wave is represented by Case 5 in the maternity ward and Case 4 (at home at that time); the fourth wave is a widespread outbreak about August 15–18, when Cases 9, 11, 12, and 13 became ill on the maternity ward, and Cases 6, 7, 10, 14 and 15 became ill in their own homes. In the absence of bacteriological data, this explanation can neither be confirmed nor denied. It is equally possible that Cases 1 and 2 (on the children's ward) had nothing to do with the outbreak in the maternity ward. Case 1 may have acquired the O. 128 strain (which was first demonstrated in his stools three weeks after he had been discharged), by cross infection from Case 3 or Case 5, during the period they were on the children's ward together.

There are other possible origins of the outbreak: the maternity ward staff nurse and the mother of Case 6. The staff nurse may have acquired the organism from the infants in her care. The mother was a maternity ward patient from July 5–19, and July 26 to August 6, her other children suffered intermittent diarrhœa for some weeks at this time: the epidemic strain of *E. coli* was not isolated from their stools or from hers.

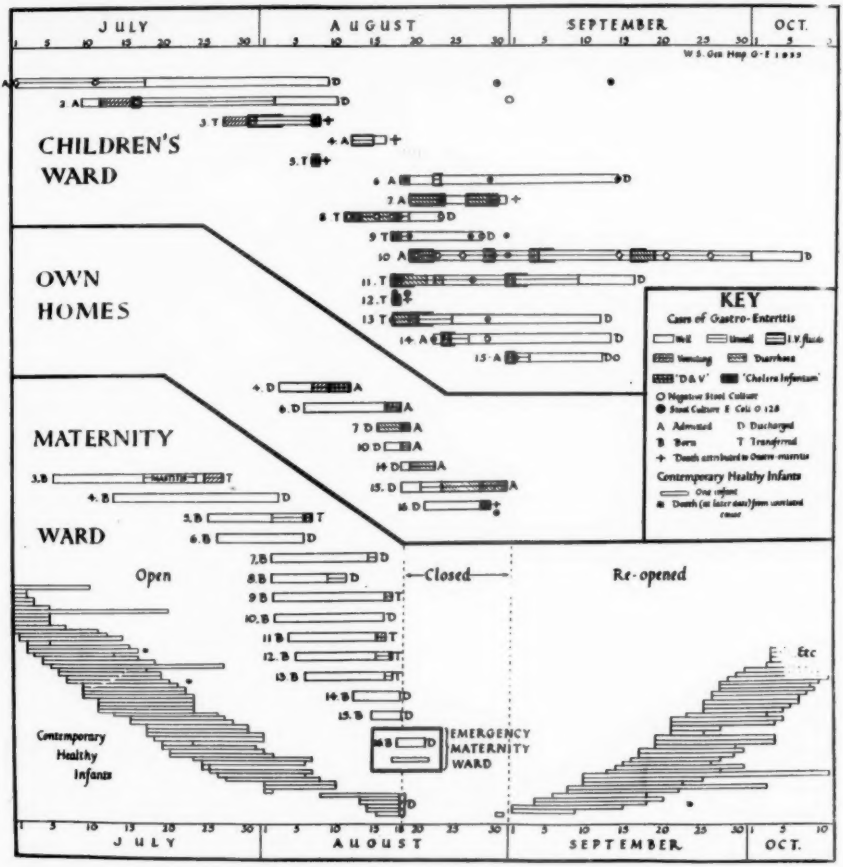

FIG. 1.—This diagram is designed to indicate by time and place the clinical course of each case of gastro-enteritis, to trace the movement of the individual infants, and to give an over-all picture of the development of the outbreak.

Individual cases (indicated by case number) are plotted on a horizontal time scale, the three separate geographical situations in which an infant might be (the maternity ward, his own home, or the children's ward) are indicated; different symbols indicate clinical features.

For example, one may follow Case 4 from birth in the Maternity Unit on July 13, discharged home on August 3; becoming ill at home first with vomiting August 7, then with diarrhœa and vomiting: admitted to children's ward August 12, and dying there four days later.

The contemporary healthy infant population of the maternity ward is also indicated on the same horizontal scale but half the ordinate scale.

Conclusions.—The personal conclusions drawn from this experience may be dogmatically stated as follows: (1) That infantile gastro-enteritis should be a notifiable disease. (2) That for practical purposes the pathogenicity to infants of serologically identifiable strains of *E. coli* should be accepted as a working hypothesis. (3) That the bacteriological investigation of cases of infantile gastro-enteritis should be entrusted to the Public Health Laboratory Service or to bacteriology departments prepared to devote special attention to this work. (4) That professorial pædiatric departments, the pædiatric research units of teaching hospitals, and the specialized gastro-enteritis units of large general hospitals, should regard the prosecution of controlled therapeutic trials in gastro-enteritis as a primary duty. (5) That every general hospital should have a Control of Infection Committee on which the Medical Officer of Health should sit or be represented. (6) That these committees should investigate and report on each hospital outbreak of infantile gastro-enteritis.

Acknowledgments.—This account is based upon the detailed case notes and epidemiological records kept by Drs. M. G. Bridger and I. B. Crawford. I am indebted to Dr. J. Dunscombe for the post-mortem reports and to Dr. R. M. Fry for the bacteriological investigations. I would particularly like to acknowledge the help and support I received from my colleagues on the enlarged Control of Infection Committee.

Neonatal Œstrogen Excretion and Its Relation to Post-natal Weight Loss

By BRUNO GANS, M.D., M.R.C.P., and J. C. THOMPSON, B.Sc., Ph.D.

Department of Pædiatrics and Group Laboratory, Lewisham Hospital

THIS work represents a preliminary report on œstrogen excretion during the neonatal period and its possible relationship to post-natal weight loss. In this investigation no account has been taken of the other known causes of weight loss, such as the weight of meconium and vernix, the catabolic effects of a difficult labour, or the insensible water losses through skin and lungs.

The hormone estimations were carried out on the twenty-four-hour urine specimens passed, during the first few days of life, by 6 normal male neonates. The urine was collected by means of a Paul's tube strapped to the penis. All 6 infants had an easy birth, and their post-natal course was normal.

The three œstrogens, œstriol, œstrone and œstradiol were estimated by the method of Brown (1955). The 17-hydroxycorticosteroids were also determined, using the method of Appleby *et al.* (1955). The findings were essentially similar in all 6 infants. There were very large (milligram) amounts of œstriol on the first day. The urinary excretion of this substance then dropped rapidly during the next two or three days, and reached values of 1 or 2 μg., similar to those found in adult males, on the fifth or sixth day. Œstrone and œstradiol were found in amounts of 1–2 μg. during the first and second day, and had disappeared by the third day.

The three œstrogens found in the infants' urine showed a pattern similar to that found in their mothers' urine during the twenty-four hours before birth.

The 17-hydroxycorticosteroids showed only slight fluctuations during the first ten to twelve days of life, and their levels appeared to be unrelated to the post-natal weight loss.

Our results show that in all 6 infants the cessation of œstrogen excretion coincides with the cessation of post-natal weight loss. They also show that all 6 infants excreted decreasing amounts of urine until weight loss and œstrogen excretion had ceased, that is, some time between the third and fifth day of life.

The completed data on 4 infants and 2 mothers are shown in Table I.

It is well known that the fœtus and neonate are hydræmic. This hydræmia disappears during the first few days of life. Thorn and Engel (1938) have shown that in experimental animals œstrogen administration leads to salt and water retention. Thorn *et al.* (1938) also found that water retention occurs in women during periods when œstrogen production is high, and that there is a diuresis and a loss in weight after menstruation and post-natally, when the œstrogen level has fallen. Preedy and Aitken (1956) confirmed these findings and found that the weight gain after œstrogen administration was associated with an increase in extracellular fluid and plasma volume. This water and salt retention was attributed by Sophian (1956) to an effect of the œstrogens on the glomerular filtration rate. Thomson (1944) and Woolf and Norman (1957) have shown that the neonate's urine becomes steadily more concentrated during the period of post-natal weight loss.

It appears, therefore, that the infant's urine is of low specific gravity at first, that it becomes more concentrated during the period when the excess water and the œstrogens are being excreted, and that this occurs in spite of the increasing intake of fluid during those first few days of life.

We suggest that some, at any rate, of the hydræmia of the neonate is due to the water-retaining properties of œstrogenic hormones obtained by the infant from its mother before birth. We have shown that these œstrogens are excreted by the infant's kidney during the first few days of life. It would appear logical, therefore, to attribute some of the post-natal weight loss to the water released from the infant's body when the maternal œstrogens have been excreted.

Finally, we would like to suggest a possible reason for the neonate excreting, rather than metabolizing or detoxicating, the œstrogens obtained from its mother. Preedy and Aitken (1956) showed that the water- and salt-retaining properties of œstrogens are particularly

marked in diseases associated with circulatory disturbances of the liver. Emery (1952) found that there is a rapid involution of the left lobe of the liver following birth, and that this involution is due to an alteration of blood flow through that lobe. It seems possible, therefore, that the newborn infant cannot destroy its mother's œstrogens because of the hæmodynamic changes taking place in its liver.

TABLE I.—SHOWING THE WEIGHT LOSS, TWENTY-FOUR-HOUR URINE VOLUME, ŒSTROGEN AND 17-HYDROXYCORTICOSTEROID EXCRETION IN 4 INFANTS, AND THE HORMONE VALUES IN THE URINE OF 2 MOTHERS

Case	Day	Weight (% of birth weight)	Urine volume (ml.)	Œstriol (μg./day)	Œstrone (μg./day)	Œstradiol (μg./day)	17-hydroxy-cortico-steroids (mg./day)

President—LOUIS FORMAN, M.D., F.R.C.P.

[*March* 21, 1957, contd. from August *Proceedings*, p. 610]

THE following cases were also shown:

Pock Mark Treated by Surgical Abrasion.—Mr. PATRICK CLARKSON.

(1) **Necrobiosis Lipoidica.** (2) **Widespread Purpura for Diagnosis.**—Dr. P. D. SAMMAN.

(1) **Neurofibromatosis and Malignant Pericytoma.** (2) **Liver Disease with Pigmentation and Diabetes Mellitus.**—Dr. OLIVER SCOTT.

Hansen's Disease.—Dr. G. B. MITCHELL-HEGGS, Dr. R. G. COCHRANE and Dr. J. D. EVERALL.

Pigmentation and Leukodermia (Following Dermabrasion).—Dr. G. B. MITCHELL-HEGGS and Dr. J. B. EVERALL.

Reticulosis.—Dr. D. I. WILLIAMS and Dr. R. H. MARTEN.

Multiple Self-healing Epitheliomata (Ferguson-Smith).—Dr. D. E. OAKLEY.

Bowen's Disease.—Dr. J. D. EVERALL. (This case was shown by Dr. G. B. MITCHELL-HEGGS on January 17, 1957, as **Acrodermatitis Continua with Vascular Changes in the Digital Arteries and Venous Channels.**)

[*April* 25, 1957, contd. from October *Proceedings*, p. 774]

Histiocytic Reticulosis.—GEOFFREY HODGSON, M.B.E., M.D.

Male, aged 7 years.

History.—Six months' history of erythematous papular brownish rash. No history of diabetes insipidus.

Clinical findings.—Small firm movable glands axillæ and groins. No splenic or hepatic enlargement.

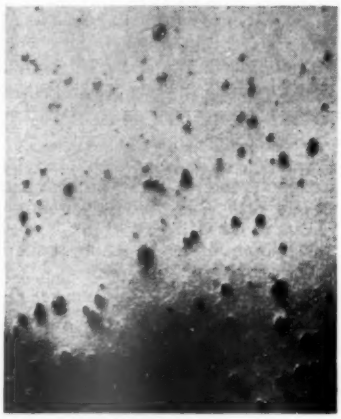

FIG. 1.

FIG. 2.

Multiple non-pruritic flat-topped light brownish pigmented slightly scaling papules 1 mm. to 5 cm. in diameter, in the skin of the face, neck and occipital scalp, back, abdomen, thighs and antecubital fossæ (Figs. 1, 2).

FIG. 3.

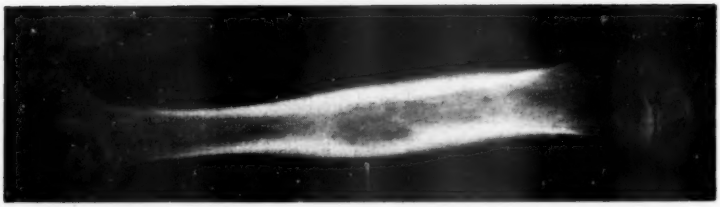

FIG. 4.

Investigations.—X-rays: Areas of bone resorption in skull and right femur (Figs. 3, 4). Chest normal. Abdomen normal.

Blood: Hb 11·8 grams per 100 ml. (80%), W.B.C. 17,600 (polys. 57%, monos. 4%, lymphos. 28%, eosinos. 11%). Packed cell volume 42%. E.S.R. 15 mm. fall in one hour (Wintrobe); corrected by P.C.V. shows doubtful increase.

Liver function tests: Serum total protein 7·0, albumin 3·8 g./100 ml. (Howe). Thymol turbidity 2 units (normal 0–4). Zinc turbidity (Kunkel) 17 units (normal 2–8).

Serum lipoids: 4·6 g./100 ml. Plasma cholesterol 180 mg./100 ml.

Glucose tolerance: Flattened normal curve. *Electrophoretic curve* normal.

Biopsy (Dr. Henry Haber).—There is an area under the epidermis which is heavily infiltrated by two types of cells. One type consists of large mononuclear cells with a vesicular nucleus and abundant cytoplasm of foamy character, and they appear to be forming a syncytial network. The foamy appearance is apparently due to the presence of fat. The second type of cells to be found are those of the eosinophil which are present in either scattered or large groups. The histology is characteristic of Letterer-Siwe disease.

Course.—Slight continued loss of weight. No alteration in X-ray bone appearances or in skin lesions in the last two months.

Three Cases of Parapsoriasis en Plaques.—BRIAN F. RUSSELL, M.D., F.R.C.P.

I.—H. D., male, aged 50. Market porter.

History.—First seen in February 1957 with three years' history of scaly patches on the wrists, arms and trunk, persisting and slowly spreading. General health good.

On examination.—Blotchy erythema of cheeks with scarring of acne. Slightly scaly atrophic greyish-pink areas on trunk in cleavage line pattern. Scaly patches on wrists. Scabbed papules on legs. No lymphadenopathy, splenomegaly or hepatomegaly.

Investigations.—X-ray of chest normal.

Blood: Hb 100%; W.B.C. 10,800; (polys. 69%, eosinos. 2%, lymphos. 25%, monos. 4%). Wassermann reaction negative.

Skin biopsy from left infra-mammary region: Slight acanthosis, focal lymphocytic infiltration in epidermis and moderate lymphocytic infiltration in upper dermis.

II.—E. M., female, aged 43. Housewife.

History.—Following an operation in October 1952 for uterine prolapse, she developed a pelvic abscess which was treated with streptomycin. Shortly after this she noticed a rash on her arms which later spread to the legs. It was not itchy. The lesions slowly extended and did not respond to any treatment. On one occasion only she complained of widespread pruritus. In 1956 she noticed increasing dryness of the skin generally and also of a sore tongue.

Present state.—Pinkish-yellow oval areas with very slight scaling, mostly on the limbs. No lymphadenopathy, splenomegaly or hepatomegaly.

Investigations.—X-ray of chest normal.

8.1.53: Biopsy from skin of arm showed slight non-specific infiltration in upper dermis. Mantoux reaction 1 : 1,000 positive.

Blood: Hb 93%; W.B.C. 9,000 (polys. 59%, lymphos. 37%, monos. 4%).

Treatment.—General ultraviolet irradiation; a course of oral calciferol, and bland local applications have been ineffective.

III.—A. B., male, aged 58. Clerk.

History.—First seen in November 1952 with a twelve months' history of dry scaly non-itchy patches which began on legs and rapidly became widespread. At that time he had plaques of pinkish-yellow slightly scaly skin on arms and legs with atrophic skin on trunk. His general health was good. In spite of treatment the lesions became progressively more extensive until in 1954 the condition resembled ichthyosis.

Investigations.—4.11.52: W.B.C. 8,000 (polys. 72%, eosinos. 1%, lymphos. 21%, monos. 6%). Wassermann reaction negative.

24.11.52: Biopsy of skin from upper arm: Patchy slight hyperkeratosis and parakeratosis, atrophy of epidermis. Slight œdema and non-specific infiltration in upper dermis.

1.7.54: X-ray of chest normal. 23.9.54: Mantoux reaction 1 : 100 negative. 21.11.55: B.C.G. given. 14.2.56: Mantoux reaction 1 : 100 positive.

Treatment.—This has included a course of ultraviolet irradiation, calciferol, mepacrine, vitamin A, thorium-X topically, and bland applications.

Dr. G. B. Dowling: I think that there may be some doubt about the labelling in the first case. For a long while we have, especially at St. John's Hospital, tried to distinguish cases which might develop into a reticulosis, regarding such cases as true parapsoriasis, from those which would never do so, and the distinction is often difficult. The benign cases we suppose to be a kind of very refractory superficial dermatitis.

Dr. Russell: For the diagnosis of parapsoriasis en plaques, I have applied the criterion of non-itchy, slightly scaly, brownish-pink plaques, of long duration, and refractory to all treatment.

Dr. J. T. Ingram: I thought all these cases were parapsoriasis en plaques and the second one I thought illustrated Brocq's leopard-skin pattern of eruption on the trunk. I do not think it is the simple type, but I think it is one of the intermediate types which have been described. I do not think there is any true atrophy, but a semblance of atrophy.

Psoriasis and Mycosis Fungoides.—K. M. HARVEY, M.B. (for BRIAN F. RUSSELL, M.D., F.R.C.P.).

J. S., male, aged 60.

History.—He has had scaly patches on arms, legs and trunk for fifty years. Diagnosed as psoriasis. Eighteen months ago he developed slightly irritable exudative patches on his face and trunk which seemed different from the previous patches. A patch on the abdomen became more irritable and superficial ulceration developed. Throughout this time his general health had been good and there was no loss of weight.

Treatment up till the time of admission to hospital had consisted of local applications only: there had been no superficial X-ray therapy.

Family history.—None of psoriasis.

On examination.—Typical scaly patches of psoriasis on legs, arms and scalp. On the trunk there are numerous infiltrated exudative areas. Two patches on the back show

definite infiltration. A large patch on the anterior abdominal wall shows superficial ulceration. There are a few discrete non-tender lymph glands in axillæ and groins. The liver and spleen are not palpable. There is a right inguinal hernia. Clinical examination otherwise normal.

Investigations.—Biopsy: Right knee: Hyperkeratosis and acanthosis with regular elongation and clubbing of rete pegs, heavily infiltrated with lymphocytes forming Pautrier micro-abscesses.

Left chest: Hyperkeratosis and upper dermal infiltration by lymphocytes.

Right hip region: Parakeratosis, regular acanthosis alternating with atrophy. Moderate infiltration especially of plasma cells and eosinophils in upper dermis.

X-ray of chest normal.

E.S.R.—39 mm. in one hour (Westergren).

Hb 76% W.B.C. 11,200 (polys. 55%, eosinos. 10%, lymphos. 30%, monos. 5%).

Progress and treatment.—Infiltrated lesions on the trunk responded to both X-ray therapy and thorium-X painting. The scaly patches on the legs and arms cleared spontaneously.

Comment.—Clinically this man appears to have had typical patches of psoriasis for fifty years and now also presents with histologically proven mycosis fungoides. It is possible that his long-standing skin eruption was premycotic; alternatively, psoriasis and mycosis fungoides may be presenting together as two separate diseases.

Dr. J. T. Ingram: In Dr. Brian Russell's case it is a retrospective diagnosis. I have never seen psoriasis pass into mycosis fungoides.

Dr. R. T. Brain: I have never seen mycosis fungoides derive from psoriasis, but I have seen typical psoriatic lesions followed by mycosis fungoides. The histology in this case shows that it is not psoriasis.

Mycosis Fungoides Developing on Parapsoriasis en plaques.—BRIAN POTTER, M.D. (for BRIAN F. RUSSELL, M.D., F.R.C.P.).

M. L., female, aged 50.

History.—This patient's eruption has gradually spread over her body since she was 19 years of age. In 1949 at the age of 42 she was seen by Dr. Ian Martin-Scott, and at that time had on the trunk and upper thighs sharply marginated, bluish-pink oval patches. There was no infiltration, the epidermis was questionably atrophic and slightly scaly, and faint brown pigmentation was apparent. There was no regional adenitis. Clinical diagnosis was parapsoriasis en plaques. The eruption has gradually extended since then, no lesions having ever disappeared.

On examination.—The patient, now aged 50, presents on the trunk and extremities a generalized erythemato-squamous eruption in irregular defined lesions, superficial on the extremities and with slight infiltration of the larger areas on the trunk, which latter also show some brown pigmentation (Fig. 1). There is some irritation from these lesions. The clinical impression is now of reticulotic change. There is no lymphadenopathy, and neither liver nor spleen is palpable. Blood count is entirely normal and the chest X-ray is clear.

FIG. 1.—Patchy pigmented erythemato-squamous eruption.

Histopathology.—A biopsy taken in 1949 does not show a specific picture. There is a moderate infiltrate of inflammatory cells in the upper corium, some of which are passing into the epidermis. There are present a number of reticulum cells with somewhat large irregular nuclei.

Biopsy taken recently shows a much more marked infiltrate, containing cells of several different types, nearly all mononuclears, including large numbers of reticulum cells, the nuclei of which show variation in size, shape and content of chromatin. Passing into

the epidermis are some mononuclear cells intermediate in size between reticulum cells and lymphocytes, and in places these are tending to form localized collections within the epidermis (Fig. 2).

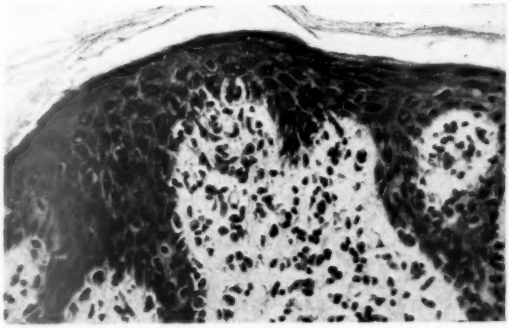

FIG. 2.—Biopsy ×210 taken 9.4.57.

Histologically this is therefore a reticulosis in which the basic cell type is the reticulum cell. Monocytic leukæmia and reticulum cell sarcoma can be excluded in view of the polymorphism of the infiltrate; Hodgkin's disease must be considered, but there is no other evidence of it. In view of the presence of pleomorphic reticulum cells in a polymorphous infiltrate and invasion of the epidermis by atypical mononuclear cells, this case is interpreted as mycosis fungoides (Helwig, 1955).

REFERENCE

HELWIG, E. B. (1955) Mycosis Fungoides. *Proceedings* of the XXth Seminar, *Amer. Soc. Clin. Path., Washington*, p. 93.

Poikilodermia (Jacobi-Lane).—J. S. PEGUM, M.R.C.P.

R. C., male, aged 55.

History.—Fourteen years ago a rash appeared on the left side of the groin. Shortly afterwards a similar rash appeared in the right groin. Since this time the rash has spread gradually over most of the trunk and parts of the legs. The rash irritates occasionally. Parts of it have been treated with X-ray therapy.

In 1956, attended the National Hospital for Nervous Diseases, Queen Square, because he could not keep his balance or walk in a straight line, a diagnosis of disseminated sclerosis was made.

On examination.—Face: Slight redness of right upper eyelid. Both axillæ, the neck, parts of the back, the abdomen, thighs, buttocks, and parts of the legs show diffuse redness, scaling, pigmentation and telangiectasia. B.P.140/90. No pathological enlargement of lymph glands, liver or spleen.

Investigations.—Hb 89%, W.B.C. 10,400 (polys. 62%, eosinos. 3%, lymphos 32%, monos. 3%).

Chest X-ray normal.

Biopsy of skin of abdomen: The horny layer shows hyperkeratosis and in places parakeratosis. The prickle-cell layer is in parts hypertrophic and in parts atrophic. Some of the cells are hydropic. In places there is infiltrate in the epidermis. The upper dermis shows a band-like infiltrate composed mostly of lymphocytes and monocytes. The capillaries are dilated.

Comment.—Clinically and histologically this appears to be poikilodermia (Jacobi-Lane). Unusual is the association with disseminated sclerosis.

Dr. G. B. Dowling: I would describe this as a classical example of poikilodermia of the Jacobi-Lane type. If the patient has disseminated sclerosis this would presumably be an unconnected condition.

Dr. J. T. Ingram: Other cases have been reported of poikilodermia following neurological illness (Katz, F., and Hoogstraten, J. (1946) *Arch. Derm. Syph., Chicago*, **53**, 333).

Poikilodermia Developing Mycosis Fungoides.—E. N. M. JOHNSTON, M.R.C.P.

H. E. E., male, aged 48.

At the age of 17 he began to develop a faint red, non-irritating rash on the neck, trunk, thighs and arms, especially affecting the flexures.

He was shown to the Section in 1936 by Dr. G. B. Mitchell-Heggs and Dr. F. W. Jacobsohn as a case of poikilodermia of Jacobi with polydactyly (*Proceedings*, **29**, 717). At that time the lesions were described as follows: "On the sides of the neck there are reddish-brown pigmented and erythematous spots, slightly depressed and surmounted by a scale within intervening white skin, atrophic in some parts. The appearance resembles reticular marbling seen in ephelis ab igne. Faintly brown erythemato-squamous lesions were present on the trunk."

The histology was reported as showing: "Upper third dermis. Dense infiltrate of round cells in an œdematous reticulum. Histocytes and chromatophores were also present. The infiltrate extended into the papillary body and had a moderately sharp lower border."

In 1936 he was treated with thorium-X with some improvement but this was not maintained.

He was first seen at St. Thomas' Hospital in 1951 and was shown to the Section by Dr. Waddington in February 1951 as a case of poikilodermia-mycosis fungoides. At that time he complained that six months previously the lesions had started to itch intensely (twenty-four years after the onset of the eruption). The areas of poikilodermia were unchanged but, in addition, there were now bluish red scaly infiltrated plaques on the left side of the chest and abdomen and bilateral inguinal adenopathy. There were no other abnormal clinical findings. A chest X-ray and several blood counts were all normal.

The histology of two biopsy specimens was reported on as follows (*Proceedings*, **44**, 675):

From infiltrated plaque: "Severe irregular epithelial hyperplasia and infiltration of the upper layer of the dermis by inflammatory cells of almost all types. The infiltrate freely invades the epidermis and extends downwards into the dermis along the line of vessels and appendages. The appearances are very suggestive of mycosis fungoides."

From area of poikilodermia: "Epithelial depigmentation and slight hyperplasia and superficial dermal and epidermal infiltration by inflammatory cells. There is also some superficial vascular dilatation and elastic tissue has disappeared from the upper third of the dermis. The appearances are compatible with the diagnosis of a premycotic eruption."

A considerable amount of radiotherapy to the more infiltrated lesions has been given with great benefit. However, further plaques have continued to appear, some infiltrated and some being little more than erythema and scaling and these have gradually increased in number until the present time.

Since 1955 raised nodules and ulcerated lesions have appeared from time to time, some showing a marked horseshoe configuration. These have been treated with superficial X-rays with very good effect. The itching is still extremely troublesome.

Mycosis Fungoides Treated with Prednisone.—L. FORMAN, M.D., F.R.C.P.

W. P., male, aged 57.

History.—Commenced 1952. Erythematous plaques, "parapsoriasis", over the trunk, not scaling, not irritable, not infiltrated. Became widespread and patterned enclosing normal areas of skin. Subsequently irritation and oozing in some of the plaques.

Section, taken 1952, at this stage was not sufficiently definite to diagnose mycosis fungoides.

Treatment (1952–53).—Thorium-X 1,000 e.s.u. per c.c. of spirit was applied to the areas resembling parapsoriasis en plaques. The treated areas involuted, but relapsed towards the end of 1953, and became almost confluent; the itching more severe, and the section more typical of the erythrodermia of mycosis fungoides.

1954: X-ray treatment was given and the eruption faded. The whole body surface was irradiated in courses until the beginning of 1956.

October 1956: There was generalized itching and relapse of the erythrodermia. Prednisone 30 mg. a day produced a prompt remission of the erythema and scaling, and of the itching, and continued from November 1956 to January 1957 when the dose had been diminished to 15 mg. a day. The eruption relapsed and small nodules have appeared on the shoulders during the past six weeks. The prednisone was again increased to 30 mg. a day and the severity of the dermatitis and itching diminished. However, no effect has been produced on the nodules.

Investigations.—W.B.C. 6,600; normal differential without eosinophilia.

November 1956: Bone-marrow showed increased plasma cells, eosinophils, megakaryocytes and granulocytes showed left shift. This finding is common in mycosis fungoides and similar conditions (Dr. R. L. Waterfield).

November 1956: Total protein 7·9, albumin 3·3, globulin 4·6 g.% (moderately increased).

November 1956: X-ray showed small areas of calcification within the brain and throughout the lung; soft tissue of the thigh no evidence of calcification—probably old miliary tuberculosis.

To-day, a typical patterned erythrodermia with nodules of mycosis fungoides is to be seen.

Section of Ophthalmology

President—R. C. DAVENPORT, F.R.C.S.

Arteriosclerotic Optic Atrophy

By DONALD J. LYLE, M.D.
(*Cincinnati*)

INTRODUCTION

WITH the lengthening of the human span of life and the increase of the aged population there is a change in the character and importance of disease. With the control or abolition of infections and a variety of heretofore undiagnosed maladies, which used to terminate life at an earlier age, the insidious diseases of senescence are coming to the fore. One of these is arteriosclerosis. As ophthalmologists we are interested in the sub-class, atherosclerosis, which may very well become the medical public enemy number one.

Atherosclerosis is not a generalized process but is manifested by local atheromatous lesions. There may be some dissemination but the distribution is confined to certain areas where there are curves and branching of blood vessels, as at the knee of the internal carotid artery, and where the vessels are restricted or fixed, as in the optic foramen. In these places the uniform flow of the blood stream is disturbed and eddies occur. These are favoured sites for both atherosclerosis and thrombosis.

Arteriosclerotic, or to be more exact atherosclerotic, optic atrophy is a definite entity. It should replace various terms such as pseudo-glaucoma, soft- and low-tension glaucoma. It is included in the so-called cavernous type of optic atrophy.

Symptomatology.—The individual with arteriosclerotic optic atrophy is past middle life. There is usually evidence of arteriosclerosis elsewhere in the body. The retinal vessels may show involvement, the mentality may be affected and other cerebral changes may be noted. However, the chief complaint is of visual loss.

Ophthalmoscopic examination reveals optic atrophy of so-called primary type with pallor of the disc and cupping resulting from axon degeneration without gliosis or fibrosis at the papilla. The cup margin frequently shows depression and degeneration, the result of sclerosis of cilio-retinal vessels (a better term might be cilio-papillary vessels) from the circle of Zinn (Haller) giving the disc rim the appearance of atrophic shelving (Fig. 1).

This depressed flange surrounding the deeper cupping is of importance in diagnosis as it indicates sclerosis of cilio-retinal vessels as well as the probable involvement of the vessels up-stream, the ophthalmic and carotid arteries and their branches, which supply the optic nerves and chiasm. This sclerotic rim must be differentiated from the scleral crescent of developmental origin, of no clinical significance, and from other circumpapillary degenerative conditions.

In this discussion we are not interested in the other types of arteriosclerosis although hyperplastic arteriosclerosis or arteriolosclerosis may influence the production of atheromatous changes. Obliterative arteriosclerosis more closely resembles atheromatous arteriosclerosis as the intima is chiefly involved in both conditions. However, the obliterative type does not have the degenerative changes as seen in atheromas. Obliterative arteriosclerosis may be seen in the larger vessels at the papilla.

Pathology.—Post-mortem examination of the areas of involvement shows sclerosis of larger vessels with hypertrophy of the subendothelial layer between the internal and elastic lamellæ, diffusely localized or in patchy plaque formation. The elastic tissue is disorganized and atheroma develops with lipid, hyaline and calcium deposits. Neovascularization may give rise to hæmorrhages within the atheroma. These lesions may be seen in the vessels at the papilla extending to the second bifurcation. The smaller vessels, including the cilio-retinal arteries, show proliferative endarteritis.

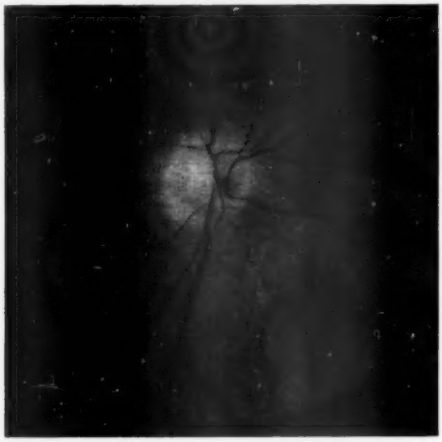

FIG. 1.—Atherosclerosis with atrophic cupping of papilla, with atrophic rim.

The chiasm and optic nerves appear to become first affected in the vicinity of the involved blood vessels, the degeneration gradually extending in both directions, in a type of cavernous optic atrophy (Schnabel's caverns).

The cupping of the optic papilla is probably the result of:

1. Atrophy and shrinking of axons.
2. Compensatory and pathologic (sclerotic) attenuation of blood vessels.
3. Recession of weakened lamina from the normal intraocular pressure.

Vascular anatomy.—Visual acuity and visual field loss in arteriosclerotic optic atrophy is produced by denied nourishment and/or destructive pressure on the optic nerves and chiasm. Occasionally the optic tract may be involved with delayed ophthalmoscopic evidence of optic atrophy.

I. Denied nourishment through arteriosclerosis may affect:

A. The optic chiasm and intracranial optic nerves which are supplied by the anterior portion of the circle of Willis, including the anterior cerebrals, anterior communicating and internal carotids. The posterior cerebrals, middle cerebrals and anterior choroidal vessels supply the posterior chiasm and optic tracts.

B. The intra-canalicular and intra-orbital portions of the optic nerves are supplied by the ophthalmic artery and its branches, chief of which are:

(1) Retinal artery of questionable blood supply to the papilla excepting through small interstitial branches which anastomose with the cilio-retinal vessels.

(2) Numerous branches which invade the optic nerve through the septal system to supply the periphery of the nerve.

(3) Recurrent central artery, a branch of either the central retinal artery or a separate vessel from the ophthalmic which supplies the axial portion of the optic nerve.

(4) Short posterior ciliary arteries to the circle of Zinn (Haller) and thence as the cilio-retinal vessels (cilio-papillary) to supply the optic papilla and surrounding area.

It might be mentioned here that the ophthalmic artery does not usually supply the intracranial portion of the optic nerve but runs subdurally and gives off no branches until it reaches the optic canal and orbit where it supplies the optic nerve. However, a normal intradural variation of the ophthalmic artery might supply the intracranial portion of the optic nerves.

I should like to mention some experiments Dr. Hunter and I performed in investigation of the blood supply to this area. This work was instigated by the occurrence on occasions, fortunately infrequent, when vision was irreparably lost following trapping operation for aneurysm in the chiasmal area. It was decided to determine the blood supply to this area. Both animal (*macacus rhesus*) and human material were used.

Yellow latex was injected through the carotid and basilar arteries into the cerebral vascular tree, after exsanguination and saline wash, with brain in situ. The vascular pattern was studied under the dissecting microscope. The procedure was more difficult in the case of human material because, during the short time elapsing between death and injection, post-mortem changes occurred which interfered with complete vascular filling.

From this study we determined that there was a rich supply or network of small nutrient arteries to the optic chiasm and intracranial optic nerves from the vessels mentioned above. We concluded that the neurosurgeon, inadvertently or of necessity, stripped away these fine vessels, thus interfering with proper blood supply to the intracranial nerves and chiasm even though there was adequate collateral circulation. Extreme caution on the part of the neurosurgeon must be exercised to prevent this occurrence.

II. Destructive pressure upon the axons may occur in:

A. The chiasmal area from the large vessels which normally are in contact with the chiasm and terminating optic nerve (Fig. 2).

FIG. 2.—Atrophy of axons in the optic chiasm caused by pressure and probably denied blood supply from sclerotic arteries.

B. Within the narrow confines of the optic foramen where the ophthalmic artery is in contact with the optic nerve.

At post-mortem examination an almost constant observation is the grooving of the chiasm by the knee of the internal carotid arteries. Although there is no grooving of the optic nerve by the ophthalmic artery in the optic foramen they are in contact in a constricted space which does not allow for expansion. Even in the retina atheromatous changes displace the structures.

DIFFERENTIAL DIAGNOSIS

Differentiation of arteriosclerotic optic atrophy from other conditions having similar symptoms may be determined by history and examination. Roentgenological observation is of great importance, particularly skull films of the sellar area. In arteriosclerosis frequently calcium deposits are seen in the knee of the carotid artery and its vicinity. (Tumours may produce evidence of their presence by destruction or hyperplastic or other changes in the bony contour.) Arteriograms are of great importance. Occasionally ventriculograms and encephalograms may show cerebral degeneration, ventricular and external changes. Measurement of retinal arterial pressure, as described by Bailliart forty years ago, is now being applied as an aid in determining the patency of the ophthalmic and carotid arteries. Further investigation may prove this test to be of great value in diagnosing arteriosclerosis as well as other conditions obstructing circulation and affecting the visual system.

The destruction of the axons in arteriosclerotic optic artery, by either pressure or denied blood supply, produces visual field loss which may be of some diagnostic importance if the lesion occurs in the carotid-chiasm area (Fig. 3). In this location nasal, binasal and altitudinal field loss, depending on the position of the vessels, may occur. This must be

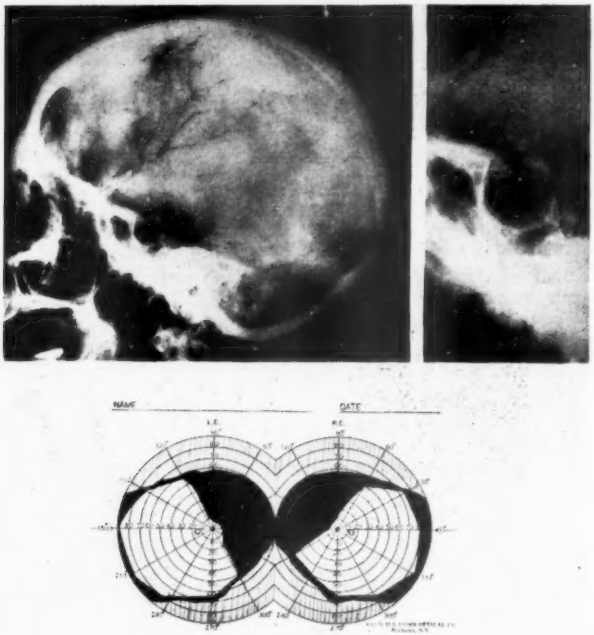

FIG. 3.—Calcium deposits seen in the knee of the internal carotid arteries which have produced binasal field loss.

differentiated from the field loss produced by other lesions most frequently producing optic atrophy. They are:

A. In the chiasmal area:
- (1) Adenoma of the hypophyseal gland.
- (2) Craniopharyngioma.
- (3) Meningioma of the tuberculum sellæ.
- (4) Internal hydrocephalus with dilatation of the optic recess.
- (5) Aneurysm in adjacent vessels.

There is a possibility that traction and pressure from opticochiasmatic arachnoiditis might cause mechanical as well as inflammatory damage to the nerve. The most characteristic field loss of hypophyseal adenoma in earlier stages is temporal or bitemporal; with craniopharyngioma there is no characteristic field loss; nor is there in aneurysm. Meningioma of the tuberculum sellæ may produce an altitudinal and temporal loss; internal hydrocephalus a bitemporal loss.

B. In the optic foramen:

(1) Constriction of the bony foramen in osteitis deformans or Paget's disease, leontiasis ossea and hyperostosis frontalis interna may produce optic atrophy but the usual cause is from vascular involvement producing chorioretinal degeneration. Other types of bony constriction are found in the young, such as osteopetrosis (Albers-Schönberg disease) but are of no significance as they are hereditary congenital developmental anomalies.

(2) Dilatation of the bony foramen with compression of its contents by invading neoplasms may occur most frequently from meningioma in the aged individual. Dilatation frequently occurring from astrocytoma (glioma) of the optic nerve, neurofibroma and retinoblastoma are in a younger age group and are therefore not significant.

Atherosclerotic involvement within the optic foramen and along the course of the optic nerve usually produces sector field loss which is not characteristic. Arteriosclerosis of the recurrent central vessel may produce central field loss which requires differentiation from

cerebro-macular degeneration from other causes, and from toxic and inflammatory conditions.

It is quite possible, and most probable, that mechanical pressure from these various conditions may be exerted, not only upon the optic nerves and chiasm, but also upon the vessels nourishing these axons and thus interfere with an adequate blood supply, with resultant atrophy.

Determination of the intra-ocular tension is of importance as there is a similarity between arteriosclerotic optic atrophy and glaucoma in the appearance of the atrophic and cupped papilla. In order to eliminate the possibility of intermittent periods of ocular hypertension not present at the time of examination, facility of outflow should be determined and the angle examined with the gonioscope. It does not seem reasonable to assume visual damage with optic atrophy has occurred in individuals with normal intra-ocular pressure.

Vascular occlusion of the ophthalmic artery and/or internal carotid artery from thrombosis must be considered. This condition is usually unilateral and in a younger age group than the arteriosclerotic, although atheromatous changes may induce the formation of thrombus. A relatively frequent location for thrombus is in the internal carotid artery above the bifurcation of the external carotid, up to and including, the ophthalmic artery. The symptoms vary according to age, extent of obstruction and location. If the collateral circulation through the circle of Willis and orbit is interfered with the condition is quite grave. As the internal carotid supplies the frontal, temporal and parietal lobes one may expect homonymous hemianopia or quadrantanopia. If the ophthalmic artery is obstructed complete ipsilateral blindness occurs unless there is adequate collateral circulation. In addition, hemiparesis and hemianæsthesia, headache, aphasia and other mental disturbances may be present. In this condition angiography is the most valuable aid to diagnosis. Ophthalmodynamometry may prove a significant adjunct.

Differentiation should be made from so-called temporal arteritis, a disease which should also include other arteries in various parts of the body. The ophthalmic artery and its branches are frequently affected. This condition occurs in elderly people with arteriosclerosis.

In arteritis there is cellular infiltration of the vessel walls with various stages of inflammation, frequently terminating in granulation and necrosis. Temporal and orbital swelling and tenderness are prominent features. In arteriosclerosis alone the degenerative process is less acute and the progress less rapid, without pain or fever, and with less marked symptoms of generalized vascular involvement.

Visual field loss in temporal arteritis is not characteristic. It may resemble any of the types found in arteriosclerosis. Ophthalmoscopic examination may reveal more activity in the fundus in arteritis, with hæmorrhages and exudates in addition to vascular inflammation, and sclerosis with degeneration and atrophy. Phlebitis, and venous and arterial occlusion of the retinal vessels occur with relative frequency.

Treatment

As the ætiology of atherosclerosis is not conclusively established treatment is far from satisfactory. It is believed that these atheromatous changes are the product of disturbed systemic lipid metabolism in which hypercholesterolæmia is a prominent feature.

Treatment must be directed toward prevention. Normal adjustment of blood lipids should be attempted. Control of systemic diseases such as hypertension, nephritis and diabetes is imperative. When diagnosed, anticoagulants are advocated (heparin and dicoumarol), vasodilators are used. Antibiotics may have a place if infection is suspected.

Prognosis depends, for a great part, on the adequacy of the collateral circulation to the circle of Willis and external carotid anastomoses.

Diagnosis of Arteriosclerosis

Diagnosis of arteriosclerotic optic atrophy can be supported by the following observations:

(1) The condition is found in elderly persons.

(2) Arteriosclerosis is present which may be suggested by the appearance of the retinal or choroidal vessels. Symptoms produced by arteriosclerosis elsewhere in the body may support the diagnosis.

(3) The optic papillæ are pale and cupped and may be rimmed with a shelf of atrophy.

(4) The most typical visual field losses are nasal or altitudinal from involvement in the chiasmal area. Peripheral segmental loss, rarely concentric constriction or central scotoma, may be found with involvement of the optic nerves. These field losses are not characteristic and not necessarily of diagnostic value.

(5) Intra-ocular tension is normal.

(6) Radiological studies reveal shadows in the knee of the internal carotid arteries in the sellar area. Arteriograms may reveal sclerosis of vessels supplying chiasm and optic nerves. Ophthalmodynamometry may determine reduced blood supply from vascular occlusion.

DISCUSSION ON HASHIMOTO'S DISEASE

Dr. R. W. Luxton (Crumpsall Hospital, and the Christie Hospital and Holt Radium Institute, Manchester):

The Clinical Aspect

Forty-five years ago, Hashimoto (1912) described the clinical, pathological and histological features of 4 patients with a goitre, and named the condition Struma Lymphomatosa. In his summary of their clinical aspect, he states that the patients were over 40, in good general health and showed no visceral disease. The goitre was discovered incidentally in all cases, had developed gradually and was freely movable, but was firm enough to suggest malignancy. It produced no severe pressure symptoms and there was no lymphadenopathy.

My task is to review the clinical picture of Hashimoto's disease as it is seen to-day. It has been described as rare, but it is much commoner than the general physician is apt to believe. It is worth consideration in any patient with a goitre and in any patient with hypothyroidism, and is the probable diagnosis when hypothyroidism is associated with a goitre in middle age, if goitrogens are excluded. Although most often seen in the fourth, fifth and sixth decades, cases arise from the 8th to the 80th year. Women predominate; of the 41 patients of my own series only 3 were men.

Clinically, the typical patient has hypothyroidism and a firm goitre, and is well illustrated in a woman aged 41, who had gained 3 st. in weight in three years, was constantly cold and mentally abnormal (Fig. 1). For one year she had had a goitre which was diffuse, firm and lobulated. Her serum cholesterol was 525 mg./100 ml. and her serum flocculation tests were abnormal.

The Goitre

The goitre is usually *recent*—having existed a matter of twelve months or so. Some patients have had a goitre for several years, however—in my series, for five, eight, nine, thirty and thirty-one years. The goitre is usually diffuse, and of small or medium size although it can be large. Clinically, it may seem to involve one lobe only, but histologically the whole thyroid is commonly affected. The texture of the goitre is characteristically firm and the surface smooth and lobulated. The gland is not fixed. As in Hashimoto's original cases, the goitre is often an incidental observation. Some patients have mild pressure symptoms (17 in my series)—a feeling of constriction in the neck and sometimes dysphagia. Hoarseness of the voice is not uncommon. Very occasionally there is pain and tenderness (noted in 2 of my patients).

There are two important variants of the clinical syndrome as regards the goitre: (1) it may be relatively soft, or soft with firmer areas, and (2) the goitre may be absent.

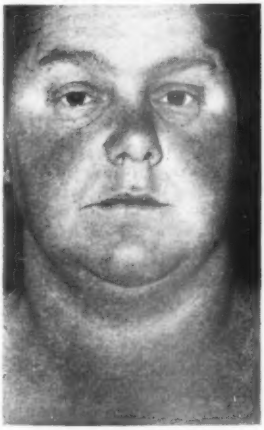

FIG. 1.

FIG. 2.

FIG. 1.—Typical Hashimoto's disease, showing myxœdema and diffuse goitre.

FIG. 2 is a photograph of a woman aged 36 who showed clinical myxœdema. She was constantly cold, with puffy face and hands, a sluggish bowel and a sluggish mind. Her serum cholesterol was 490 mg. per 100 ml. and her radio-iodine uptake was at myxœdema level. The serum flocculation tests were negative. In the absence of a goitre and with negative flocculation tests, primary myxœdema was diagnosed. However, the thyroid isthmus was palpable, not because it was enlarged but because it was firm. The serum precipitin test was strongly positive. Finally, biopsy of the thyroid gland showed histology typical of Hashimoto's disease.

After subtotal thyroidectomy, it is unusual for a goitre to reappear, but this happened in one of my patients two years after operation. When a hemithyroidectomy is done, the remaining lobe not uncommonly enlarges and may cause pressure symptoms, as in 2 of my patients. In one such case, the goitre recurred seven years after operation. Recurrence of goitre may follow cessation of treatment with dried thyroid gland. The regional lymph nodes are not often enlarged *clinically*.

Hypothyroidism

Gross symptoms of myxœdema may be present when the patient first attends, but often the patient's only complaints are the minor symptoms of hypothyroidism—gaining weight, feeling cold and general slowing down of physical and mental processes. "Rheumatic" pains are common in muscles and joints. I am impressed with the frequency not only of osteoarthritis but also of rheumatoid arthritis in this disease. Mental changes were present in 5 of my patients. Great apprehensiveness is a feature and leads to a refusal of investigation or photography until after they have regained their morale and good looks by treatment with dried thyroid gland.

Hashimoto made no reference to hypothyroidism in his patients until after operation. Although the natural course of the disease leads to hypothyroidism, a small proportion of patients have hyperthyroid signs and symptoms at the onset, and a larger proportion are euthyroid when first seen. Of 16 pre-operative patients 9 were hypothyroid, 5 euthyroid and 2 hyperthyroid. It would appear that although many thyroid follicles may be damaged, the remainder can compensate for long periods.

Hyperthyroidism

Hyperthyroidism is well recognized as an early phase. Typical symptoms and signs, including eye signs, have been described, and the B.M.R. recorded up to +69%.

FIG. 3.

FIG. 3, taken in 1951, shows a woman then aged 42. As hyperthyroid symptoms she had lost 1 st. in weight in four months and showed sweating, tremor and upper lid lag. The B.M.R. was +38%. She had noticed a goitre for one month, it was diffuse and moderately firm. The spleen was palpable. Serum flocculation tests were abnormal. A diagnosis of Graves' disease was made and methyl thiouracil given in average dosage for four months, when she showed hypothyroidism and a larger and harder goitre. A thyroid biopsy showed advanced Hashimoto's disease. Despite the hyperthyroid onset, after five years' treatment with thyroid grains 3 daily, this patient is now euthyroid and the goitre has disappeared.

Euthyroidism is commoner than hyperthyroidism when the patient is first seen.

A woman aged 36 was admitted to hospital for abdominal pain which led to a laparotomy. A goitre was an incidental observation. The serum flocculation tests were abnormal. She was clinically euthyroid and the serum cholesterol was 188 mg. per 100 ml. Histologically, the thyroid showed Hashimoto's disease.

Visceral Involvement

Hashimoto recorded that his cases showed no visceral involvement. I believe that visceral disturbance may arise in this disease.

Liver.—In 1947 a woman with myxœdema showed a diffuse goitre and hepatomegaly. The spleen was not then palpable. Two years later, after radiotherapy to the goitre, and thyroid grains 2 daily, she was euthyroid and without a goitre. Later, the spleen became palpable. In 1955 laparotomy revealed a grossly cirrhotic liver and splenomegaly but the portal venous pressure was normal. To-day this patient is jaundiced, hypercholesterolæmic, with liver palms, spider nævi and ascites. The hepatic histology was very unusual (Dr. James Davson): "The picture was that of rather advanced diffuse hepatic cirrhosis.

Normal lobules were barely recognizable. The liver cells formed compact nodules of different sizes, apparently due to regeneration hyperplasia. The nodules were separated by bands of cellular vascular connective tissue, often wide, the infiltrating cells being mainly plasma cells and lymphocytes. An unusual feature was the absence of proliferating bile-ducts. The histogenesis of this cirrhosis was not clear. Cholangio-hepatitis and cirrhosis developing in a fatty liver were unlikely causes. Post-hepatitis cirrhosis was a possibility. There was no evidence of sarcoidosis, brucellosis, or hæmochromatosis."

It is worthy of note that plasma cells, connective tissue, lymphocytes and aggregates of lymphocytes are present—reminiscent of the histological changes in the thyroid gland in Hashimoto's disease. I am tempted to describe it as "Hashimotosis of the liver"! Of course, one cirrhosis does not establish a complication any more than one swallow establishes a summer, but each makes one look for others.

In 1952, the above case, and others with palpable spleens, led to a study of liver function tests in Hashimoto's disease, especially of plasma proteins by qualitative methods. At about the same time, Dr. R. T. Cooke, Pathologist at West Hartlepool, also observed, independently, that the serum flocculation tests may be abnormal in Hashimoto's disease. The figures I shall quote are from my own patients, but the general conclusions about the tests were reached jointly with Dr. Cooke, when he and I made an analysis of our combined cases (Luxton and Cooke, 1956).

Table I shows results of serum flocculation tests in 39 cases of Hashimoto's disease in relation to treatment. The diagnosis was confirmed histologically in 34 cases. Previous treatment by surgery, X-radiation or dried thyroid affects the results of the tests:

TABLE I.—SERUM FLOCCULATION TESTS IN 39 CASES

Untreated	16
Tests abnormal	14
Surgery ± X-radiation	5
Tests abnormal	3
Surgery ± X-radiation and thyroid	18
Tests abnormal	1

Dr. Cooke and I concluded:

(1) In untreated patients, the serum flocculation tests are positive sufficiently often to make them of diagnostic value.

(2) In the *typical* case, the best treatment is thyroid by mouth, as indicated by Crile (1954). Thus treated, hypothyroidism disappears, the goitre lessens considerably in size, and plasma proteins and flocculation tests return to normal. Many months—up to two and a half years—may elapse before the reversion occurs.

(3) The colloidal gold test is a little more sensitive than the thymol turbidity, but not always, and both tests are necessary.

Spleen.—The spleen was persistently palpable in 6 of my first 24 patients, but in only 1 of the next 17 patients.

Kidney.—In myxœdema, a moderate trace of albuminuria, peripheral pitting œdema and hypertension occur quite commonly as separate manifestations, without implying renal disease. On that account, when these 3 clinical findings *coincide* in an individual with hypothyroidism, the diagnosis of underlying chronic renal disease may be rejected prematurely.

Repeated examination for albuminuria was made in 37 patients with Hashimoto's disease. 15 showed an occasional trace of protein; 6 further cases showed persistent albuminuria. 4 of the 37 patients had evidence of a nephropathy. I present these cases with some reserve as I could not investigate them fully but hope to have opportunity for further study.

In 2 cases a nephrotic syndrome occurred and some details thereof are given in Table II.

TABLE II

Pitting œdema	Urine albumin (grams/litre)	Total serum protein (grams/100 ml.)	Serum cholesterol (mg./100 ml.)	Blood pressure	Comment
++	3	5	776	130/80	Casts +
++	12	4·3	880	150/85 rising in ten months to 240/115	Urea clearance 15%

Features common to the two patients are—both were aged 54 years, both had changes of rheumatoid arthritis in the hands, both were hypothyroid and in neither case did the renal symptoms improve when dried thyroid was given, the serum protein showed decreased albumin and increased α_2-globulin. Amyloid disease is a possibility but further evidence is needed.

Two other patients with nephropathy had persistent albuminuria and hypertension bu. no œdema or increase in blood urea (Table III).

TABLE III

Age	Albuminuria	Blood pressure	Comment
58	Persistent	190/110	I.V.P. normal
65	Persistent	225/125	Euthyroid

So far as I can discover, nephropathy in Hashimoto's disease is hitherto not recorded.

Association of Hashimoto's Disease with Paget's Disease of Bone

The patient previously described with hyperthyroidism and Hashimoto's disease developed pain in the back in 1952 and routine X-ray of the pelvis revealed Paget's disease in the left ilium and ischium, naturally regarded as incidental. Three years later two clinical cases of Paget's disease combined with Hashimoto's disease were seen:

FIG. 4.

E. H., female, aged 42. Goitre for three months (Fig. 4). Clinically euthyroid. Serum flocculation tests positive. Right tibia, bowed, thickened, warm (Fig. 5). Radiology of tibia: characteristic of Paget's disease. Surgical biopsy of thyroid: definite but early Hashimoto's disease.

FIG. 5.

A. Y., female, aged 48. Goitre for three months. Clinically hypothyroid. B.M.R. −15%. Serum flocculation tests positive. Surgical biopsy of goitre: struma lymphomatosa. Left tibia was thickened, bowed, tender. Changes, clinical and radiological, were present in a metacarpal. X-ray appearances had suggested polyostotic fibrous dysplasia in left tibia, one metacarpal and right great trochanter. A bone biopsy of left tibia showed cement lines and mosaic pattern typical of Paget's disease.

During 1956 a limited radiological bone survey was made in 35 patients with Hashimoto's disease by my colleagues Dr. J. Blair Hartley, Dr. J. B. Fawcitt and Dr. J. Cowen. In all, 7 of the 35 patients showed radiological bone changes of Paget's disease. Statistical analysis shows that the prevalence rate of Paget's disease in this series of patients with struma lymphomatosa is highly significant (Luxton, 1957). If confirmed, it may offer a clue to the pathogenesis of Paget's disease of bone.

Dr. Deborah Doniach, Mr. R. Vaughan Hudson and Dr. I. M. Roitt (Middlesex Hospital and Courtauld Institute of Biochemistry):

Diagnostic Aspects of Lymphadenoid Goitre

In classical cases of Hashimoto's disease which present with advanced myxœdema and a large, firm, symmetrical goitre, a presumptive diagnosis can be made on the clinical findings. In practice such cases must be rare since it is estimated in the literature that only 20% of lymphadenoid goitres are diagnosed correctly before operation. The demonstration of the auto-immune process has brought together a group of thyroid conditions which were formerly kept distinct on histological grounds, such as lymphocytic thyroiditis and the various subgroups of chronic non-specific thyroiditis. A great many of these cases

are difficult to differentiate from other non-toxic goitres. More important still, when a Hashimoto goitre is very firm it may be almost impossible to distinguish it from carcinoma of the thyroid by the physical signs.

However, with the laboratory methods available to us, it should be possible to make a correct diagnosis in the majority of these patients without resorting to surgery.

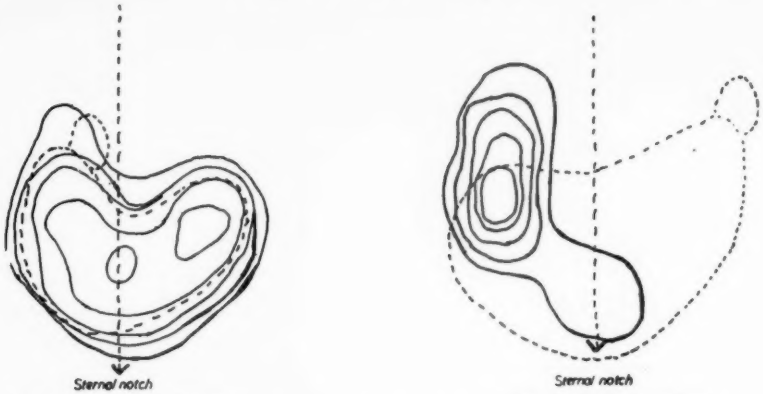
As repeatedly pointed out by Crile and his collaborators in recent years and as shown by Dr. Luxton's present results which we can fully support from our own experience, these goitres regress to almost normal size on administration of thyroid hormones. We find that pressure symptoms usually disappear within two months on this treatment, so that it is of great advantage to the patient not to have her thyroid removed.

The diagnostic value of the older thyroid function tests will be briefly discussed but stress will be laid on the laboratory methods arising from recent work, which include the electrophoretic separation of serum proteins, the flocculation reactions and the thyroglobulin precipitin test.

Radioiodine and B.M.R. Results

As may be expected in view of the gradual lymphoid invasion and slowly progressive destruction of the thyroid follicles by the auto-immune process, the B.M.R. and twenty-four-hour uptake of I^{131} vary according to the amount of functioning tissue left and its response to compensatory T.S.H. stimulation. In early cases both are within normal limits unless the patient has an underlying thyrotoxicosis. When the degree of thyroid destruction is such that the production of thyroid hormones decreases below normal, the output of T.S.H. is presumably increased and at that stage it is common to find an iodine uptake which is well above the normal, while the B.M.R. is still normal. Later, the gland is unable to make sufficient thyroid hormone in spite of the T.S.H. overstimulation and the B.M.R. decreases below normal, though the iodine uptake may remain high until the basal metabolism has reached myxœdematous levels. Finally, so little functioning thyroid remains that even the iodine uptake is gradually reduced below normal. Thus in patients with lymphadenoid goitre one frequently finds a marked discrepancy between the iodine uptake and the B.M.R. and the combination of these tests is more useful than each separately. The only other untreated thyroid condition in which one sees high iodine uptakes with low B.M.R.s is familial goitrous cretinism, where a congenital absence of certain thyroid enzymes leads to insufficient thyroid hormone production.

Some other parameters of iodine metabolism give results which are in keeping with the small thyroidal iodine pool to be expected in view of the extensive lymphoid replacement in the Hashimoto thyroid: the forty-eight-hour plasma radioactivity is relatively high and can be in the thyrotoxic range even in the presence of clinical myxœdema, and the biological half-life is short.



The iodine uptake cannot be increased by injections of T.S.H. since the gland is already under full stimulation, and potassium perchlorate produces a discharge of iodine in these goitres (Morgans and Trotter, 1957), owing to an interference with organic binding of which the mechanism is not yet elucidated.

From the point of view of differentiating Hashimoto's disease from carcinoma of the thyroid, however, by far the most useful test is the topographic survey of iodine distribution over the goitre area (Fig. 1), since, owing to the diffuse nature of the Hashimoto lesion, the isocount picture usually follows the outline of the palpable swelling, with more uptake on the larger side, whereas in carcinoma of the thyroid the uptake is nearly always one-sided and is absent or much diminished over the tumour.

Biochemical and Immunological Tests

The majority of untreated Hashimoto patients have abnormally high gamma globulins and as a consequence show raised values in the thymol and zinc sulphate turbidities and the colloidal gold flocculation. These serum protein changes have already been described in detail by other authors and ourselves and we propose to confine the present discussion to the correlation between the results of these tests and the demonstration of the thyroglobulin antibodies.

The details of the precipitin technique for thyroid antibodies are described elsewhere (Doniach and Roitt, 1957) and a diagram of the test is given on page 959 of the present issue (Fig. 1B, Section of Experimental Medicine). In strong sera the precipitin line becomes visible in about sixteen hours, is often double, and thickens within the next week, as increasing amounts of antibody and antigen meet and combine to form visible aggregates. When the test is done on serial dilutions of serum, the precipitin line is most compact at the equivalence zone of the system (*see* page 959, Fig. 1A, tubes 3 and 4), becoming less dense and wider in increasing dilutions, with a movement of the leading edge of the precipitate towards the serum layer. Positive precipitins were seen in up to 1/128 dilution of the serum in Hashimoto patients.

A.—J. R., female, aged 52. B.—W. V., female, aged 59.

FIG. 1.—Isocount pictures of radioiodine distribution (solid lines) to illustrate the diagnostic value of topographical surveys in differentiating between lymphadenoid goitre and carcinoma of the thyroid. Dotted lines represent extent of palpable swelling. *Case J. R.* (A), *Hashimoto's disease:* One year goitre, lassitude and lack of interest. I^{131} uptake 37%/24 hr. with symmetrical distribution. B.M.R. = +1%, E.S.R. = 23 mm. (Wintrobe), gamma globulins 2 g.% (29·7% of total), flocculation values raised. Thyroglobulin precipitin test positive, showing double line. *Case W. V.* (B), *Carcinoma of thyroid:* Two months' painful neck swelling. Large, firm, apparently diffuse goitre. I^{131} uptake 17%/24 hr., limited to right upper pole of thyroid. B.M.R. = −26%, serum cholesterol 390 mg.%, E.S.R. = 37 mm. (Wintrobe), gamma globulins 1·3 g.%, flocculation values normal.

In occasional sera the precipitate appears much more slowly, taking ten to twelve days to become visible, with a single precipitin line which is hazy and wide, and whose upper and lower edges are both fluffy. This appearance is probably not due to low antibody content, for these sera can have high gamma globulin and flocculation values, and look quite different from high dilutions of a normally precipitating serum, where the line becomes visible in two to four days and has an abrupt lower edge, however weak the antibody.

Fig. 2 shows the distribution of serum flocculation values in Hashimoto patients and

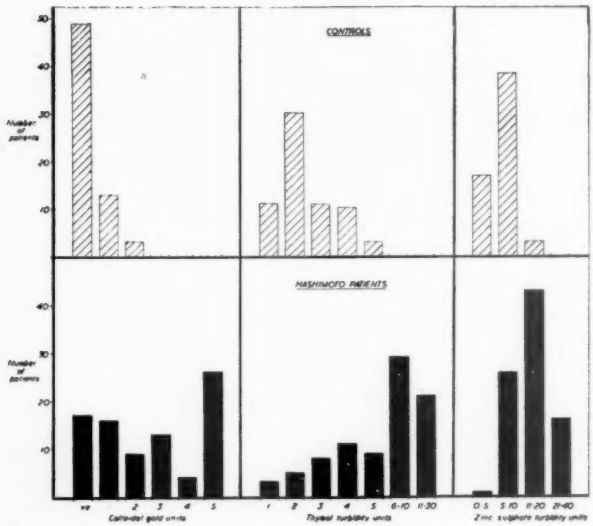


FIG. 2.—Distribution of serum protein flocculation values in Hashimoto patients treated with thyroid or untreated, and a series of controls consisting of non - toxic nodular goitres and thyrotoxics. The majority of untreated Hashimoto patients had raised flocculations. Those showing normal values were mostly treated for some years with thyroid extract. Thyroglobulin precipitins were demonstrable even after prolonged therapy.

controls. All these sera were also tested for thyroglobulin precipitins. The controls were cases of non-toxic nodular goitre and thyrotoxicosis most of whom were subsequently

verified histologically. In the Hashimoto series we included patients operated on up to three weeks before the tests since we found a lag of several months in the return of the tests to normal; patients thyroidectomized months or years previously were not included. We did not estimate the gamma globulins quantitatively in all these patients since the flocculation tests appeared to provide a more sensitive measure of the serum protein changes than the rather crude method of scanning electrophoretic strips or eluting the dye from them. The Hashimoto cases who had normal flocculation tests were mostly patients with small goitres or those treated for some years with thyroid extract and the latter generally had quite strong precipitins.

Table I shows the correlation of the serum flocculation tests with the thyroglobulin

TABLE I.—CORRELATION OF SERUM PROTEIN FLOCCULATION* TESTS AND THYROGLOBULIN PRECIPITINS IN HASHIMOTO PATIENTS

	No. of patients	+Pptins +Floccs	+Pptins −Floccs	−Pptins +Floccs	−Pptins −Floccs

Treated with thyroid hormones ..	37	14	15	5	3

*Flocculation tests included thymol and zinc sulphate turbidities and colloidal gold flocculation.

precipitins. It can be seen that with the precipitin test alone, we can expect to miss about a quarter of the cases though it is on the whole more sensitive and certainly more specific than the flocculation tests. Fortunately, in many patients with negative precipitins the flocculation tests are positive and should therefore be done in every suspected lymphadenoid goitre. Some of the patients who gave negative results by both tests were early cases diagnosed only by histology. Most of them gave positive complement-fixation tests against thyrotoxic thyroid extracts as did the patients with negative precipitins and raised flocculation values.

Our finding of thyroglobulin precipitins in 4 cases of subacute thyroiditis (*see* Table II, page 960) was not altogether unexpected since thyroglobulin is known to be released from follicles damaged by the underlying virus infection in this condition (Eylan *et al.*, 1957). 2 of the cases had recovered from the acute attack and had become myxœdematous, one with persistence of the goitre, the other without thyroid enlargement. The other 2 patients were interesting in that the precipitin could be demonstrated three and five weeks after the onset of the disease. One patient has been followed up for nine months. Her precipitin titre gradually rose from 1/2 to 1/16 at five months, then slowly decreased, reaching 1/4 nine months after the acute attack. The flocculation tests were normal at first, rose to fairly high values with the rise in antibody titre, then returned to normal as these decreased again. The patient has so far remained euthyroid without substitution therapy.

The differential diagnosis between subacute thyroiditis and Hashimoto's disease can be difficult on clinical grounds since quite a few Hashimoto patients have painful goitres, and some cases of subacute thyroiditis are first seen when their acute symptoms are subsiding. Since in both conditions a high E.S.R. and evidence of thyroid auto-immunization can occur, the clinical diagnosis must be reinforced by the results of B.M.R. and iodine tests, by adequate follow up and the effect of treatment. In subacute thyroiditis the B.M.R. is often slightly raised in the presence of a complete suppression of iodine uptake by the gland, and these tests can be particularly helpful if they can be shown to return to normal as the acute stage subsides. In Hashimoto's disease the B.M.R. is more likely to be low from the start and the iodine uptake normal or high. The precipitin titre is likely to be higher in the established auto-immunization of lymphadenoid goitre, where in subacute thyroiditis it appears to be low at first, and may rise on repeated testing.

In carcinoma of the thyroid the gamma globulins are normal and the precipitin test has been negative in the few cases we have tested so far. Nodular colloid goitre is also associated with normal results on these tests unless the auto-immunization process has been grafted on a pre-existing simple goitre; in fact we have seen several patients with a history of goitre since puberty, who in middle life developed pressure symptoms fairly rapidly with a change in the size and consistency of the goitre. At operation they proved to have extensive lymphadenoid changes superimposed on colloid goitre. Two such patients had a high titre of thyroglobulin precipitins in their serum and raised flocculation values.

Dr. A. D. Thomson (Bland-Sutton Institute of Pathology, Middlesex Hospital):

The Pathology of Hashimoto's Disease

Since the publication by Mr. Vaughan Hudson and his colleagues of the possible role of auto-sensitivity in the pathogenesis of Hashimoto's disease and the introduction of the "precipitin test" (Roitt *et al.*, 1956) as an aid to the clinical diagnosis of the disease I have had the opportunity of examining many of the thyroid glands with positive "precipitin tests". The histological features I am about to describe are based mainly on the study of this recent thyroidectomy material from the Middlesex Hospital.

Naked-eye appearances.—The enlarged thyroid gland in a typical case of Hashimoto's disease shows a smooth lobulated capsular surface which on cross section shows a replacement of the normal glistening appearance by firm homogeneous white or pink tissue traversed by fibrous trabeculæ (Fig. 1).

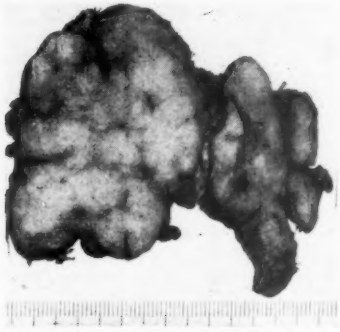

FIG. 1.—Showing the enlarged thyrcid gland in Hashimoto's disease.

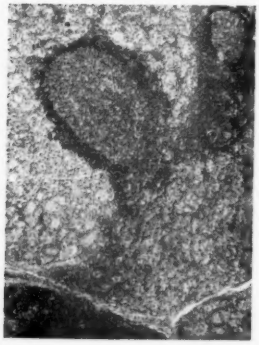

FIG. 2.—Showing the focal lymphoid tissue and the diffuse cellular infiltration between the thyroid epithelium. Colloid material is still present. Thyroid removed in 1943. × 20.

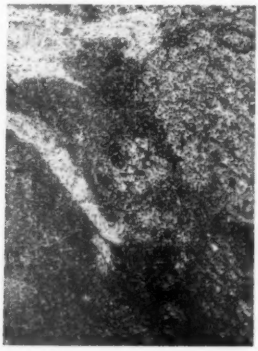

FIG. 3.—Showing a diffuse cellular infiltration between the residual thyroid epithelium. Note the absence of colloid material and the increased fibrosis. Thyroid remnant removed in 1950 from same patient as Fig. 2. × 25.

Microscopical appearances.—Histologically the features in the well-developed case are characteristic. There is a conspicuous lymphoid infiltration with prominent follicle formation (Fig. 2). The thyroid epithelial cells are abnormal in their arrangement, their cytoplasm is increased in amount and stains intensely with eosin while colloid production is impaired resulting in disorganization of the normal thyroid gland structure (Figs. 2 and 6). These epithelial changes are degenerative in nature. In addition to the lymphoid tissue with a focal distribution there is a diffuse cellular infiltration composed of lymphoctyes

FIG. 4.—Showing a colloid goitre with the cellular changes of Hashimoto's disease. × 30.

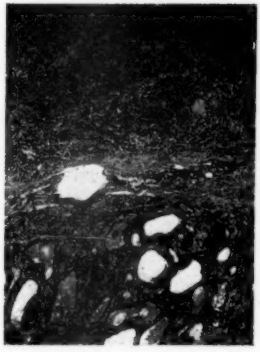

FIG. 5.—Showing a toxic goitre with the cellular changes of Hashimoto's disease. × 35.

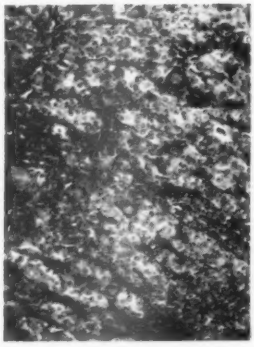

FIG. 6.—Showing the epithelial changes of Hashimoto's disease with a lymphocytic and plasma cell infiltration and many giant cells. × 75.

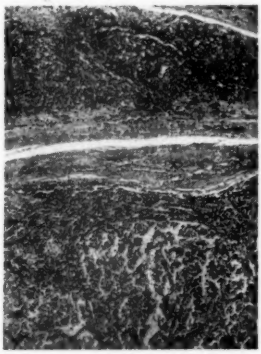

FIG. 7.—Showing Hashimoto's disease in the thyroid gland adjacent to a carcinoma. × 30.

and plasma cells which permeate between the residual thyroid epithelium. In areas this infiltrate becomes confluent and the plasma cells may exceed the lymphocytes in number. In some parts of the thyroid there is a virtual disappearance of the epithelium and the tissue is then composed of lymphocytes and plasma cells buried in fibrous tissue of varying collagenization and vascularity. As the disease progresses the cellular infiltrate and the fibroblastic tissue increase at the expense of the epithelial elements but the pathology in all cases remains confined within the capsule of the thyroid gland.

The changes I have described are found in fully developed examples of Hashimoto's disease and in these cases the "precipitin test" is positive in a high proportion of patients. A positive "precipitin test" may, however, be obtained with thyroid glands showing other histological features in addition to those already described.

(1) *Hashimoto's disease with colloid goitre.*—Some patients with a history of a goitre extending over many years develop myxœdema and the "precipitin test" proves positive. The subsequent histological examination of the thyroidectomy specimen reveals the characteristic features of a simple colloid goitre with the superimposed changes of Hashimoto's disease (Fig. 4). It appears that the long-standing clinical manifestation of an enlarged thyroid is due to the colloid goitre and the Hashimoto's disease is merely superimposed on this original pathology.

(2) *Hashimoto's disease with toxic goitre.*—A few patients have shown the classical signs

and symptoms of thyrotoxicosis with a termination in myxœdema. In these cases a thyroidectomy performed soon after this transition reveals the histological changes of Hashimoto's disease superimposed on the cellular picture of a toxic goitre (Fig. 5). Some examples with this type of pathology have a positive "precipitin test".

(3) *Giant cell thyroiditis.*—Two patients with a rapid onset of a painful goitre were diagnosed clinically as subacute thyroiditis and histological examination of the thyroidectomy specimen shows the histological changes of Hashimoto's disease with many giant cells (Fig. 6) simulating the appearance of a giant cell thyroiditis. These two examples had positive "precipitin tests".

(4) *Hashimoto's disease with thyroid carcinoma.*—An incidental finding at a recent autopsy revealed a swelling in the neck which on histological examination proved to be a papillary carcinoma with the changes of Hashimoto's disease in the adjacent thyroid gland (Fig. 7).

From this account it will be seen that the histological features of Hashimoto's disease may be superimposed on a previously normal thyroid gland, a colloid or a toxic goitre, or in the tissues adjacent to a thyroid carcinoma. In addition, when the thyroid enlargement is of more rapid onset the histology may show the lymphoid infiltration and the epithelial changes of Hashimoto's disease but containing many giant cells as described in giant cell thyroiditis.

It has been found that with a positive "precipitin test" the essential minimal histological changes are:

(*a*) Infiltration by lymphoid tissue.

(*b*) Diffuse infiltration by lymphocytes and plasma cells.

(*c*) Eosinophilic degenerative changes in the epithelium.

The subsequent progression of the pathology produces the further histological features of the fully established Hashimoto's disease. This progressive nature of the disease process can be studied when serial surgical material from the same patient is available. Fig. 2 shows the appearance of a thyroid gland partially removed in 1943 which on microscopy reveals the lymphoid infiltration and the eosinophilic degeneration of the thyroid epithelium but there is no increased fibrosis and colloid material is still visible in the thyroid vesicles. The thyroid remnant slowly enlarged during the next few years and further surgery was performed in 1950. Fig. 3 shows progression of the disease in the same patient with disappearance of the colloid, disruption and disorganization of the thyroid structure with a profuse lymphoid, lymphocytic and plasma cell infiltration of the gland with increased fibrosis.

Histologically therefore the changes in Hashimoto's disease are those of a progressive pathological process whereby an increasing amount of thyroid tissue becomes disorganized and eventually destroyed and this change may occur in a previously normal or in a previously pathological thyroid gland. The precise causation of this destructive process remains debatable but the recent demonstration by White (1957), using Coons' technique, of an antigen-antibody reaction within the thyroid gland lends support to the view of Roitt *et al.* that auto-sensitization plays a part in the pathogenesis of Hashimoto's disease.

DISCUSSION ON AUTO-IMMUNITY AND THYROIDITIS

Dr. R. G. White (London Hospital):

An Immunological Investigation of Hashimoto's Disease

The demonstration by Roitt *et al.* (1956) that a precipitin reaction was given between sera of patients with Hashimoto's disease and a saline extract of normal thyroid, or a purified thyroglobulin, has given us the chance to investigate a new auto-immunization process, with the possible advantage of a defined antigen, thyroglobulin.

We of course wish to know whether the serum constituent which precipitates is really antibody, whether thyroglobulin is the antigen relevant to the process in the diseased gland, whether other antigens besides thyroglobulin are involved and so on. These are some of the questions that I have investigated at the London Hospital with the help of Professor C. F. Barwell, Dr. W. F. T. Gammie and Dr. C. R. Robinson.

The curve of inter-reaction between purified thyroglobulin, prepared for me by Dr. Ingbar by the method of Derrien *et al.* (1948) and the serum of a patient with Hashimoto's disease resembles the classical precipitin curve. When increasing amounts of antigen reacted with a constant volume of serum the amount of precipitate rose to a maximum and then fell. A test of the supernatant at optimal proportions showed an absence of both antigen and antibody. At this point subtraction of the weight of added antigen should yield the weight of antibody in the precipitate. This was 5·0 mg. per ml. of serum (neglecting the weight of complement)—an impressively high value. In other patients the curve of precipitation was more complex, with the formation of two precipitating zones, indicating the existence of at least two antibodies in the sera of patients with Hashimoto's disease.

The complement-fixation test using a saline extract of thyroid as antigen showed that complement was fixed by heat-inactivated sera of the patients with Hashimoto's disease. In general the results correlated well with the precipitin test. However, more patients (12) showed fixation than gave a precipitin test using an agar diffusion technique (8). All except 2 of those giving a positive precipitin result gave a positive complement fixation result. The situation is complicated by the existence of two zones in a titration of antigen (purified thyroglobulin) using complement fixation, and the correlation between the two serological tests requires further experience.

We have now explored the distribution of the antigenic substances in thyroid tissue relevant to the precipitin in the sera of Hashimoto patients by the fluorescent antibody technique for the localization of antigens in frozen tissue sections. Our chemical manœuvres to introduce fluorescein into the antibody of a globulin fraction of serum from a patient with Hashimoto's disease will, of course, result in the similar conjugation of fluorescein with other serum proteins. Such a fluorescein-conjugated globulin applied to a section of normal thyroid may localize to iso-antigens as well as the relevant auto-antigen. However the results were sufficiently constant with thyroid glands from a variety of sources to belittle this doubt.

Fig. 1 shows the distribution of fluorescein (bright areas) indicating the localization of the antigenic substance in a thyroidectomy thyroid (toxic goitre). The antigen which has localized the Hashimoto antibody is present within the follicles. Some variation exists between different follicles in the intensity of the fluorescence of their contents and some are void. Some antigen is also present as round globules within follicular epithelial cells.

We can get over the difficulty of iso-antigens by using our fluorescein conjugate on the thyroid sections of the same patient. Fig. 2 shows the result of such a procedure.

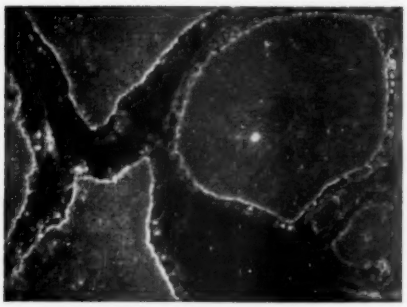

FIG. 1.—Fluorescence micrograph. Frozen section of a thyroidectomy thyroid (toxic goitre) treated with a fluorescein conjugate of the serum globulin of a patient with Hashimoto's disease. The fluorescence is localized to intra-follicular colloid and to discrete areas within the cells of the follicular epithelium. × 128.

FIG. 2.—Fluorescence micrograph. Frozen section of thyroid of a patient with Hashimoto's disease treated with a fluorescein conjugate of the patient's own serum globulin. Two follicles are lined by faintly fluorescent epithelial cells. Outside the follicles bright irregular fluorescent areas are scattered among the cells of the granulomatous infiltration, some of which show intracytoplasmic fluorescent areas. × 512.

The antigen is present within the follicles which are much reduced in size. The antigen is also present in the cells of the follicular epithelium, but there is also antigen outside these, in and among the cells of the granulomatous infiltration.

These appearances suggest that in Hashimoto's disease the antigen of the thyroid colloid freely passes from within the follicles, out, and into contact with the cells of the granuloma. It is easy, here at least, to see why antibody production should result. It does not follow that we have here the mechanism which initiates antibody production, This may well be different, but once an immune response against some element of thyroid tissue has been produced, damage to the cells may follow and this picture of escape of antigen may result. In other words, we may be witnessing how the vicious circle is kept up but not how it is initiated.

Finally, what is the source of the antibody? The histological appearances—the infiltration with plasma cells and the development of lymphoid nodules with germinal centres suggest that an antibody-producing cellular response is present in the thyroid gland itself. Another possible source of antibody is the cervical glands. In the surgical specimens from cases of Hashimoto's disease which I have examined, up to 6 lymph nodes were found closely applied to the specimens, being dissected out with them. These have been examined with a modification of the fluorescent antibody technique in order to reveal the presence of antibody (Coons *et al.*, 1955). Frozen sections treated in this way and with the necessary controls to distinguish antigen from antibody showed the peripheral lymph sinuses of the node crowded with large reticulo-endothelial cells with cytoplasmic spherical granules of antibody. The simplest explanation of this extraordinary finding is that thyroid antigen reaches the node via lymphatics and in the presence of the antibody of the lymph forms precipitates which are taken up by the sinus lining phagocytes. Also, in the medullary cords of the node were colonies of plasma cells and their precursors. Within and surrounding these was fluorescence indicating antibody.

These illustrations suggest that in Hashimoto's disease a circle of increasing immune cellular response and damage to follicular tissue is receiving prolonged stimulation from antigen continuously produced in the thyroid follicles, and we see the disease when the process is so far advanced that little follicular tissue is left and the patient is myxœdematous. Earlier stages of this process must exist, lacking circulating antibody with thyroids which still consist mainly of follicular tissue. In point of fact we have seen thyroids, which the pathology department had no hesitation in classifying as diffuse toxic goitre, in which there were small areas of lymphoid tissue and antigen in and among these cells. The sera of some of these cases had a low titre of antibody.

Professor Ernest Witebsky (University of Buffalo School of Medicine):

Experimental Evidence for the Role of Auto-Immunization in Chronic Thyroiditis

Ehrlich and Morgenroth (1900) observed the occurrence of immune iso-antibodies against red blood cells of different individual goats. By injecting goat A with blood cells of goat B, iso-agglutinins appeared which were capable of acting upon the red blood cells of goat B and some other goats without acting upon the cells of the antibody-producing goat A. Injecting a goat with its own red blood cells never resulted in the production of auto-agglutinins. On the basis of these experimental observations, Ehrlich formulated his law of *horror autotoxicus*, implying that auto-antibodies are incompatible with normal life. This law seems to be as valid to-day as it was a half-century ago, in spite of certain important exceptions.

The unique properties of thyroglobulin as an organ-specific antigen were first recognized about thirty years ago by Hektoen and his co-workers (1927). Being engaged in the study of organ specificity of brain and lens tissue, the speaker then became immediately interested in the antigenic behaviour of thyroglobulin (Witebsky, 1929). Thyroglobulin was obtained by 50% ammonium sulphate precipitation from crude thyroid extracts of several species. Thyroglobulin antisera produced by intravenous injection reacted with the thyroglobulin used for immunization, but failed to give complement fixation with the crude thyroid extract from which the thyroglobulin was isolated. It was therefore felt that during the process of isolation this protein had become denatured. This problem has intrigued the speaker ever since, and about six years ago, collaborating with Dr. Noel R. Rose and Dr. Sidney Shulman, a practically undenatured thyroglobulin was prepared (Witebsky *et al.*, 1955; Rose and Witebsky, 1955; Shulman, 1956). This was accomplished by carefully controlling the pH, working in the cold, and using several other precautions. Antisera obtained against this purified preparation of thyroglobulin reacted quantitatively with the crude thyroid extract from which it was isolated. Conversely, antiserum obtained against crude thyroid extract reacted equally well with its isolated thyroglobulin fraction.

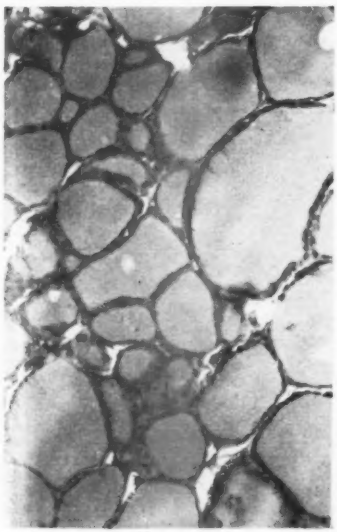

FIG. 1.

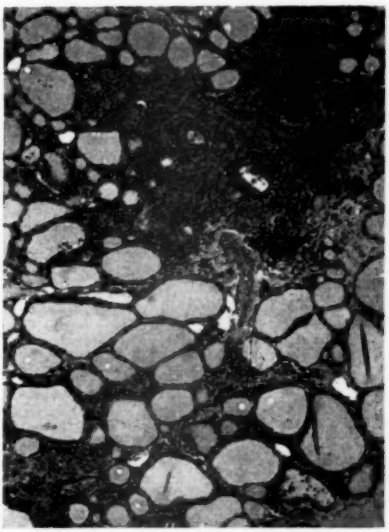

FIG. 2.

FIG. 1.—Thyroid gland of normal rabbit fixed in buffered formalin and stained with hæmatoxylin and eosin (× 95).

FIG. 2.—Rabbit 294: Injected with pooled rabbit thyroid extract (with Freund adjuvants) intraperitoneally on December 28, 1954, and February 22, 1955. Thyroids removed April 11, 1955. The photograph shows one of the numerous areas densely infiltrated by lymphocytes and eosinophils. The follicles in these areas are compressed and contain little colloid. The original follicular pattern is seen along the borders of the infiltration, although even there some cellular desquamation and exudation into the colloid can be seen.

We subsequently used crude thyroid extracts and isolated thyroglobulin almost interchangeably in all our experiments.

Crude thyroid extracts, initially containing as much as 60%–80% thyroglobulin, seemed to present a good instrument to challenge the validity of the *horror autotoxicus* law. These experiments were carried out in the belief that we could substantiate rather than disprove it. The experimental results of this undertaking, however, proved surprisingly different. About one-third of the rabbits injected intradermally with pooled rabbit thyroid extracts incorporated in Freund adjuvants produced circulating antibodies demonstrable by complement fixation and precipitation (Witebsky and Rose, 1956; Witebsky *et al.*, 1956). The percentage of rabbits with detectable circulating thyroid antibodies in their blood stream could be increased considerably by using the tanned cell hæmagglutination test introduced by Boyden (1951). Tanned rabbit cells or human cells of Group O when coated with rabbit thyroid extract were agglutinated by the serum of immunized rabbits sometimes in dilutions as high as several thousand. The tissue specificity of these antibodies was proven by testing various rabbit organ extracts by complement fixation. Only the thyroid extracts, and not the extracts of other organs, gave positive reactions. To exclude further the possible interference of iso-antibodies, rabbits were thyroidectomized and injected with extracts of their own thyroid gland. Again, even under these conditions thyroid antibodies appeared, strongly suggesting that one was dealing with a true auto-antibody, and not an iso-antibody.

It took us some time, as a matter of fact several months, before we became curious enough to find out what happened to the thyroid glands of normal non-thyroidectomized rabbits which had developed circulating thyroid antibodies following injection of pooled rabbit thyroid extract (Rose and Witebsky, 1956). Fig. 2 shows typical changes observed in the architectural structure of the thyroid glands in one of these animals, as compared with a section of a normal rabbit thyroid gland (Fig. 1). These histological alterations, which were sometimes even more extensive than the illustration shows, furnished further evidence for the auto-antibody nature of the antibodies produced. We are forced therefore to conclude that certain constituents of the thyroid gland, presumably

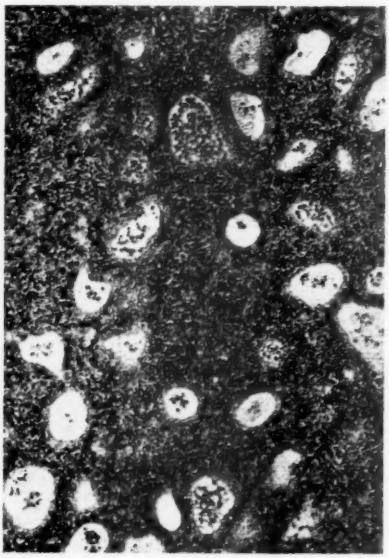

FIG. 3.

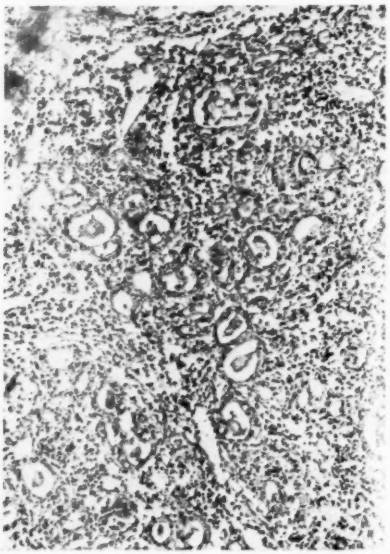

FIG. 4.

FIG. 3.—Dog 1196: Injected with pooled dog thyroid extract (with Freund adjuvants) on September 20, 1954, December 24, 1954, and January 28, 1955. Thyroid removed May 23, 1955. The photograph shows a dense infiltration of lymphocytes with a somewhat nodular arrangement. Most of the follicles contain leucocytes and desquamated epithelium with very little colloid remaining.

FIG. 4.—Patient Tho, chronic thyroiditis.

thyroglobulin, are potentially true auto-antigens. In addition, the auto-antibodies produced can act upon the normal thyroid gland of the antibody-producing animal itself, causing an experimental thyroiditis. Similarly, dogs and guinea-pigs were treated with pooled extracts of their own species in exactly the same manner as the rabbits. A section through the thyroid glands of one of these dogs is shown in Fig. 3. Again, considerable changes are apparent in the thyroid gland in spite of the fact that in this case no antibodies were demonstrable in the serum. In dogs and guinea-pigs the correlation between circulating antibodies and the histological changes was not as marked as in the case of the rabbits. The question then arises as to whether the circulating antibodies *per se* are responsible for the tissue changes or whether other types of antibodies, such as the cell-bound antibodies, might actually be the agents responsible for the tissue damage in the immunized animals. Indeed, skin tests performed on immunized rabbits gave positive reactions of the delayed type, which again were specific and limited to rabbit thyroid extract rather than to the extracts of other rabbit organs. In examining the sections of the thyroid glands of animals immunized with pooled thyroid extracts of their own species, the similarity to certain diseases of the human thyroid becomes obvious. Unfortunately, it has taken us quite some time to collect a sufficient number of sera, as our hospital has no special thyroid clinic. Roitt *et al.* (1956), in a preliminary communication, reported that they found precipitins directed against thyroid extract in the serum of patients with so-called Hashimoto's disease. Using exactly the same techniques as applied in the serological examination of experimental animals, we also found a considerable number of patients with antibodies directed against human thyroid extract. From the serological point of view, the tanned cell hæmagglutination test in our hands was found to be considerably more sensitive than the precipitation test. The tanned cell hæmagglutination test permits us to detect thyroid antibodies in the serum of many patients which failed to give precipitation. Incidentally, the complement-fixation test in human cases of thyroiditis proved the least satisfactory.

I should like to present an example of a patient (Tho) having thyroiditis (Fig. 4) whose serum contained both precipitins and antibodies demonstrable by the tanned cell hæmagglutination test, as well as another case (Bur) of thyroiditis (Fig. 5) where the tanned cell hæmagglutination test alone allowed the recognition of thyroid antibodies (Table I).

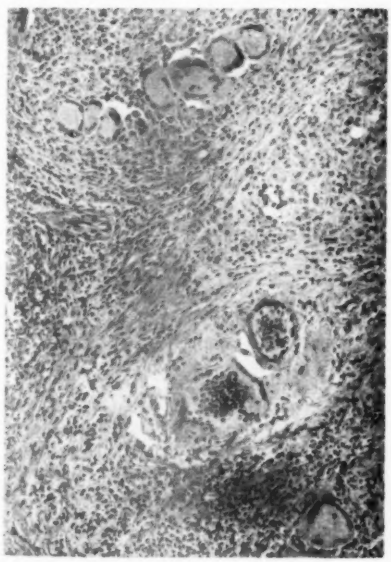

FIG. 5.—Patient Bur, chronic thyroiditis (granulomatous type).

TABLE I

A. Hæmagglutination Test

Dilutions of patient's serum	Patient Tho	Patient Bur
1 : 3	+++	+++
1 : 9	+++	+++

B. Precipitation Test

Dilutions of human thyroid extract	Patient Tho	Patient Bur
Undiluted	+	–
1 : 10	+++	–
1 : 100	+	–
1 : 1000	–	–
saline	–	–

"+++" to "–" indicate the various degrees of agglutination or precipitation respectively.

A, Human erythrocytes (Group O) were treated with highly diluted tannic acid and coated with heated human thyroid extract. The cells were added to serum dilutions and agglutination determined after overnight incubation at 4° C. (*see* Witebsky and Rose, 1956).

B, Undiluted, active patient's serum added to dilutions of human thyroid extract. Amount of precipitate graded after overnight incubation at 4° C. (*see* Witebsky *et al.*, 1955).

Our papers on chronic thyroiditis and auto-immunization (Witebsky *et al.*, 1957*a*, *b*) dealing with the further correlation of experimental and human thyroiditis will be published in the near future.

In investigations of this type it is important to exclude the possibility that the antibody involved is an iso-antibody directed against a group specific antigen present in the tissues of some human beings and not in others. To exclude this possibility, hæmagglutination tests were set up using as antigens thyroid extracts from 14 different individuals. In each case a reaction was obtained with essentially identical titre. In addition, attempts were made to inhibit the reaction of a thyroiditis serum with human thyroid extract by adding extracts of human liver, spleen, kidney, gastric mucosa, and serum to the patient's serum before the tanned and coated cells were added. Thyroid extract was the only one to inhibit the reaction at all. All this evidence indicates that the antibody involved is a specific thyroid antibody rather than an iso-antibody of any sort.

In the case of thyroiditis we are therefore facing an interesting situation. Extracts prepared of an animal's own thyroid gland proved to be antigenic for the individual animal itself. Undoubtedly therefore we are dealing with a true auto-antigen, presumably thyroglobulin, which produces antibodies capable of acting upon the normal thyroid tissue of experimental animals. The equivalent in humans is seen in certain kinds of chronic thyroiditis, where apparently a constituent of the patient's own thyroid gland becomes antigenic, for reasons yet unknown. Chronic thyroiditis then, I believe, is a clear-cut example in which auto-immunization has been proven to play a major role in the pathogenesis of the disease, substantiated by reproducible evidence in experimental animals.

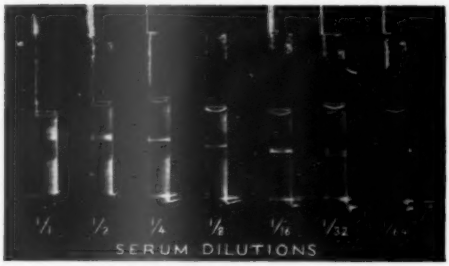
Dr. I. M. Roitt and Dr. Deborah Doniach (Courtauld Institute of Biochemistry and Institute of Clinical Research, Middlesex Hospital Medical School):

Auto-immunization in Thyroid Diseases

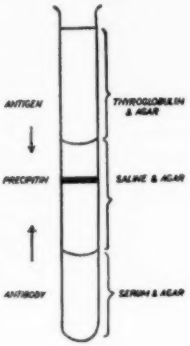
The finding of raised gamma globulins and abnormal serum protein flocculation results in Hashimoto's disease, their gradual return to normal after removal of the goitre (Luxton and Cooke, 1956; Skillern *et al.*, 1956; Doniach and Hudson, 1957) as well as the infiltration of the thyroid gland with antibody-producing cells, led us to postulate that these changes were due to an immune process directed against the thyroid. The sera of patients with this type of goitre were found to contain precipitating antibodies against human thyroglobulin (Roitt *et al.*, 1956).

The thyroglobulin precipitins were demonstrated by double diffusion in agar using a modified Oudin technique (Doniach and Roitt, 1957) (Fig. 1).



The antibody was proved to be specifically directed against thyroglobulin, negative results being obtained against extracts of other human tissues. The precipitins were equally demonstrable when crude thyroid extracts from normal or thyrotoxic glands were used. The antibody furthermore showed a narrow species specificity.

Localization of the precipitating antibody in the gamma globulins was demonstrated after fractionation of the patient's serum by zone electrophoresis on cellulose columns and by immuno-electrophoresis.



A proportion of sera gave a double precipitin line (Fig. 2) and this was shown to be due to the presence of two immunologically distinct proteins in the thyroglobulin preparation.

Quantitative studies (Heidelberger and Kendall, 1935) done with purified thyroglobulin showed that the sera of some patients contained as much as 5 mg. of antibody protein per ml. Two types of precipitin curves were seen in different patients; one type resembled the rabbit precipitating system with complete precipitation in antibody excess, while the other was more akin to the curve obtained with horse flocculating antibody, showing partial or almost complete solubility of the antibody-antigen complex in excess antibody.

By using radioactive thyroglobulin it was possible to show that the ratio of antibody to

FIG. 1.

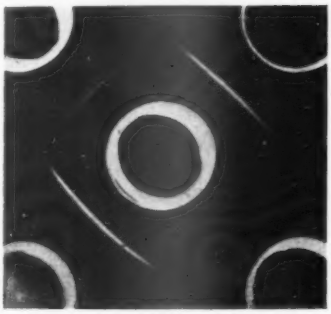

FIG. 2.

FIG. 1A.—Thyroglobulin precipitin test done on serial dilutions of serum from a Hashimoto patient, using 5 mg./ml. thyroglobulin as the antigen. Precipitins were visible to 1/64 dilution of the serum. The compact band seen in 1/4 and 1/8 tubes indicates equivalence of antibody and antigen. The leading edge of the precipitate approaches the serum layer with progressive dilution.

FIG. 1B.—Demonstration of thyroglobulin precipitins: the Oudin technique. The antigen and antibody diffuse towards each other in the neutral zone. A precipitate occurs when they meet in suitable proportions.

FIG. 2.—Precipitin reaction done by the Ouchterlony agar diffusion technique. Central well contained 5 mg./ml. thyroglobulin solution. 4 different Hashimoto sera were placed in the peripheral wells. One of these shows a double precipitin line.

antigen in the specific precipitate varied from 4 : 1 in the region of antibody excess to 2 : 1 in the zone of antigen excess. These ratios are considerably lower than those found in studies with the rabbit antibody against hog thyroglobulin (Heidelberger, 1938), where values of up to 40 : 1 have been obtained and this may be related to the narrower specificity of the auto-antibody.

Results of the thyroglobulin precipitin test: A total of 107 Hashimoto sera were examined by the precipitin test (Table I). Seventy of these patients were either untreated or treated

with thyroid hormones without surgical removal of the goitre and of these 52 gave positive precipitins and 18 were negative. All but one of the sera which were negative by the precipitin test gave positive results when tested by complement fixation, using extracts of thyrotoxic gland as the antigen (Trotter *et al.*, 1957). The serum which was negative by both methods was further studied by a more sensitive precipitin method using radioactive thyroglobulin and rabbit-antihuman-gammaglobulin serum. By this means the patient was shown to have some antibody, but in amounts insufficient to give a visible precipitate by the Oudin technique. Of 37 post-operative Hashimoto patients tested, only 14 gave positive precipitin tests, the incidence of negative results increasing with the amount of thyroid tissue removed and the length of time elapsed since the operation.

The sera of 238 patients with other thyroid diseases were examined by the precipitin test. Results are shown in Table II. None of the patients with thyrotoxicosis or non-toxic nodular goitre had any precipitins but the sera of two thyrotoxic patients, who developed myxœdema following thyroidectomy and I^{131} respectively, contained complement-fixing

antibodies. Quite strong precipitins were found in 6 patients with primary myxœdema without goitre and in 4 cases of subacute thyroiditis. The only case of true Riedel's disease tested was negative by the precipitin test, though her serum contained weak complement-fixing antibodies.

The ætiology of Hashimoto's disease.—The demonstration of circulating antibodies against the patient's own thyroid gland in chronic thyroiditis and the known cytotoxic effects of experimentally induced auto-immunization suggested that the disease might arise by a self-perpetuating destructive process depending upon an immune response to thyroglobulin or some other protein in the thyroid gland. Since thyroglobulin is normally confined in the follicles and does not circulate freely, individuals will not have acquired an immunological tolerance to it (Medawar, 1956).

It is of considerable interest that Witebsky and Rose (Rose and Witebsky, 1956; Witebsky *et al.*, 1957) have succeeded in immunizing several animal species against extracts of homologous thyroid glands and have observed lesions in the thyroids of animals so treated which have many features in common with human chronic thyroiditis. Thus it can be supposed that in the human subject, any release of thyroglobulin from the follicle could elicit an auto-immune response and stimulate invasion of the gland by lymphoid elements with local antibody production, causing possible damage to adjacent follicles with further release of colloid. In time the thyroid gland may become diffusely involved and distant parts of the reticulo-endothelial system may be implicated in the production of antibodies. The unusually high level of circulating antibody in these patients is a reflection of this hyperimmunization, probably resulting from prolonged and continuous leakage of antigen from the gland.

Classical Hashimoto's disease represents a late and extreme example of this process. When the glandular elements are almost completely destroyed and the antigenic stimulus has diminished, it is conceivable that the lymphoid elements regress, leaving a fibrotic thyroid gland which, if judged on histological grounds only, may be indistinguishable from Riedel's thyroiditis. However, true invasive fibrous thyroiditis as defined by rigid operative and clinical criteria (Woolner *et al.*, 1957) may be a distinct condition though the finding of weak complement fixation by the serum of our patient who answered these criteria cannot be disregarded. It was kindly tested for us by Dr. R. G. White and independently by Dr. G. Belyavin, with concordant results. Dr. White also tested this serum against the extracts of other human organs but was only able to detect weak antibodies against the thyroid.

The finding of precipitins in the sera of patients with primary myxœdema without goitre accords well with the frequent lymphoid infiltration found in the small fibrotic glands of myxœdematous subjects. It is likely that the development of a goitre as a result of thyroid auto-immunity depends on the ability of the gland to respond to T.S.H. Similar wide individual variations exist in the goitrogenic reactions of thyrotoxic patients treated with antithyroid drugs: in some cases, over-treatment to the point of hypothyroidism produces no enlargement of the goitre, whereas in a few subjects, the slightest overdosage gives rise to a marked goitrogenic effect.

It appears that thyroid auto-immunity is not always progressive since the majority of patients with subacute thyroiditis recover without sequelæ despite the finding that thyroid precipitins can be present quite early on in the disease. It may be that the mere release of thyroglobulin and the development of precipitins against it are insufficient to perpetuate the damaging chain reaction in the thyroid gland and that a cellular hypersensitivity of an as yet unknown nature is involved.

We are grateful to Mr. R. Vaughan Hudson for his co-operation and interest and to Dr. P. N. Campbell for helpful discussion.

Dr. W. R. Trotter, Dr. G. Belyavin and Dr. A. Waddams (University College Hospital Medical School):

Precipitating and Complement-fixing Antibodies in Hashimoto's Disease

Since the publication of Roitt and Doniach's preliminary report (Roitt *et al.*, 1956), we have examined the sera of a number of cases of thyroid disease, using the agar gel technique for detecting precipitating antibodies. The antigen employed in these tests was a simple saline extract made from slices of normal thyroid obtained at post-mortem. The results obtained were extremely similar to those described by previous speakers, so I shall not refer to them in detail.

We have also looked for complement-fixing antibodies in the serum of cases of Hashimoto's thyroiditis. The initial results were uniformly negative even with sera in which precipitating antibodies were easily demonstrable. At that stage we had a most informative discussion with Dr. White, in which he told us that he had been able to obtain complement fixation in several cases of Hashimoto's thyroiditis. His antigen, however, was derived from a thyroid obtained at operation from a case of thyrotoxicosis, whereas ours came from a normal thyroid obtained at post-mortem. We therefore made a saline extract from a thyrotoxic thyroid and found that this fixed complement when set up against sera from all our proved cases of Hashimoto's thyroiditis (using a method of complement fixation described by Belyavin (1953) and 2 M.H.D. of complement).

Table I gives some examples of the antigens we have used. Sera containing precipitating

TABLE I.—THYROID EXTRACTS USED AS ANTIGENS

Number examined	Type of thyroid	Source	Precipitating activity	Complement-fixing activity
4	Normal	Post-mortem	+	−
1	Normal	Operation	+	−

4	Toxic diffuse goitre	Operation	+	+

antibodies have given consistently positive precipitin tests against all the thyroid extracts so far tested; but complement-fixation has been obtained only against the extracts of the four thyrotoxic thyroids. This does not seem to be because they were obtained fresh at operation, because a normal thyroid obtained in the same way was negative. Thyroglobulin, which was most generously supplied by Dr. Roitt, has been tested in dilutions varying from 0·5 to 8·0 mg. per ml., and the results have been consistently negative against a range of sera known to contain complement-fixing antibodies.

Table II shows the results of a preliminary attempt at separation by high-speed centri-

TABLE II

Procedure	Precipitin titre	Optimal C.F.T. titre

Untreated	1 : 80	1 : 5
Centrifuged at 20,500 *g* for 1 hour ..	1 : 40	negative

fugation. Two different extracts of the same thyrotoxic gland were used. Both were of the same strength (20% w/v), but in one instance the thyroid was homogenized whereas in the other it was sliced and left in contact with saline for twenty-four hours. Some differences can be observed between the precipitating and complement-fixing antigens. The amount of precipitating antigen was about the same in both extracts; but there was much less complement-fixing antigen in the extract of the slices. Centrifuging the homogenate at 11,300 *g* got rid of some of the complement-fixing activity, but precipitating activity was unchanged. Centrifuging at 20,500 *g* eliminated both antigens from the homogenate. When the extract of the slices was centrifuged at this speed the supernatant contained precipitating, but not complement-fixing activity.

Table III summarizes the results obtained to date by testing sera from a number of

TABLE III

Probable Hashimoto ..	14	8	12
Spontaneous myxœdema ..	9	3	5
Thyrotoxicosis	10	0	4

different thyroid diseases. It will be seen that the complement-fixation test has been positive in all except 2 patients with Hashimoto's disease. In the 2 negative cases the diagnosis has not been proved histologically. The precipitin test has been less consistently positive, even in unoperated cases.

The number of normal subjects tested so far is exceedingly small and as one of these gave a positive complement-fixation test we cannot claim that this test is necessarily specific for thyroid disease. On the other hand the cases of simple goitre have so far been consistently negative.

It is not very surprising to find that a proportion of cases of spontaneous myxœdema has reacted positively to both tests. When extreme atrophy has not occurred, the histology of the thyroid in this condition is remarkably similar to that seen in Hashimoto's thyroiditis. Patchy lymphadenoid change is likewise seen in some toxic goitres, so that again it is not surprising that occasional positive results have been obtained in thyrotoxicosis. It is of some interest to note that one thyrotoxic patient, whose thyroid had been shown to contain the complement-fixing antigen, did not have demonstrable complement-fixing antibodies in her serum.

The present work is at an embryonic stage, and some obvious control experiments have not yet been performed. For instance we have not as yet examined organs other than the thyroid for the presence of complement-fixing antigen. Similarly we have not examined serum from patients with non-thyroid disease for complement-fixing antibody. The specificity of the complement-fixation test is therefore as yet quite unproved. But even at this early stage in the investigation we feel that certain preliminary conclusions can be cautiously advanced. On the one hand we have evidence that certain thyrotoxic thyroids contain a substance which behaves like an antigen in the complement-fixation test. All we can say about this substance at present is that it does not appear to be thyroglobulin. On the other hand we have evidence that corresponding antibodies are present in serum from almost all cases of Hashimoto's thyroiditis, most cases of spontaneous myxœdema, some cases of thyrotoxicosis and occasional normal subjects. It is known that lymphadenoid change is universal in Hashimoto's thyroiditis, usual in spontaneous myxœdema, not infrequent in thyrotoxicosis and occasionally found in normal thyroids. It is possible therefore that there is a correlation between lymphadenoid change and the presence of complement-fixing antibodies; but at the moment this correlation is still hypothetical. The most hopeful aspect of the present work would appear to be that it provides an opportunity for learning something of the mechanisms involved not only in Hashimoto's thyroiditis, but also in thyrotoxicosis.

DISCUSSION ON THE PENETRATION OF DRUGS INTO THE CEREBROSPINAL FLUID

Dr. **Hugh Davson** (Medical Research Council, Department of Physiology, University College):

Physiological Aspects of the Penetration of Drugs into the Cerebrospinal Fluid

The problem of the penetration of drugs into the cerebrospinal fluid is just one aspect of the more general problem of the nature of the barriers between blood, on the one hand, and the cerebrospinal fluid and central nervous tissue on the other, i.e. the so-called blood-C.S.F. and blood-brain barriers. When a substance is injected into the blood it finds its way rapidly into the extracellular fluids of most parts of the body; in the central nervous system, however, this penetration is usually much slower, so slow indeed with some substances that their presence cannot be detected either in the cerebrospinal fluid or in the central nervous tissue even after some hours. It is this phenomenon that has given rise to the concept of a barrier that slows down the passage of material from blood to the cerebrospinal fluid and nervous tissue. We must consider first, then, the anatomical pathways available for penetration from blood to cerebrospinal fluid. It is believed that the fluid is elaborated as a secretion of the epithelium of the choroid plexuses of the ventricles; the fluid is formed continuously, passes into the cisterna magna and thence through the rest of the subarachnoid spaces at the base and over the convexities of the brain, to be drained away into the dural sinuses. If the substance we are considering, for example a sulphonamide, is able to enter the secretory cells of the choroidal epithelium, we may expect it to appear in the primary secretion of cerebrospinal fluid and flow with it over the surface of the brain; if we maintain a constant concentration of the drug in the plasma over a long period we may therefore expect the concentration to rise in the cerebrospinal fluid continuously; it will rise more rapidly in the ventricles than in the subarachnoid fluid, and we may expect the subarachnoid fluid of the spinal cord to lag behind the fluid elsewhere if circulation of fluid here is less continuous and rapid. Experiments show, however, that there is another possible route of penetration from blood to cerebrospinal fluid; this is by way of the capillaries of the nervous tissue, into the extracellular space of the tissue and thence into the ventricles and subarachnoid space. In other words, penetration into the cerebrospinal fluid may involve passage through the *blood-brain barrier*. For convenience, we may describe the blood-C.S.F. barrier as the barrier between blood and C.S.F. in the ventricles, i.e. the epithelium of the choroid plexuses; the blood-brain barrier becomes the barrier between the capillaries of the nervous tissue and the extracellular fluid of this tissue—it may be the capillary endothelium or it may be the so-called pia-glial lining supposed to cover this endothelium.

In general, physiological experiments have shown that these two barriers are very similar, in the sense that if a substance passes rapidly into the one compartment, e.g. the cerebrospinal fluid, then it also passes rapidly into the other. As with cellular permeability it is essentially the degree of lipoid-solubility of the substance that determines its ability to cross the barrier; thus alcohol and urethane pass so rapidly that it is difficult to measure the rate at which the blood comes into equilibrium with the cerebrospinal fluid after an intravenous injection of either of these substances. It is for this reason that many sulphonamides pass readily into the cerebrospinal fluid; thus sulphapyridine and sulphanilamide have high lipoid-solubility and appear rapidly in the fluid after an intravenous injection. Sulphadiazine and sulphathiazole have lower lipoid-solubilities and penetrate more slowly. Penicillin has a very low lipoid-solubility and it is difficult to detect its penetration; Chloromycetin is quite lipoid-soluble and penetrates easily. In general, if a drug has a partition coefficient—Concn. in Oil/Concn. in Water—greater than that of sulphadiazine, namely 0·035, we may expect it to penetrate sufficiently rapidly to permit of its therapeutic use.

So much for the general problem; some particular aspects that may have an important bearing on the choice of a drug are as follows:

Different regions of the cerebrospinal system.—As indicated above, the ventricles may be considered to be the most favoured with regard to coming into equilibrium with the blood plasma. This is found to be true in practice, the lumbar fluid lagging well behind the cisternal fluid. The discrepancy becomes small, however, with substances that penetrate very rapidly. Thus, if a substance penetrates with some difficulty, e.g. sulphadiazine, then we may expect the concentration in the lumbar fluid to be much less than that in the ventricles.

The abnormal barrier.—In meningitis it is considered that the barrier between blood and cerebrospinal fluid is broken down; presumably the blood vessels of the pia mater allow material to escape into the subarachnoid fluid. Under these conditions drugs that were unable to cross the barrier in the normal subject do penetrate the cerebrospinal fluid in measurable amounts.

Measurement of drug penetration.—For results to be of general value it is desirable that the concentration of the drug in the blood plasma be measured at intervals during the penetration of the drug into the cerebrospinal fluid. Thus, if a single intravenous injection is given, and blood is sampled say one, fifteen, thirty and sixty minutes later and the cerebrospinal fluid just once at sixty minutes, it is possible to compute a transfer constant that permits comparison with other values. It is worth noting, also, that the blood-aqueous barrier, i.e. the impediment to penetration from blood into the aqueous humour of the eye, is very similar to the blood-cerebrospinal fluid barrier. If it is known that a drug penetrates rapidly into the aqueous humour it can be accepted that it will also penetrate rapidly into the cerebrospinal fluid.

Dr. Honor V. Smith (Department of Neurology, Radcliffe Infirmary, Oxford):

The fact that certain substances normally present in blood, or artificially introduced into the blood stream, either do not appear in the cerebrospinal fluid (C.S.F.) or do so only in minute amounts is one that has an important bearing on both the pathogenesis and treatment of certain neurological diseases. Dr. Davson has discussed the basic physiological problems of this blood-C.S.F. barrier, and I shall attempt to describe briefly certain studies carried out in recent years in Oxford, and to consider some of their clinical implications.

Of the substances we have studied, the first in clinical importance are those used in the chemotherapy of neurological infections. It is now established that, when the meninges are normal, none of the usual chemotherapeutic agents except the sulphonamides and iso-nicotinic acid hydrazide (I.N.A.H.) will enter the C.S.F. in anything except negligible quantities. It is, however, widely held that inflammation of the meninges greatly increases the permeability of the barrier, and that therefore penicillin or streptomycin, when given systemically in cases of active meningitis, will appear in the C.S.F. in therapeutic concentrations. This important assumption clearly requires careful verification. Unfortunately penicillin and streptomycin are not themselves ideal indicator substances to use in studying the effects of inflammation and other conditions on the permeability of the blood-C.S.F. barrier, since they can only be estimated quantitatively by biological methods that, of necessity, carry a considerable margin of error.

We have, therefore, studied the partition of bromide, magnesium and calcium between blood and C.S.F. in a large variety of neurological conditions. These are all substances that can be accurately estimated in body fluids even in very low concentrations (Hunter, 1955; Hunter and Stott, 1956). In many cases, too, we have studied the rate of passage of radioactive sodium, Na^{24}, from blood to C.S.F. Much of this work is still at an early stage, but we have already found consistent departures from the normal in old age, in diseases of the basal nuclei such as Parkinson's disease, and in inflammatory conditions of the nervous system (Bourdillon *et al.*, 1957). It is with these last that I am particularly concerned to-day.

Cohen's law.—Earlier workers have found that in active meningitis substances normally present in higher concentration in blood than C.S.F. increase their concentration in the C.S.F., whereas those that are normally at a higher concentration in the C.S.F. decrease (Cohen, 1924). This generalization is sometimes known as Cohen's law. It may be expressed by saying that whatever the normal ratio of the C.S.F. concentration to that of the serum, this ratio is altered in meningitis in the direction of unity. Table I shows the

TABLE I

	Magnesium		Calcium		Bromide	
	No. of cases	C.S.F./S.	No. of cases	C.S.F./S.	No. of cases	C.S.F./S.
"Normal"	17	1·35	13	0·51	34	0·39
Tuberculous meningitis	15	0·94	13	0·64	15	0·96

mean values for the ratio of C.S.F. to serum concentration for magnesium, calcium and bromide, in 15 cases of active tuberculous meningitis compared with 17 so-called "normals". These latter were cases in which lumbar puncture was indicated in the course of their investigation, but where no evidence of progressive neurological disease was found.

In broad outline these findings conform to Cohen's law. Thus, with calcium, where normally the concentration in the C.S.F. is only about half that of serum, in tuberculous meningitis the C.S.F. concentration increases so that the ratio of C.S.F. to serum rises. Magnesium, on the other hand, is normally present in higher concentration in C.S.F. than blood; and the effect of the meningitis is to lower the ratio. Cohen, discussing the alteration of the chloride distribution in meningitis, stated that he never found the C.S.F. chloride concentration to fall below that of the serum, but, as our figures show, the magnesium

ratio can actually be reversed. This effect may be even more marked with the bromide ratio. Although in the normal the C.S.F. concentration is only about one-third that of blood, in active tuberculous meningitis not only are ratios of the order of unity the rule, but on occasion they may be as high as 1·4.

Tuberculous meningitis as opposed to other varieties of meningitis.—It cannot, however, be assumed that similar results will be obtained in all types of meningitis, irrespective of their ætiology. On the contrary, experience has shown that the blood-C.S.F. barrier is more profoundly and more consistently affected in tuberculous meningitis than in other varieties of meningitis showing comparable changes in the C.S.F. The difference is indeed sufficiently well marked to serve as the basis of a useful diagnostic test (Hunter *et al.*, 1954).

The one other condition in which the effect on the barrier seems to be consistently of the same order as in tuberculous meningitis is neoplasia of the meninges. Thus, although in cases of brain tumour as a whole the bromide ratio has been normal, in 2 cases of oligodendrogliomatosis and one of carcinomatosis of the meninges the ratio was unity.

The effects of a specific inflammation on the blood-C.S.F. barrier.—It is clear, then, that except in the most general terms, no rule can be formulated as to the result of meningeal inflammation as such on the permeability of the blood-C.S.F. barrier. But not only does the effect on the barrier vary with the ætiology of the inflammation: we have evidence that the effect of a given inflammation is not necessarily the same for all substances. This is well seen when the effects of the intrathecal tuberculin reaction of the blood-C.S.F. barrier are considered (Smith *et al.*, 1955). By the intrathecal tuberculin reaction is meant the transient wave of sterile meningitis that follows the introduction of tuberculin into the spinal fluid of a subject sensitized to tuberculin. We have used intrathecal tuberculin in the treatment of various diseases; and since, on the whole, the changes provoked in the C.S.F. have proved remarkably constant in both occurrence and pattern, we have taken advantage of these reactions to study the effects of a given inflammation on the permeability of the blood-C.S.F. barrier.

Systemic versus intrathecal tuberculin.—In the first place, the barrier to tuberculin itself appears to be absolute. In the sensitized guinea-pig the cisternal injection of tuberculin is followed by an intense inflammation involving not only the meninges but also the perforating vessels of the neuraxis (Bosanquet *et al.*, 1953). If, however, a fatal dose of tuberculin is given by intraperitoneal injection, no significant meningeal exudate is found *post mortem*. In man, intramuscular tuberculin, when given as an adjuvant to the chemotherapy of systemic tuberculosis, produces no concomitant changes in the C.S.F.; nor is the passage of either penicillin or bromide from blood to C.S.F. in any way affected (Swithinbank *et al.*, 1953; Fig. 13).

Changes with intrathecal tuberculin.—Contrast this with the effects of tuberculin when given as the Purified Protein Derivative, P.P.D., directly into the cerebrospinal fluid of a highly sensitized subject (Smith *et al.*, 1955; Fig. 1). Twenty-four hours after an injection of 3·75 mg. of P.P.D. the C.S.F. typically contains many hundreds or, more commonly, thousands of cells and the protein content is also markedly increased. Both the cell counts and protein content then fall abruptly until towards the end of the first week, when a second rise takes place. During the first phase of the reaction most of the cells are polymorphonuclear leucocytes; during the second phase they are virtually all lymphocytes. The first phase is accompanied by a sharp rise in the bromide ratio, to the order of unity, and this rise usually continues to increase until the second phase of the reaction is beginning to subside. Even then it may be many weeks before the barrier is fully restored.

One of the reasons why bromide has proved such a useful tool in studies of this kind is that it is excreted so slowly that there is ample time for equilibrium to take place between blood and C.S.F., while in these concentrations the ratio is independent of the absolute amounts of bromide present (Hunter *et al.*, 1954; Fig. 1).

In summary then, the intrathecal tuberculin reaction exerts a dramatic effect on the blood-C.S.F. barrier to bromide; but while the permeability of the barrier increases most rapidly during the first phase of the reaction, the maximal increase in permeability is delayed until the second phase has developed.

The penetration of penicillin.—The effect of the reaction on penicillin is rather different, in that the increase in penetration during the first phase of the reaction is often negligible while during the second phase a considerable increase in penetration takes place. Indeed, the increase in the penicillin content of the C.S.F. appears to be dependent on the second phase of the reaction; and in anomalous reactions, where the lymphocytic phase did not develop, the C.S.F. was never found to contain more than a trace of penicillin, even though thousands of polymorphs might appear during the first phase of the reaction, with a sharp increase in the permeability to bromide.

It appears, then, that intrathecal tuberculin exerts a specific effect on the blood-C.S.F. barrier; nor have we been able to find any record of a comparable effect with any other

factor. This appears the more significant as the amounts of tuberculin given are probably of the same order as those present in tuberculous meningitis.

The effect of cortisone.—The effect of intrathecal tuberculin appears to be antagonized by cortisone. Thus in one case 2 reactions were produced at different times to the same dose of P.P.D. in the same subject. Before the second reaction 50 mg. cortisone was given by mouth the same morning as the P.P.D. The polymorphonuclear component failed to develop though the second phase of the reaction was unaffected. Even under the influence of this single small dose of cortisone the barrier was less affected than in the unmodified reaction and was restored more rapidly (Smith *et al.*, 1957; Fig. 4).

Conclusions.—These findings go some way towards explaining the divergence of opinion that still persists as to the necessity or otherwise of giving penicillin and streptomycin by intrathecal injection in the treatment of meningitis. To take the question of penicillin first: As the results obtained in the intrathecal tuberculin reaction show, the penetration of penicillin into the C.S.F. does not run parallel with the intensity of the inflammation as measured by height of the pleocytosis and the protein content of the C.S.F. In fact, during the first or polymorphonuclear phase of the reaction, when the C.S.F. is often indistinguishable from that in a case of purulent meningitis, little or no penicillin may be found in the C.S.F. This is in line with our clinical experience, that the passage of penicillin from blood to C.S.F. is far too erratic to be depended upon in the treatment of such a serious disease as purulent meningitis. For example, though it is often claimed that pneumococcal meningitis can be adequately treated by intramuscular penicillin, we have failed to detect more than a trace of penicillin in the C.S.F. of a child of 7 months, weighing 7·7 kg., who was suffering from pneumococcal meningitis and who was receiving 5,000,000 units of penicillin by intramuscular injection every two hours (Smith, 1951). Moreover, reports of sizable series of unselected cases of pneumococcal meningitis in which the mortality has been reduced to the order of 10%, have, so far as I know, still only come from centres where intrathecal medication is given.

The position with regard to streptomycin is rather different. In untreated tuberculous meningitis we have frequently found from 5–15 units per c.mm. in the C.S.F. six hours after the intramuscular injection of a gram of streptomycin. This is well above the *in vitro* bacteriostatic level for virulent human bacilli. Yet it has been conclusively shown that the results obtained in the treatment of tuberculous meningitis with streptomycin alone are significantly better when both intrathecal and intramuscular injections are given than when the systemic route is used alone (Medical Research Council, 1948). It therefore seems logical to ascribe the improved results to the very high concentrations in the C.S.F. that persist for some hours after an intrathecal injection.

It is often said that the advent of I.N.A.H. has made the intrathecal administration of streptomycin unnecessary. Though this is not the time to discuss the merits of systemic treatment alone versus combined systemic and intrathecal medication (Smith *et al.*, 1956), it is perhaps worth saying that at Oxford, where combined treatment is still given, we have seldom been kept so busy with requests from elsewhere to take patients whose response to treatment has been disappointing as during the last year to eighteen months. It is tempting to relate this increased demand for our services to the growing tendency to dispense with intrathecal therapy.

It has now been shown that the increase in barrier permeability caused by meningitis varies both with regard to different substances and with regard to the ætiology of the infection. Before, therefore, any one drug can be accounted effective in the treatment of any case of meningitis, it must be shown that, in that particular infection that particular drug is capable of crossing the blood-C.S.F. barrier in therapeutic amounts. It must also be remembered that if cortisone is used in treatment the effect may well be to restore the barrier at the very time when maximal penetration of the drug is most urgently required.

[The biochemical work reported here has been financed by grants from the Nuffield Foundation.]

DISCUSSION ON THE MANAGEMENT OF MASS CASUALTY SITUATIONS IN TIME OF WAR

Lieutenant-General Sir Alexander Drummond (Director-General, Army Medical Services):

INTRODUCTION

The Organization of the Medical Services of the Army for Mass Casualties

The prime objective of the Army in planning methods of handling and treating mass casualties is to find ways and means of maintaining the standard of treatment it is accustomed to give to the individual patient. The fewer the casualties requiring professional, as opposed to lay skill, the easier it is to maintain this standard. Preventive measures are therefore the first essential. All ranks or, colloquially speaking, the man in the street, must have knowledge of and be skilled in the practice of first aid to an hitherto unparalleled degree. Following a nuclear incident or a series of nuclear incidents there will be no time to think or read somebody else's experience, neither will there be scope for professional individualism in the treatment of the injuries. Some surgeons had to learn this lesson again after the landing in Port Said.

The principles of military as distinct from routine civilian surgery have grown out of bitter experience and must, if our patients are not to suffer, remain inviolate. The experienced forward surgeon knows well that his role is the preparation of wounds for delayed primary suture in five to seven days' time, the stepping stones to which are efficient debridement and the firm support of traumatized muscles in the same manner as fractures are cared for. If these principles are adhered to the formation of scar tissue is minimized, compound fractures are converted into simple ones and the patient's limbs and life are not jeopardized. To ensure this standard of treatment the more experienced surgeons must be posted to forward units to supervise those with less skill.

The medical and nursing personnel at hospitals and field units must be protected from being swamped by an influx of minor casualties or unsuitable operative risks. They must also be organized in order to prevent fatigue and overwork. For example, if surgical teams have to sustain their effort and work unremittingly for seven to nine days they can only undertake 12 serious cases per day, no more. Again, to obtain the maximum effort the staff must be provided with a suitable environment in which to work and rest, as in times of stress they must not be worried and annoyed by administrative detail.

As practised in the Great War and World War II, casualties in the forward area should be separated into those who now can be efficiently taken care of by nursing orderlies, the transportable risk cases and those who are seriously or dangerously ill. It is only this last group that should concern the receiving hospitals. Having been diagnosed by an experienced clinician, there will be no need for the patient to go through the routine of the reception or the casualty department at the receiving hospital, a procedure which in these circumstances is a waste of time and medical man-power. The Army practice is for convoys of 5–6 ambulance cars to be sent to a particular hospital or receiving unit. Admission is then direct to the ward. Here the patients are taken over by the nursing and documentary staff and bedded down. If suffering from burns or abdominal injuries intravenous drips and, where necessary, gastric suction are started immediately. Sedation and antibiotics are given as required. In 60 minutes 100 patients can be comfortably settled in bed or on stretchers, having been placed on sustaining treatment, and be waiting for the medical officer to do his round and re-assess their condition. The aim is that the ward will be as quiet and as peaceful as, say, the wards of your hospital on a Sunday morning. If extra skill such as surgical teams is not available, those at the receiving unit must be prepared to sustain and care for their patients for the first few days. The difficult period is the first three or four days; after this pressure should lessen. The likelihood of having settled blood available in the first few days is not strong.

The problem of casualties occurring in enormous numbers is an important administrative one, which has in two World Wars been successfully handled. There is no reason why it should not be so in any future war. The surgeon and physician problem is that all casualties cannot be dealt with in the first six or even ninety-six hours. However, with careful selection and sustaining treatment there is little reason to doubt that at the end of seven to nine days the vast majority of patients will have been successfully treated.

Administratively an important question is to determine beforehand how many beds for seriously ill patients hospitals can maintain. This figure is the limiting factor. I feel that the crisis expansion cliché is a snare and delusion. The conception of beds placed cheek by jowl with patients on stretchers underneath them is fraught with danger. If a hospital has 400 beds, can its staff, which in all probability will be depleted, adequately look after 400 seriously or dangerously ill patients? Is it right to ask them to expand by 50% or even 15%? Experience shows that crisis expansions are possible only if a goodly proportion of the patients are suffering from skin disease, ingrowing toe nails or dyspepsia.

Having determined the critical figure—that is the number of seriously ill patients the hospital can look after, not merely accommodate—that number and that number only should be admitted. The hospital gates should then be locked. Otherwise instead of doing the most good for the greatest number one will do a great number a disservice. If, however, you can augment the staff by putting in a medical company consisting of say 3 medical officers, 6 State-registered nurses, 3 cooks, plus 37 nursing orderlies, the hospital will be able to accept a further 100 seriously or dangerously ill patients.

To-day a medical company whose establishment is 49 is expected to have a 100-bedded-tented hospital erected, opened up and with the majority of its patients admitted and on sustaining treatment within two hours of arriving on site. Field ambulances or casualty filtering units operating within a specified sector will give the rearward hospitals breathing space in which to orientate their organizations.

In the Army we are emphasizing forward surgery. We believe that where possible mobile hospitals should move right into the devastated area to deal with the desperately injured.

Colonel T. M. R. Ahern: *Sorting, Early Treatment and Evacuation*

The city we are about to consider is in Britain and has one million inhabitants. A 10-megaton (hydrogen) bomb has fallen on its centre. Houses are destroyed or damaged and streets blocked by debris for a radius of fifteen miles. There are 210,000 immediate casualties excluding the dead. Of these, 60,000 are light cases and 150,000 are seriously hurt. Of the latter, 100,000 are trapped and some will be released, dead or alive, to-day and over the next few days. There are 50,000 untrapped serious casualties, to be evacuated to hospitals as soon as possible. This is the debit side of the ledger. On the credit side there are over 50,000 hospital beds at distances of from 5 to 15 miles from the edge of the devastated area—just enough to care for the untrapped serious cases, but not enough for the trapped cases who will follow. The majority of these beds are, by current civil defence planning, more accurately, stretchers or mattresses on the floors of schools or churches.

This represents almost the worst possible civil defence situation. There is here a greater disproportion between the medical task and available medical means than is likely to be faced by the armed forces in the field. If we can plan for this situation, the plan can be adapted to any lesser task in the field.

What really happens when a sudden disaster, even a much smaller disaster, hits a community?

There are many well-documented accounts of disasters which caused large numbers of casualties—tornados in the United States of America, bombing of this country, the famous fire storm at Hamburg in 1944, the first atom bomb at Hiroshima. In all these disasters, medical men, among many others, tended to be overwhelmed by the size of the problem and to act irrationally. Casualties suffered because there was no clear-cut plan for the disposal and treatment of large numbers of injured. The case of Dr. Sasaki at Hiroshima is not un-typical. He was working in a hospital, trying to deal with crowds of wounded soon after the nuclear explosion. The account states: "Tugged here and there in his stockinged feet, staggered by numbers, bewildered by so much raw flesh, Dr. Sasaki lost all sense of profession and stopped working as a skilful surgeon and sympathetic man: he became an automaton, mechanically wiping, daubing, winding, wiping, daubing, winding."

It becomes clear that a system of casualty sorting is needed, to be applied well forward of the hospitals, to the whole accessible periphery of the nuclear explosion. Sorting is the process of dividing the injured into categories, so that they can be properly routed either for early emergency treatment or on to medical installations appropriately situated and equipped for their care. This is not a new idea. The method was widely employed during the last war, and is needed whenever there are more injured than can be immediately attended by the available medical force. The criteria for sorting will vary according to the number of patients awaiting medical care and the available medical facilities: the sorting criteria used by the Royal Army Medical Corps in the 1939–45 war would not apply to this situation.

Study of the effects of nuclear weapons suggests the categories for medical sorting which would best permit the largest possible number to receive adequate medical care:

Minor treatment.—Those who, after first-aid treatment, can care for themselves, at least for a few days—40%.

Immediate treatment.—Candidates for immediate life-saving surgery or transportation. Hæmorrhages from an easily accessible site, cases needing tracheostomy, incomplete amputations—20%.

Delayed treatment.—Those with non-critical injuries who can await treatment until they reach hospitals farther back—20%.

Expectant treatment.—Patients with critical injuries, for whom appropriate treatment is unlikely to be available; who are unlikely to survive evacuation or to benefit by treatment—20%.

Starting from these sorting categories, and the rough forecast of the proportions in which they are likely to occur, it becomes possible to plan an appropriate "filter unit" to meet the requirements. I suggest that there may be a critical size for such a unit, above which it becomes wasteful of medical personnel and below which it becomes incapable of full economic function. The total complement, nearly 300 persons, of a unit which might be expected to deal with some 6,000 casualties in twenty-four hours may appear large, but nearly half this total comprises unskilled stretcher bearers, who may, in the event, be provided by local inhabitants.

The present thought on the filter unit is that it should comprise some 10 doctors, 120 nurses and nursing auxiliaries and 160 non-skilled people to act as stretcher bearers, police, &c. In military equivalent this corresponds roughly to the present Royal Army Medical Corps field ambulance to which is added a company of infantry for stretcher-bearer and police work.

The filter unit is designed (Fig. 1): (1) to monitor and, if necessary, to de-contaminate the wounded (of radio-active dust or material);

Diagrammatic layout of a filter unit.

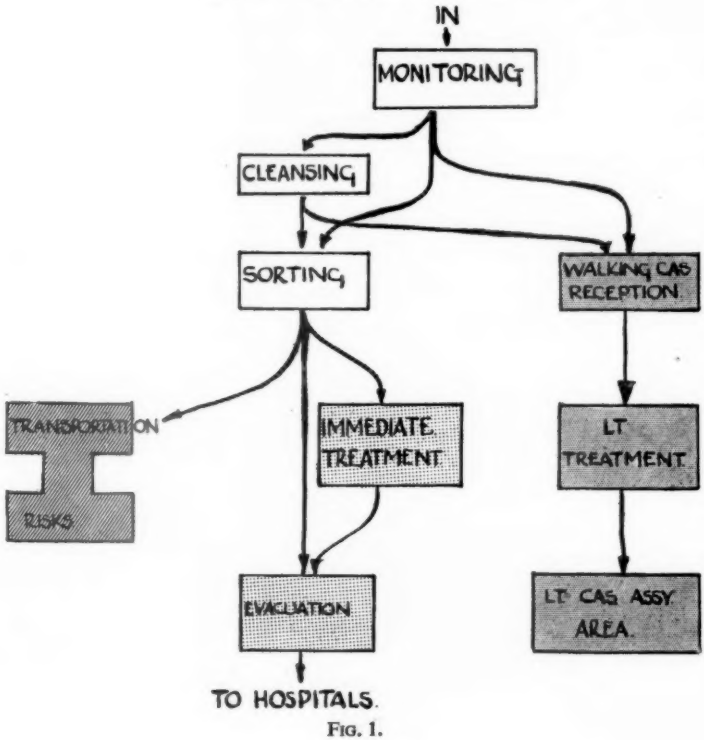

FIG. 1.

(2) to separate the lightly from the seriously wounded. This is a rough sorting procedure which separates the first category from the other two. The test here is to establish whether a man can walk, and, if so, whether he can fend for himself for a few days. If he can do this, he is a light case. After first-aid treatment, he is sent on to the welfare section of the Civil Defence organization and out of medical ken and carriage;

(3) to pass all other than light cases through the sorting department. An experienced surgeon works here over-seeing the work perhaps of other doctors. This is the heart of the filter unit. The injured will be sorted into categories. First, those who will be saved by simple immediate surgery, and who, lacking this, will quickly die. These will be sent direct to the immediate treatment department. Second, those whose condition allows them to wait for surgery. They go direct to the evacuation department, and so on to the hospitals farther back. Thirdly, the "transportation risk" cases who should be held in a hospital specially set aside for this purpose. These are the grimmest results of the sorting process. They have not much chance of survival, and their disposal will be discussed later.

Is it a waste of surgical skill to employ the best and most experienced surgeon here as a referee, rather than working in his operating theatre? Which scale is more heavily weighted—the one holding the fifteen or so cases he might have operated upon in the first thirty-six hours, or that holding the three or four thousand he may have placed in their correct categories in this time? Is surgical experience so important at this point? Decisions on sorting, which are literally of vital importance, will have to be made rapidly, without diagnostic aids and relying wholly on clinical acumen. All must depend on the ability and experience of the individual who has responsibility for making these decisions.

The "immediate treatment department" is for those whose injuries will soon prove fatal unless some simple surgical procedure—ligature of an artery, tracheostomy, completion

Filter unit. Breakdown of 6,000 casualties in twenty-four hours.

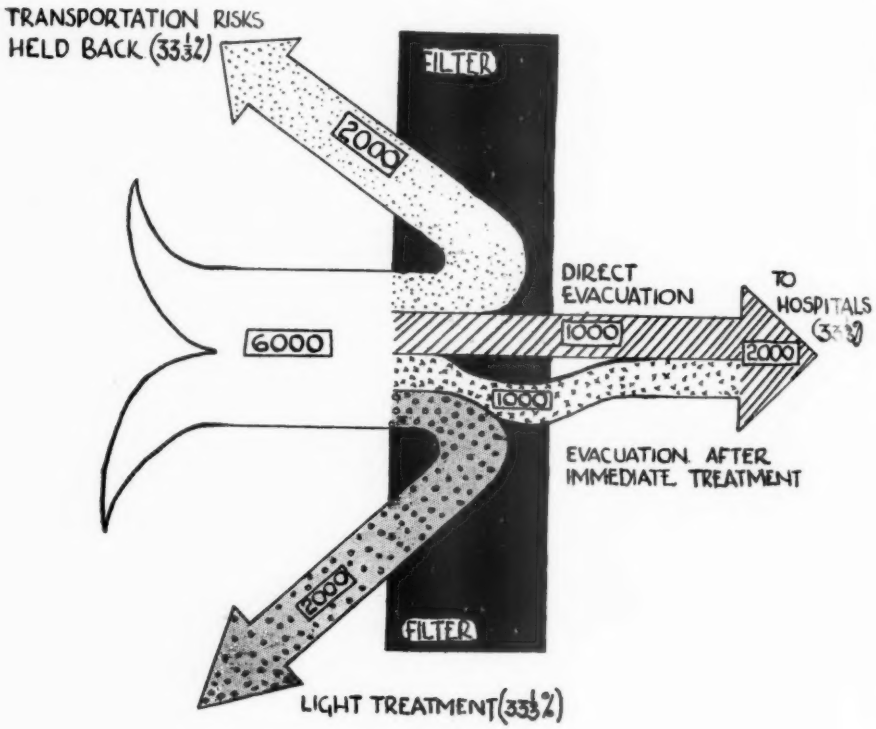

FIG. 2.

of a partial amputation—is quickly performed, but who will then be able to wait for more thorough treatment. It aims to convert bad surgical risks to good ones. If it is to do this successfully there must be team work of a high order, and medical auxiliaries must perform many tasks and accept responsibilities well beyond those normally required of them. New training directives will provide for the training of every army medical service other rank in such procedures as injections, intravenous infusions, catheterization, taking blood pressure, and to assist at such advanced procedures as burns care, tracheostomy, aspiration of the pleural cavities, lumbar puncture and plaster of Paris technique. Men (or women) trained in this way, and trained to work as teams, could adequately staff this immediate treatment department.

The "evacuation department" is a convenient place to hold casualties who are bound for the rearward hospitals, until transport becomes available. It will manage the loading of ambulances in an orderly and economical manner, and make sure that those cases given a high priority by the sorting surgeon go on first.

A "holding department", to hold 100 transportation risk cases, has been incorporated with the filter unit. There are all sorts of reasons why these unfortunates should not be sent farther back than necessary, but, initially, there will be no near-by installation ready for them. Until a special hospital can be set up near-by it will be best to provide facilities on the spot to care for some of them. The great majority of these patients will have little or no hope of survival. No drugs may be available for them except perhaps sedatives or narcotics. There may not be nearly enough transfusion fluid, or surgical or nursing time and effort, even for those who may be expected to recover. It would be unrealistic to expend them on such as these: but it would be indefensible to abandon them. If their condition improves, their category will be re-assessed. As a personal opinion, a small part of the all too scarce medical effort should be devoted to their comfort for the four or five days most of them can expect to live.

Lastly, there is the non-skilled labour, without which the filter unit could not function. Policing is likely to be a real necessity. The filter unit will be invaded by people searching for missing relatives. Its store of food and drinking water will attract those who are without these things. It could easily be overrun unless drastic plans are made to prevent this from happening. Then, there is the stretcher-bearing problem. Remember that some 4,000 stretchers are to be carried through the departments, and then loaded into transport each twenty-four hours. This entails a major labouring effort for at least 100 men.

I am going to suggest to you that hospital arrangements farther back may be competent or chaotic accordingly as casualty sorting at this vital level succeeds or fails. Sorting is the key to effective management of large numbers of casualties.

If the filter unit sorts and treats 6,000 casualties in twenty-four hours successfully it will have achieved the following (Fig. 2):

(*a*) Treated and cleansed the light cases (33·3% of the total) and then diverted these to non-medical welfare channels.

(*b*) Separated the non-transportable cases from the rest.

(*c*) Given emergency life-saving surgery to over 1,000 persons, who should now survive and will be evacuated to acute hospitals—and who would not otherwise have survived to reach these hospitals.

(*d*) Arranged the evacuation of those other serious casualties who do not require immediate treatment at this level.

(*e*) In all, diverted about two-thirds of the casualties (i.e. the light cases and the non-transportables) from the use of medical transport and the doors of the hospitals.

The problem here has been to make available a minimum useful standard of professional treatment to the greatest possible number but to be sure the standard does not fall below this minimum. Remember that there may be at least 6,000 waiting for each 6,000 treated. The surgeons have, on an average, two minutes to categorize each case. Responsible surgical opinion says this is feasible in the circumstances. The treatment teams here can afford an average of nine minutes for each emergency surgical case. Are they going to be able to do real good in this short time? Thank God we none of us have experience. The guess I give you is that they can.

Finally, here is an extract from the report on the Worcester (Massachusetts) incident of 1953. The author is summing up his findings, and the report reads:

"There is an attitude among doctors and administrators in civilian hospitals which opposes the suggestion that assignment of patients should be made by any central authority. This over-confidence in the independence of one's own hospital varies in its expression from extreme belligerence to a guarded willingness to consider the recommendations of central authority. It was present among most of the physicians and administrators encountered in this survey, and it must be reckoned as an attitude of mind which will need consideration in future planning."

Lieutenant-Colonel R. E. Waterston: *Treatment of Fractures of the Extremities*

It is essential that we have a plan for the management of the less severely injured, as well as for the serious cases. In the next few minutes I am going to put forward a scheme for dealing with some of the fractures—fractures of the upper limb, and of the lower limb below the knee. These are cases which would normally be treated in the out-patient departments of our hospitals. What we want is a standardized scheme of treatment which fulfils the following three criteria:

(1) that there is the least possible demand on doctors;

(2) that the patient can return home or to a welfare centre and not be dependent upon a hospital bed;

(3) that it is safe and requires a minimum of attention for four to five days when the patient can have his final definitive treatment.

It will be universally agreed that for fractures some form of splintage will be necessary, but standard first-aid methods vary enormously and largely depend on improvised splints and most of them do not fulfil the criteria we demand. Our Director-General, Lieutenant-General Sir Alexander Drummond, suggested the use of plaster of Paris for this purpose, and working on this idea a standardized technique of six basic "P.O.P. splints" has been worked out.

At the "filter unit" cases requiring this treatment are selected by the responsible doctor examining the cases, each is labelled according to his injury and the case passed to the team of orderlies who apply the plaster.

The basis of this whole method of treatment is the use of plaster of Paris in the form of *slabs* or *gutters*—these are applied in the long axis of the limb and are fixed by an open-wove cotton bandage, which is cut when the plaster has set. An essential feature is that in no instance is a limb actually encircled by plaster.

The chief advantage of plaster over other splints is, of course, that it moulds to the contour of the body, and can therefore be applied directly to the body surface without risk of pressure. There is no reason why a slab should not be applied over a silk stocking, a shirt sleeve or a sock, but not over a trouser leg or a jacket sleeve and not over a shoe.

The splints shown in Fig. 1 are, of course, intended for the treatment of simple fractures but the method is also applicable to the treatment of compound fractures with the proviso that the patient would have to remain under close medical care. Also, and most important,

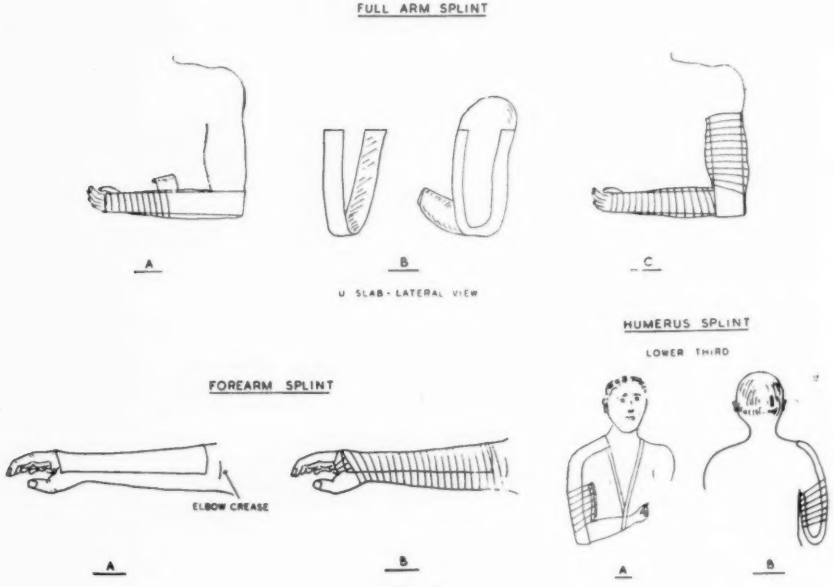

FIG. 1.

the slab would have to be applied over a dressing and when the plaster had set the cotton bandage would be cut all the way up. Our orderlies who are taught to apply these plasters work in teams of two, one to apply the plasters assisted by the second who supports the limb. They are taught to instruct patients to elevate the limb afterwards to avoid reactionary swelling.

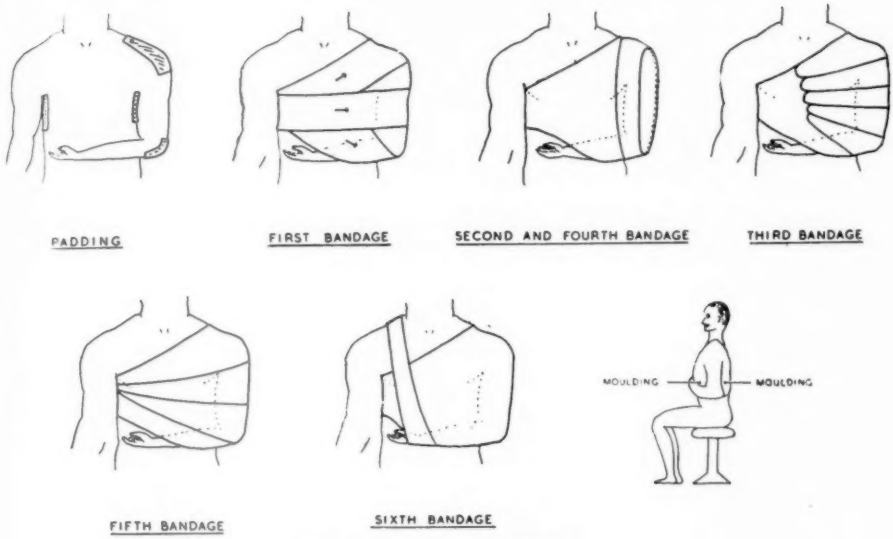

FIG. 2.—Thoraco-brachial splint.

The next "P.O.P." is the thoraco-brachial plaster (Fig. 2). This splint is included in the series because in the last war it proved to be such an invaluable splint for evacuating cases of shoulder injury and fractures of the upper end of the humerus. It is applied with four pads to protect pressure points and though it encircles the chest the arm is not encircled.

Lower limb P.O.P.s.—Fig. 3 demonstrates:

(1) *Below-knee plaster for fractures in ankle region.*

The method for the below-knee P.O.P. is to apply this with the patient prone. With two-men teams this is the simplest method for applying plaster though not of course for maintaining the reduction of the fracture. I should explain that in all these cases we do not expect orderlies to reduce the displacement though they are expected to correct any angular deformity. The patient's final treatment takes place four to five days later under medical care.

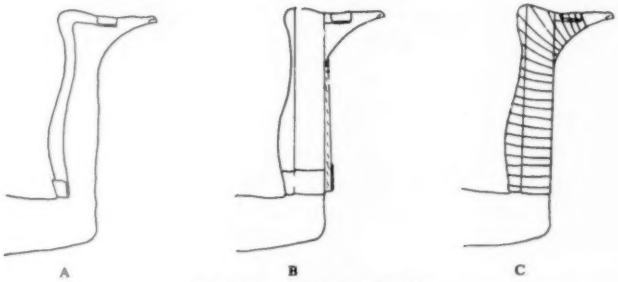

FIG. 3 (1).—Below knee splint.

(2) *Long-limb P.O.P.*—This plaster is intended for fractures of the shaft of the tibia. With some support behind the knee, two long antero-medial and antero-lateral slabs are applied from mid-thigh to foot. These are fixed with an open-wove bandage. The foot is steadied by one orderly while the second does the plastering.

FIG. 3 (2).—Long leg splint.

These methods are applicable to patients being treated at the filter unit, but it may well happen that a patient admitted to hospital with another injury may also have a fracture, in which case a plaster splint could be made in the hospital ward. This is the reason why I include a chest plaster—a simple plaster encircling the thorax—which has been devised in consultation with thoracic surgeons for bilateral rib fractures or floating sternums in which there is paradoxical movement of the chest wall. I am assured that this plaster does help to fix the chest wall and enable the patient to use his diaphragm to the best advantage.

Lieutenant-Colonel R. S. Hunt: *The Treatment of Mass Burns Casualties*

The effects of the Japanese bombs, H-bomb tests, and various civil disasters have been the basis of all planning. However, in the Services let us remember that we may have to face nuclear attack anywhere in the world, on land, on sea, in a city or in a desert. Wherever it may be, the number of casualties will far exceed the available medical aid. The magnitude of the problem is illustrated by the estimate that if a 10-megaton weapon exploded over London, there would be 135,000 cases of burns!

The questions are *what* do we do in the way of treatment, and *how* do we do it?

As far as burns are concerned we must apply the principles adopted in peacetime, modified to suit these particular circumstances. Our main object is "to do our best for the most". Authorities tell us that one-third of the burns will be "minor" cases able to look after themselves and each other, one-third will be "moderate" and will require energetic treatment, and one-third will be so severe as to be "non-transportable"; a better term than "hopeless". It is the middle group that we must concentrate on, 20 to 40% body surface burns, and they will include women and children as well as young people and old. Throughout treatment we must do our utmost to keep their spirits high.

I think it is agreed that the care of the burnt surface is of secondary importance and should be deferred until the general state has been stabilized by adequate fluid replacement. Here we run into difficulties straight away. First, blood will be virtually unobtainable and plasma expanders will have to be used instead. Second, many of the usual sites for intravenous infusions may be burnt and "cut downs" will be needed to introduce plastic tubes. To avoid repeated operations of this sort and to encourage the drip to run for longer it helps to put 10 c.c. of a 1% solution of procaine into the infusion bottle. Fluids must not be given at random but according to physiological needs with a balanced intake and output. In times of stress like this, with a gross shortage of staff, anything that will help us to calculate the volume of fluid required and to measure the output is to be commended. For the first of these the chart shown in Fig. 1 contains much useful information. For the second, it has been suggested that an indwelling catheter draining into a bottle would be a quick way of seeing if the urinary output was adequate.

Penicillin and streptomycin are probably the antibiotics of choice but there may be no choice and any that are available will have to be used instead. Sedatives will be needed too, but here again the choice may be limited.

There is a great difference of opinion about the best way to treat the burnt surface by "exposure" or "dressings". I do not honestly think that in these circumstances there will be any doubt as to which we will have to use. It will be the "exposure" method. Obviously there are exceptions for which the dressings available should be reserved. For example if a case was burnt back and front one surface would have to rely on dressings. Another example is burns of the hands which are best immobilized in the position of function in dressings. Now, in spite of all I have said there is one thing certain in a disaster like this, there is no room for differences of opinion. All cases will have to be treated according to a generally accepted method. To give way to the "man who knows a better way" will cause chaos. It is a waste of time and effort to keep changing treatment.

I cannot leave the heading "*What to do*" without briefly mentioning four urgent procedures.

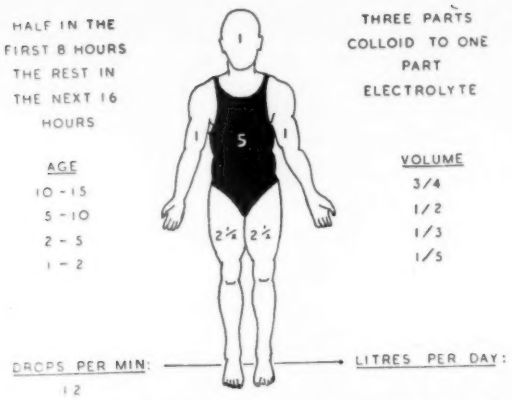

FIG. 1.—The figures on the limbs and body denote the number of standard transfusion bottles of fluid required in the first twenty-four hours.

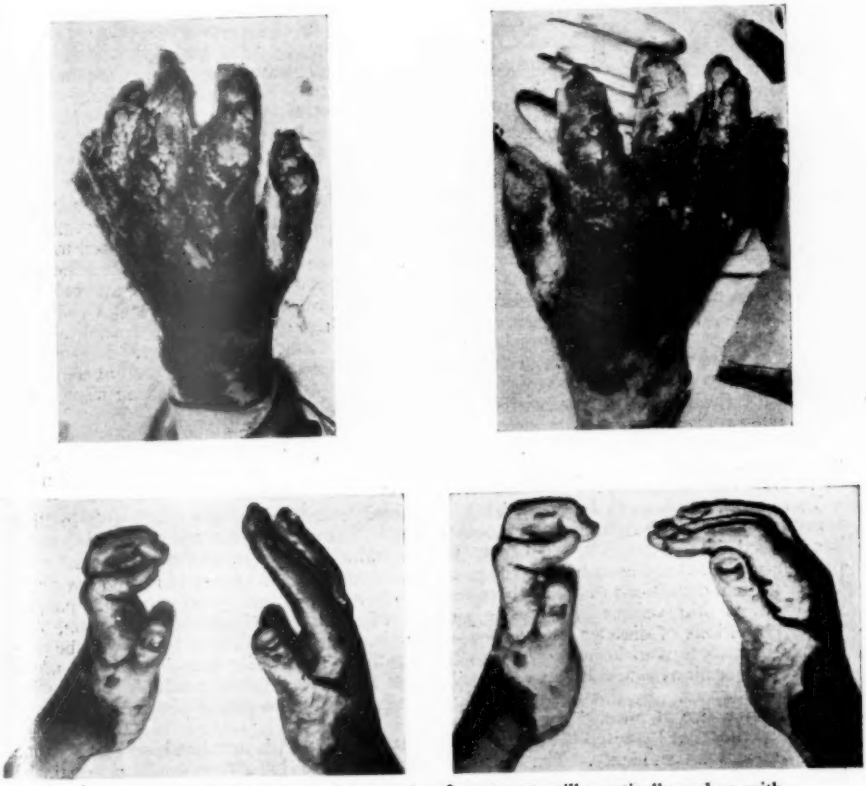

FIG. 2.—Hands, before and after months of treatment, still practically useless, with disorganized, immobile joints.

Tracheotomy for burns of the air passages, tarsorrhaphy to lessen the chances of blindness, and gastric suction for those who develop acute dilatation of the stomach. Last, but not least, amputation. I am sure that amputation in selected cases will convert severe cases to moderate ones or even moderate to mild ones. The obviously pickled hand with thrombosed veins and marbled insensitive skin is better off than allowed to remain and intoxicate the patient in the chance that something useful could be made of it after months of suffering and effort. Fig. 2 is an example of what I mean. The same applies to a completely charred limb.

When thinking of operation it is important to remember that it should be done within the first forty-eight hours if healing by first intent is to take place. After this time the effects of radiation, causing leucopenia, begin and healing is delayed with an increased risk of infection. Do not forget that burns cases may have other injuries as well which require operation before the burn can be treated!

So much for the general principles. Now *how* to carry them out with this vast disproportion between patients and staff? I think there are two main elements in this compound problem, one is *time* and the other *numbers*. We must reduce the *number* of patients and increase the medical man-power! Both can and must be done if the nation is to survive. How?

(i) *By evacuating likely target areas of all but essential workers.—Not* a medical responsibility but a great help.

(ii) *By educating the public in methods of self-protection and self-help.—Partly* a medical responsibility. A part of training which we all tend to forget.

(iii) *By the careful sorting of casualties.*—This is the most important consideration of all for doctors. To be effective it must be done by the most experienced doctor available, as near the scene of the disaster as possible and as soon after it as possible. The choice of category lies between the following, or any combination of them, and it may be very difficult:

Minor burns.
Moderate burns.
Severe burns.
Complicated burns—with other injuries as well.
Partial skin thickness.
Full skin thickness.
In the young and in the old.

As a guiding rule young people would take preference over the old in this fight for survival. No case will be denied treatment simply because the patient has been exposed to radiation.

Minor burns will not be a full medical responsibility. They will be encouraged to look after themselves and each other and here there is a tremendous scope for someone with a little imagination and organizing skill. Imagine a centre on the lines of a "help-yourself" canteen. A man at the door to direct you to the appropriate counter according to whether you had face, hands or body burns. Drugs and dressings on the counter, instead of buns and biscuits, to put on your tray or into a bag that you collected at the door. Instructions instead of price tabs and a drink of "salt and soda bic." instead of paying cash at the desk! Do not be too critical of this rough idea. It is merely food for thought and I suggest a visit to the Business Efficiency Exhibition might give better ideas!

So much for some ways of reducing the patients. Now to increasing the medical man-power, particularly the nursing strength, for the nursing of burn cases is of paramount importance. There are many ways but one is outstanding and time prevents discussion on the others. It is *training*.

Team work is essential, *but* it is virtually impossible to have trained teams able to stick together and be at the right place at the right time. To overcome this our Director-General has decreed that everyone in our Corps shall be trained to carry out a limited number of procedures considered essential for the preservation of life for a period of four or five days. Under normal conditions many of these would only be performed by fully qualified people, for example intravenous infusion, aspiration of pleural cavities, catheterization, &c. Under conditions of disaster it would be justifiable, and indeed essential, that they be performed by people who know *how* to do them without necessarily knowing *why* or *when*. These two questions would be the responsibility of the medical officer available to deal with hundreds of cases. By this means it will always be possible to get a fully trained team of at least some size at once.

I said earlier that I wanted to say something about *time*. This problem is so vast because it all happens so suddenly. The time taken to produce 135,000 cases is concertina'd into a few seconds. *Time* has been lost to us. If when we plan we start by thinking how to make up for lost time we will automatically make time to deal with more cases, and make time for the small staff to do more work, or in other words, we will increase the man-power.

BOOK REVIEWS

Postural Drainage. By E. Winifred Thacker, M.C.S.P. (Pp. viii + 56; illustrated. 8s. 6d.) London: Lloyd-Luke (Medical Books) Ltd. 1956.

This little book by the Superintendent Physiotherapist at Harefield Hospital admirably achieves the objectives of the author which are to illustrate the technique of postural drainage and to demonstrate the important place which expert physiotherapy occupies in the treatment of chest disease. As Mr. T. Holmes Sellors remarks in his Foreword: "This development in the realm of physiotherapy is a special contribution that has been made by British workers . . .", a statement which this book bears out. It is short, it is clearly written, and it is fully illustrated. Miss Thacker has been at pains to lay stress upon the practical details of the subject and she gives many valuable hints in the management of patients which are seldom found in other accounts. This monograph can be confidently recommended to anyone who is interested in this side of chest work.

Functions of Autonomic Transmitters. The Abraham Flexner Lectures, Series Number Thirteen. By J. Harold Burn, M.D. (Pp. ix + 228; illustrated. 40s.) Baltimore: The Williams & Wilkins Co. London: Baillière, Tindall and Cox. 1956.

The Abraham Flexner biennial lectures at Vanderbilt University form a heterogeneous series but all have been given by experts and Professor Burn's contribution keeps up the tradition.

The first lecture of general interest is, appropriately enough, on medical education. Here he makes a plea for the greater use of the preclinical sciences and their exponents in the teaching of clinical medicine in Britain, and in his short review of the development of the medical sciences he comments on the latency of important ideas until the time or the necessary techniques are ready to show them to advantage. The next five chapters, on acetylcholine and the heart, ciliary movement, norepinephrine, common properties of different classes of drugs, and the supersensitivity and subsensitivity of denervated structures, form a unified whole leading us through many of the by-ways of pharmacology in search of a common principle of action. The relation of acetylcholine to the genesis of the heart beat is a subject the author has made peculiarly his own. The pharmacology of ciliary movement is dealt with similarly on the theory that rhythmic activity is maintained by the local production of acetylcholine. Then norepinephrine, the most recent addition to the autonomic transmitters, is studied and contrasted with epinephrine. In the chapter devoted to common properties of drugs an endeavour is made to relate these to common modalities of action. This is followed by a study of the factors involved in the sensitivity of denervated structures and its complexity is made obvious. The last chapter is in some ways out of context, dealing with alcohol and nicotine, but even here the Oxford laboratory has contributed to this type of problem. The lectures are a distillate of the work of an active school of pharmacology in which the author has provided many of the stimuli and it is a delight to see the many strands of information brought together and beginning to show a pattern. Since it cannot be regarded as a systematic treatise there is more place for the discussion of matters still open, thus giving an insight into the trends of present-day physiology and pharmacology and allowing the reader to draw his own conclusions. The style is characteristic and clear and the production of the book excellent.

Physiopathology of the Reticulo-Endothelial System. A Symposium organized by the Council for International Organizations of Medical Sciences. Edited under the direction of B. N. Halpern by B. Benacerraf and J. F. Delafresnaye. (Pp. xii+317; illustrated. 45s.) Oxford: Blackwell Scientific Publications. 1957.

The group of workers brought together for the symposium has been selected with sufficient catholicity for the result of their discussions to give an adequate coverage of the present-day knowledge of the functions of the reticulo-endothelial system in health and disease. The introductory lecture by Vallery-Radot on the development of the ideas on phagocytosis and the reticulo-endothelial system is very interesting. His personal links with many of the more important earlier workers give his descriptions an intriguing liveliness. After a description of the reticulo-histiocyte, the principles of the determination of the shape and size of globular proteins are discussed. Then some of the factors involving physiology of the phagocytic function come under review. The general physiology of phagocytosis and the clearance of particles from the blood stream; the effects of variations in particle size on the rate of clearance; the importance of the rate of blood flow through the main RES organs such as the liver, and the effects of blockage by previous particle injections are next considered. Then the liver and the Kupffer cell and the interrelationship with cholesterol metabolism and the role of the RES in hæmatoclasia and iron metabolism come under

review in relation to the general functions of the spleen. The later papers deal with the involvement of the RES in the response to infections and endotoxins and the mechanisms of hypersensitivity reactions and changes in RES storage capacity. The last main paper contains a general discussion on the cells of the RES in health and disease. The interconnexions of this system in liver, splenic and humoral pathology are well outlined. Each paper has a summary either in English or French. The French editors have produced not only a well-edited symposium but an up-to-date reference work on the subject. The book is well produced and the price reasonable.

The Doctor, His Patient and the Illness. By Michael Balint, M.D. (Pp. x+355. 40s.) London: Pitman Medical Publishing Co. Ltd. 1957.

This book sets out the results of research into the doctor-patient relationship made over a period of two or three years by fourteen general practitioners and a psychiatrist. The general practitioners attended once a week as far as possible. To quote the author:

> The special nature of the research not only required frank disclosure by them of many intimate personal details of their daily work, details which by general tacit consent are hardly ever made public; it also required acceptance of thorough and searching criticism of such details. Anybody reading this book cannot but be impressed by the amount and severity of criticism that was given and taken in good spirit during the research; all irritation, hurt personal feelings, vexation were either disregarded or tolerated to enable the research work to proceed.

Needless to say the author is a psychoanalyst. For the ordinary reader vexations have resulted which, it might be thought, can be neither disregarded nor tolerated. Case histories are set out at length, having been faithfully recorded by a secretary, and nothing has been pruned for fear that hidden motives might determine the selection. The result is an intolerable prolixity. The author arrives at conclusions with which few would disagree and he has explained to us why we do not always go down well with our patients. Thus we are told that to tell a patient with symptoms that he has nothing wrong with him is a bad thing to do since it is clearly incorrect. Surely simple propositions of this kind are now accepted even in the teaching hospitals of whose deficiencies the author seems to be so aware.

Even if the reader is left wondering whether his journey through the book has been really necessary, there can be no doubt of the sincerity and conviction with which it has been written.

Rheumatic Diseases, Rheumatism and Arthritis. By Heinrich Brugsch, M.D., F.A.C.P. (Pp. xiv+330; illustrated. 80s.) Philadelphia and Montreal: J. B. Lippincott Co. London: Pitman Medical Publishing Co. Ltd. 1957.

This book is not intended to be a textbook, but an introduction to the subject of the rheumatic diseases. It does not, therefore, suffer from the usual defect of larger books on the subject, namely the obscuring of practical advice by an abundance of theorization, and reports of purely negative research. In spite of the rather tiresome title, the book gives a succinct and largely accurate account of the practical handling of those painful disorders of locomotion for which no satisfactory group title has yet been found.

In format the book closely follows the larger textbooks on the subject, the clinical theme being developed through chapters on statistics, anatomy and physiology, clinical examination and laboratory procedures. In addition to chapters on the chronic articular rheumatic diseases, there are chapters on the diffuse collagen diseases, and on infective arthritis. It is somewhat surprising to find Sjögren's syndrome included in the latter. It is also somewhat confusing that the last chapter is entitled "Diseases Simulating Rheumatic Diseases", whereas the first section of this chapter is devoted to "Nonarticular Rheumatism". The information given is up to date, lucid and practical, though certain surprises await the British reader. For instance, we are told that the term "atrophic arthritis" is preferred in Great Britain; that cinchophen should be used in chronic gout; and that a diagnosis of pleurodynia is acceptable in the presence of a pleural effusion. These defects, however, are few though the excellence of the text is somewhat marred by the poor quality of some of the illustrations.

This is a book which can be thoroughly recommended to the senior student, and as initial reading for the post-graduate student. The latter may well take advantage of the extensive bibliography which appears at the end of each chapter.

Surgery of the Anus, Anal Canal and Rectum. By E. S. R. Hughes, M.D.Melbourne, M.S.Melbourne, F.R.C.S.England, F.R.A.C.S. (Pp. xi+304; illustrated. 50s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

In this book the author describes theory and practice in the surgery of the anus, anal canal and rectum which he has found to be adequate; he has not sought to write a reference book. His training in this speciality and present opportunities to practise it have fitted him to achieve his objective. The general classification of the subject-matter follows the accepted helpful

pattern; the early chapters deal with surgical anatomy, symptoms and investigations. In the former chapter the extent of the rectum is defined as from the recto-sigmoid junction to the ano-rectal ring but the author states it is difficult to define the position of the junction with the sigmoid. This is an important point in deciding whether an anterior resection of the rectum should be done for carcinoma. The author points out that anatomists place the junction opposite the third piece of the sacrum; at this point the sigmoid mesentery ends and it is about 15 cm. from the anal orifice on sigmoidoscopy. The treatment of ano-rectal surgical wounds is of practical interest and the author describes the advantages of primary suture and primary free skin grafting. After excising a large fistula the control of hæmorrhage may not be adequate for immediate skin grafting and a delayed primary skin graft is advocated. Technical difficulties encountered with the latter are outweighed by the advantages obtained by the patient.

It is gratifying to read in the post-operative treatment of hæmorrhoids that the rectal tube has no particular value and that the bowels can act when the urge arises within twenty-four to thirty-six hours after operation. The author deals with carcinoma of the rectum in a full and practical manner—the standard operation is the abdomino-perineal excision of Miles and the synchronous combined method is well described. Regarding the perineal dissection the author rightly states that the posterior end of the wound heals better if it deviates to one side of the mid-line out of the natal cleft and a wide area of skin need not be excised. But is it always necessary, or advisable, to excise the coccyx? If the carcinoma invades the vagina it should be stressed that a Wertheim's hysterectomy should be combined with the Miles' procedure.

The author regards the anterior resection of the rectum as the procedure of choice for tumours in the upper third of the rectum. It must be clearly stated that patients for the operation must be selected carefully and a meticulous operative technique employed to minimize the risk of recurrence. The historical appendix forms a fitting ending to a book which is well written, replete with illustrations clear and valuable, and full of practical instruction for those who are engaged in this speciality. This book is a most helpful addition to the literature of the subject and is strongly recommended.

Operative Surgery. Editors: Charles Rob, M.C., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. In 8 volumes and index. (Volume 4 Head and Neck and Clearance of Lymph Nodes. Vascular Surgery. Endocrine Glands: illustrated. £5 10s.) London: Butterworth & Co. (Publishers) Ltd. 1957.

With the appearance of the fourth volume, the half-way point has been reached, and one can begin to form a judgment on the work as a whole. The favourable impression created by the earlier volumes is confirmed, and it now seems unlikely that the subsequent volumes will alter this verdict. The subjects now dealt with are the head and neck, clearance of lymph nodes, vascular surgery, and the endocrine glands. Only minor procedures are dealt with in the Head section, and presumably major procedures will be considered in a subsequent volume. This section illustrates the difficulties of selection confronting the editors of a work such as this, but it is questionable whether excision of a sebaceous cyst of the scalp merits inclusion. Since it has been included, it is a pity that the author has rejected the very simple and efficient procedure of transfixion-enucleation. Throughout the Neck section, the importance of cosmetic skin crease incisions is rightly stressed, but in some chapters might have been more stressed. There are very few neck operations in which long skin crease incisions, if necessary multiple, cannot be made to give perfect access. In this section, Raven's chapters on carcinoma of the pharynx and Ewing's on block dissection of the neck may be specially mentioned. In the chapter on excision of axillary lymph nodes, one is surprised to see the fallacy still persisting that excision of the sternal part of the pectoralis major is necessary for adequate exposure of the axilla. There are good accounts of the various operations for carcinoma in the region of the oral cavity, but in the chapters on carcinoma of the tongue and lip, there is no mention of any other treatment but surgery. If radiotherapy is to be completely ignored, why have a paragraph on indications at all? In the section on the salivary glands, if Pattinson's advice on the technique of sialography is followed, the damage so often caused by this procedure in the parotid gland will be avoided. There is a description of parotidectomy with conservation of the facial nerve modified from the technique of Redon, who in France during the last war was responsible for the establishment of the operation as a standard procedure. Up till now, detailed accounts of this operation in the English literature have been both rare and difficult of access. In the operation of removal of the submaxillary gland, the importance is emphasized of Hayes Martin's manœuvre of identifying the cervical branch of the facial nerve as it crosses the facial vessels and before these vessels are secured. It is surprising how many surgeons still do not realize that by omitting this simple little anatomical exercise during removal of the submaxillary gland they

are condemning 50% of their patients to a permanent wry mouth. In the Vascular section, Cockett's article on ligation of the ankle perforating veins, and Eastcott's on exposure of and grafting operations on arteries are worthy of special mention, as well as Mowlem's straightforward account of excision of subcutaneous tissues for lymphedema, in which once classical procedures which have failed to stand the test of time are mercifully not mentioned. In the section on the Endocrine Glands, it is interesting to note that the author has come down on the side of routine identification of the recurrent laryngeal nerve during thyroidectomy. The inclusion of a chapter on interstitial irradiation of the pituitary, however, is premature. In the section on operations on the adrenal glands, the lumbar, abdominal, and transdiaphragmatic routes are all described. Space will not allow of further detailed criticism, but enough has been written to indicate why this volume has created a favourable impression in spite of some minor weaknesses.

Modern Trends in Geriatrics. Edited by William Hobson, B.Sc., M.D., D.P.H. (Pp. vii + 422; illustrated. 72s. 6d.) London: Butterworth & Co. (Publishers), Ltd. 1956.

"Modern Trends in Geriatrics" is an excellent textbook on the subject and although it is obviously intended mainly for medical personnel many others working in a therapeutic team will find much of interest to study in this work.

It is clear that Professor Hobson has a deep interest in and a wide grasp of the subject and of its importance in the field of Medicine.

In editing this work and writing two sections himself he has made a valuable contribution and as the remaining sections have also each been written by experts a high standard has been maintained throughout the book.

For many the first chapter on "General Problems of Ageing" will prove a most interesting introduction, as it includes a short historical survey and refers to Demographic Changes, Social Pathology of Old Age, The Growth of Social Services for the Aged and Prevention of Disease and Disability in the Elderly. This section contains much useful information, reflects a sound philosophy on the subject and offers sound advice.

Next follow several fascinating chapters on "Ageing from a Biological and Cellular point of View" by Bourne. "Normal Values and the Interpretation of Biochemical Data in the Elderly" by Jordan and "Psychological Aspects of Ageing" by Welford. These sections bring to the clinician results of research and thus explain some results and reactions found amongst the elderly not hitherto fully understood.

These chapters are followed by subjects more familiar to the clinician including "Arteriosclerosis and Hypertension", "Glycosuria and its Significance", "Chronic Bronchitis in the Elderly", "Skin Conditions in the Elderly", "Gynæcology in Senescence and Senility", and "Orthopædic Surgery in the Elderly". Each chapter deals with the subject in a modern and scientific yet practical way and discusses problems which are of considerable importance to those working in the respective fields of Medicine.

The chapters on "Therapeutics in the Elderly" and "Nutritional Problems of the Elderly" each cover a large subject briefly in such a way as to be equally instructive to the student and to the graduate.

Among the final chapters "Hospital Care of the Elderly" by Morton is useful in summarizing the role and general principles of a geriatric unit which have now been in operation in the earlier-established units for about fifteen to twenty years, and which may therefore be used as a safe pattern on which to build for the future.

It is very appropriate that the last two chapters deal with "Problems in the Home Care of the Elderly" and "Employment, Retirement and Health", for no study of Geriatrics could be considered as complete without consideration of these aspects.

The whole textbook is well illustrated with diagrams, graphs, figures and photographs and has a good index.

This is a book which should be read widely and studied by practitioners and consultants working in all fields of Medicine and should find a place in all hospital libraries.

The subject, an important one, is presented well with interest, factual data, the results of modern research and with sound practical advice based on experience.

"Modern Trends in Geriatrics" is treated essentially from a medical point of view, but sufficient reference is made to the social impacts upon old age and ways in which these can be treated to make it more useful and more practical than the average textbook of medicine.

The problems of the elderly sick and the role of Geriatric Medicine in the health of the population is known to many, but how much can be done to prevent disease and to alleviate, in a scientific way, the ills and disabilities of the old is still only partially appreciated and Professor Hobson has done well to introduce the subject for study in an academic atmosphere.

Clinical Electrocardiography. Interpretation on a Physiological Basis. By Manuel Gardberg, M.D. (Pp. xi + 315; illustrated; 95s.) London: Cassell & Co. Ltd. 1957.

There has been a recent spate of works dealing with clinical electrocardiography; this book adds to the flood. It purports to interpret the cardiogram on a physiological basis, and rightly emphasizes the influence of the heart's position on the tracing both in healthy subjects and in patients with heart disease. None the less, no advantage is taken of the valuable procedure of partially correcting the heart's unusual lie in relation to a high diaphragm by recording the tracing from a lead connected with the left leg during deep inspiration.

The author's zeal for explaining every departure of the cardiogram from the normal by reference to the electromotive forces, has meant the introduction of numerous complicated line diagrams whose reading is exceptionally laborious. The quality of the electrocardiograms is often indifferent, and the tracings are frequently artificially improved, while the obsolete lead CF_4 is sometimes shown.

The order in which the various cardiographic changes are described is haphazard. Thus, left and right ventricular preponderance are dealt with in chapters separated by three others. Again, injury to the heart, instanced by cardiac infarction, is separated from a description of coronary disease by four chapters, and of ischæmia by three. Many conditions like hypertension, syphilitic heart disease, mitral and aortic valve disease, congenital cardiovascular disease, pericarditis and anæmia, get scant attention.

To those who appreciate a physiological exposition of the changes in the electrocardiogram in diseased states, this book may give satisfaction, but it is not recommended as a comprehensive work on electrocardiography as applied to the elucidation of the condition of the heart affected by diverse diseases.

Vitamin A. By Thomas Moore, Sc.D.Cantab., D.Sc.Belfast. (Pp. xx + 645; illustrated. 76s.) Amsterdam, London, New York, Princeton: Elsevier Publishing Co. London: Cleaver-Hume Press Ltd. 1957.

In this substantial monograph, the author has presented a broad and detailed survey of present knowledge of the biochemistry of vitamin A and its place in the metabolism of man and animals. It may be stated at once that the whole treatment is scholarly and authoritative. Not only has Dr. Moore himself taken for many years a foremost part in investigations upon this vitamin, but he has been indefatigable in collecting and collating the work of some two thousand other authors whose publications are reviewed and recorded in his very comprehensive bibliography.

The book is divided into eight parts. The first four, comprising thirteen chapters, are devoted to the biochemistry of the vitamin, its estimation by various methods, its chemical structure and its sources in nature. These chapters will prove of especial value to biochemists and others who may be interested in this branch of nutrition, for they contain a wealth of practical information. These parts are succeeded by a long one containing ten chapters upon physiology and metabolism, which in turn is followed by three parts, divided into sixteen chapters, in which the manifold pathological effects of deficiency or excess of the vitamin on man and animals are considered in great detail.

In its general plan, each chapter is more or less independently constructed as an historical essay—the sequence of relevant discoveries being traced successively from the earliest and most nebulous suggestions to the clearer and more defined concepts current to-day. A book primarily designed on such chronological lines has advantages and drawbacks. While it records the development of ideas clearly, and with fairness to many pioneers in vitamin research now in danger of being forgotten, it equally entails the perusing of much material, some of it now greatly outdated, before the current views in the particular matter are reached. The book will therefore prove particularly attractive to biochemists and physicians to whom a study of the evolutionary development of this branch of the science of nutrition presents an especial appeal. In this scholarly approach, the book is a model of clear exposition.

Dr. Moore has produced a monograph that reflects great credit on British biochemistry; it will long remain an authoritative source of information and reference upon all questions that relate to the chemistry, physiology and pathology of this important vitamin. The production of the book, which has been beautifully printed in Holland, could hardly have been improved upon, and the author and publishers are to be congratulated on the many aids to ready reference that they have introduced for the convenience of readers.

Medicine and the Navy, 1200–1900. Volume 1 (1200–1649). By J. J. Keevil, D.S.O., M.A., F.S.A., M.D., Surgeon Commander R.N. (retd.). (Pp. viii + 254; illustrated. 40s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

It is indeed remarkable that until the present time no comprehensive work has appeared on the history of our Navy's medical service, but it is a matter for congratulation that the omission is now to be so handsomely corrected. The Wellcome Trustees have supported the present enterprise and there can be no one better qualified in every way than Surgeon Commander Keevil to carry it out.

The author has precisely the right attributes for the task in hand. A regular medical officer in the Royal Navy, he served with gallantry and distinction in the recent war, latter being responsible for the production of a new manual for sick berth attendants. Since the war he has become an historian and antiquarian of note and two delightful books "Harvey the Stranger" and "The Stranger's Son" have already appeared from his pen. His present task: to trace the story of naval medicine from 1200 to 1900 is obviously his *magnum opus* and the first volume which takes us up to the execution of Charles I is a fascinating work, a veritable source book for an immense amount of little known material and written withal, in a pleasant easy style.

No one who has had to prepare a Hurt Certificate for a naval rating could fail to be intrigued with its antecedents "The Laws of Oléron" which Henry II's Queen Eleanor brought to this country in 1154. In mediæval times, there were few provisions for the sailor who fell sick, or what was much less likely, wounded in battle. Hospitals like that of St. Mary at Chichester provided care for a few who were then tended by monks.

The old conflict between physician and surgeon found its counterpart afloat and the ship's surgeon, who for centuries professed little physick, was at a great disadvantage when so many more of his charges died from conditions allied to the inadequate victualling of ships for long voyages and so few from the wounds of naval engagements. William Clowes, in the latter part of the sixteenth century, stands out as the leading barber-surgeon author afloat but he was to leave the Navy and join St. Bartholomew's hospital staff. Clowes knew much about scurvy, one of the greatest scourges of seamen and associated it with their diet, but a hundred years earlier Richard Hawkyns, a model commander if ever there was one, had discovered "that which I have seen most fruitfull for this sicknesse, is soure Oranges and Lemmons. . . ."

This excellent book is an essential for every medical library and there can be few doctors who have served afloat who will not want to own it for themselves. The subsequent volumes will be awaited with eagerness and pleasure and the completed series will become a standard work of reference. The typography is good and the index and chronology admirable but the wide pages with their long lines of print are tiring to the eyes. If the size of volume is to remain the same it would be a real comfort to have it printed in double columns on each page.

Pelvimetry. By Herbert Thoms, M.D. (Pp. 120; illustrated. 37s. 6d.) London: Cassell & Co. Ltd. 1957.

This small book is written by an acknowledged master of the subject of X-ray pelvimetry. Within its compass it encloses detailed and comprehensive information on a subject which is now regarded as an essential part of modern obstetrics. No part of the subject is omitted. There are descriptions of the techniques of taking and interpreting X-ray pelvimetry and the clinical aspect, including the importance of taking clinical findings into account with the radiological findings, is always kept in the reader's mind.

Dr. Thoms has developed his own essentially logical classification of the basic shapes of the pelvis; this is at variance with that, perhaps better known, of Caldwell and Moloy, though from a practical point of view the differences in classification are mainly academic. There is also little to be found about cephalometry and of the fact, so essential in the diagnosis of cephalo-pelvic disproportion, of the importance of the size of the fœtal skull in relation to the maternal pelvis.

Dr. Thoms is an enthusiast for X-ray pelvimetry and recommends that at least one view of the pelvis should be taken in every primigravida. No doubt his manuscript was finished before work in this country and elsewhere drew attention to the possible dangers of irradiation of the unborn child. Many obstetricians will now feel reluctant to undertake X-ray pelvimetry except in cases where it is felt necessary on clinical grounds to have an accurate assessment of pelvic capacity, such as can only be obtained by the use of X-ray pelvimetry.

Obstetricians and radiologists will find this book of the greatest value, not least for its concise and well-written text and for its excellent illustrations.

Section of Anæsthetics

President—KATHARINE G. LLOYD-WILLIAMS, C.B.E., M.D., F.F.A.R.C.S.

Problems of Anæsthesia in Relation to Cardiovascular Surgery

By OLE SECHER, M.D.
(*Copenhagen*)

CARDIOVASCULAR surgery was started in the University Hospital, Copenhagen, about ten years ago, under the direction of Professor Husfeldt. During this decade there has been great development in this field; not only in surgery, but also in diagnostic procedures and anæsthetic technique. Diagnosis has become more accurate, new operations have been introduced, and a greater variety of heart malformations have become treatable by surgery. Anæsthetic technique has improved tremendously; new fields have been opened up by means of hypotension and hypothermia, and we have developed a safe standard technique, using superficial anæsthesia in combination with curarizing drugs; all these have contributed towards ensuring a satisfactory outcome for the patient.

The number of cases presenting for heart surgery has steadily increased over the last ten years: by January 1, 1957, there was a total of 1,005, of which 172 occurred in 1956. In this paper I shall discuss some of the problems which may be encountered in this more specialized form of surgery and anæsthesia. Table I represents a summary of the material on which our experience is based and which covers nearly all the branches pertaining to this form of surgery. In other centres, a greater total number of cardiac operations has been performed, but the field has not been so wide.

The largest section of this material is divided into three main groups: patent ductus, tetralogy of Fallot and mitral stenosis. In the other groups a large number of atrial septal defects has been treated and also many pulmonary stenoses with only one fatality. The number of aortic stenoses has been very small and the results extremely bad. Operations for the relief of coronary sclerosis have been few.

I should like to say a few words about some of the physiological principles underlying the choice of anæsthetic technique. A clear understanding of the importance of CO_2 elimination is necessary in order to provide the surgeon with the best operating conditions, and to maintain the patient in a satisfactory physiological state.

Cardiac disease can be divided into two main categories, congenital and acquired. The first can be subdivided into cyanotic or non-cyanotic. The presence of cyanosis will depend upon the pressure conditions in the right and left side of the heart and the character of the shunt. Therefore it may be seen that any excessive positive pressure used for ventilation which causes diminution of the pulmonary circulation is undesirable in a patient already suffering from a poor pulmonary circulation. For this reason we have given up completely the use of a respirator for these operations. A diminished pulmonary circulation will also result in a slowing down of the time of uptake and exchange of anæsthetic gases, and therefore it is advisable that only the rapidly acting anæsthetic gases should be used. For this reason ether has been given up completely; it also increases hæmoconcentration, and

this is an undesirable side-effect in a patient with a very high hæmoglobin, such as may occur in cases of tetralogy of Fallot.

Maintenance of effective ventilation of the patient is difficult during certain parts of cardiac operations, firstly on account of the collapsed lung, and secondly due to the effects of a partial or complete clamping of the pulmonary artery in a patient already suffering from an inadequate lung circulation. Furthermore the delicate surgical work in progress demands that movements of the mediastinum shall be minimal. Therefore, for children, a special anæsthetic technique is used in which a rapid, small-pressure ventilation of from 40–60 per minute is maintained by means of specially designed equipment (Secher and Nyrop, 1955), utilizing a closed "to-and-fro" system with absorption ensuring a very small "dead space". Measurements of body temperature during the use of this equipment have shown that no elevation occurs—even on a warm summer day.

Anæsthesia is normally induced in adult patients by giving a barbiturate intravenously; when sleep ensues N_2O is added using either a "to-and-fro" or a circle system. Relaxation is obtained with curare, Flaxedil or Laudolissin. With regard to the more specialized anæsthetic apparatus an electrocardiograph working in combination with an oscilloscope is considered necessary. Also of great importance is an electric defibrillator and an electric thermocouple to measure temperature. A capacity manometer is used for assessing the results of the surgery during the course of the operation. All this apparatus is mobile and can easily be transported on one trolley.

Patients with a high hæmoglobin tolerate thirst badly and are therefore operated upon early in the day. Patients with pericarditis should have the chest aspirated before commencement of anæsthesia. Digitalization is only carried out if considered essential. For the

majority of cases we use morphine-atropine premedication, and complications from this have not arisen (Baden *et al.*, 1955).

Cyclopropane is the anæsthetic of choice for children following induction with nitrous oxide. We usually carry out induction with the child sitting up. The use of the curarizing drugs is restricted to older children and adults. The reasons for this choice of anæsthetic technique are, firstly, that with cyclopropane it is always possible to have the patient fully conscious at the conclusion of the operation and, secondly, we find it difficult to calculate the dose of curarizing drugs necessary for the small child, also we wish to avoid the use of atropine and neostigmine post-operatively. The latter criterion applies also to adults. During operation we avoid the use of additional drugs (such as procaine, quinidine, &c.) apart from those used for the treatment of cardiac arrest. After the thorax is opened, blockage of the vagus on the same side as the operation is carried out with local analgesic.

One result of the development of cardiac surgery is that a substantially larger number of poor-risk cases come for surgery. This is seen especially in the case of children under one year having exploratory thoracotomies, pleural patent ductus cases with a high pulmonary pressure, and in the number of reoperations.

A number of patent ductus cases have been operated upon under hypotension, and some of the worst-risk patients have undergone hypothermia. Hypotension has been used for coarctation operations with excellent results.

The difficulties encountered when undertaking anæsthesia for the patient with cardio-vascular disease are often fewer in number than might be expected in these poor-risk patients. On the other hand when complications do arise, they will as a rule be of a more serious nature than those commonly met with in other branches of surgery. Some of the frequently occurring problems may be classified as follows:

(1) *Apparatus.*—Very often we are called upon to treat babies and very small children, and here special baby-equipment is required which reduces "dead space" to a minimum if complications are to be avoided. The technique used is of less importance, but it is vital that a free airway and adequate ventilation be maintained.

(2) *Anæsthetic complications.*—Most patients tolerate anæsthesia exceedingly well and when difficulties arise they are most commonly related to ventilation rather than to the actual anæsthesia. Frequently patients suffering from the more severe forms of heart disease will be better oxygenated under anæsthesia than in either the pre-operative or post-operative period. One complaint arising from the use of light plane anæsthesia and curare technique has been that some patients have said that they were awake during the operation, although they did not experience pain.

A fall in blood pressure is tolerated badly during cardiac surgery, especially when the cardiac reserve is small, but if possible we try to avoid the use of drugs in the treatment of this condition. Suspension of the operation and gentle inflation of the lungs is often sufficient. This sudden occurrence of hypotension is frequently seen when turning the patient at the start or end of the operation.

(3) *Free airway.*—Cases of vascular ring present a problem in the maintenance of a free airway because obstruction of the very soft trachea easily arises during the dissection. Lung œdema occurring during anæsthesia and operation has not been seen.

(4) *Cardiac function.*—Under this heading, or under that of cardiac arrest occur most anæsthetic errors of judgment, but it does not often prove possible to isolate these from other contributory factors. Poor heart action may result from inadequate ventilation performed with too high a pressure (this combination caused one of our deaths), overdosage of anæsthetic drugs, pressure on the heart, herniation of the heart through the pericardium, clamping of vessels and hæmorrhage. Anoxia and retention of carbon dioxide are also important. Poor cardiac function will usually improve if the operation is stopped and the lungs gently inflated.

(5) *Cardiac arrest.*—We have seen a large number of cases of cardiac arrest and although reluctant to obtain experience in this field, we have learned a great deal about the treatment of this condition. As a rule one can say that if cardiac arrest occurs where valvular stenosis is present, completion of the valvotomy is essential before any other treatment is attempted. Heart massage should be commenced at the earliest possible moment and further treatment will depend upon the condition of the heart in each individual case. We have achieved success with cardiac massage alone, with calcium chloride alone, or in combination with procaine and adrenaline; ventricular fibrillation has responded to the use of the electric

defibrillator and in 22 cases we succeeded in making electrocardiographic recordings during the period of cardiac arrest. [Examples were shown.]

(6) *Surgical complications.*—Hæmorrhage is by far the most dangerous complication. It may arise as a result of sutures cutting out, ligatures slipping, or directly from the rupture of vessels or myocardium. Maintenance of the blood volume presents the biggest difficulty. We prepare for this eventuality beforehand by setting up two intravenous drips, and by this means it is possible to give a large quantity of blood in a very short time. For example, in one case where an aortic aneurysm ruptured 11 litres of blood were given in twenty minutes.

(7) *Transfusion.*—Determination of blood loss during operation is often a major problem, especially when operating upon very small children, or when severe hæmorrhage occurs. In cardiac disease it is only too easy to give excessive amounts of blood or fluid. In our series there occurred two cases where one of the main factors leading to a fatal result was overtransfusion. During one period we attempted to estimate blood loss by swab washing; this method gave good results and helped to train the staff in estimating blood loss. Unfortunately, we were forced to abandon this method due to the laborious nature of the technique. The development of a rapid and accurate technique for the estimation of blood requirements during operation would be an invaluable aid to this type of surgery. We commonly find difficulty with blood from the bank as it seems to block the filters in the giving sets very easily; this may occur at a vital moment. As a rule we use percutaneous drips for adults, but in small children cut down on a vein and insert a polythene catheter. When urgent transfusion is required a form of roller pump is used.

(8) *Post-operative complications.*—Apart from the post-operative conditions common to any type of surgery, the main complications following cardiovascular surgery appear to be emboli, hæmorrhage (especially after Barrett's operation), cardiac insufficiency and difficulties in maintaining fluid balance. Manual ventilation in the immediate post-operative period may prove necessary, as respiratory insufficiency and the patient's inability to cough are likely to give rise to pulmonary complications. In cases of congenital heart disease relatively large doses of morphine post-operatively are advisable as uncontrolled pain will cause a build-up of "pressure respiration", accompanied by severe cyanosis, which must be avoided. In the case of patients operated upon for mitral stenosis, the circulation is unable to stand large quantities of fluid in the post-operative period, and only the very minimum which will maintain the patient in fluid balance should be given. If the operation has proved successful, the circulation will soon be able to mobilize the fluid in the tissues. A special group of patients are those who suffered anoxia during the operation; these were usually cases in which a period of cardiac arrest had occurred. I should like to illustrate this point with two short case histories; the difficulty of giving a prognosis in these cases will also be seen.

Case I.—Thoracotomy and valvotomy were performed upon a 48-year-old woman. Anæsthesia consisted of a barbiturate and nitrous oxide supplemented by Scoline and Laudolissin. Before the valvotomy, measurement of the pressure in the left atrium and ventricle was carried out by means of a capacity manometer. It proved impossible to perform a valvotomy by means of the finger alone, consequently a valvotomy saw was used. During this manœuvre, which occupied nearly five minutes and proved extremely difficult, a severe hæmorrhage occurred, the action of the heart became inadequate and cardiac arrest followed. Cardiac massage was immediately instituted, and 5 ml. of 10% calcium chloride was given to help maintain the tone of the heart muscle. This dose was repeated twice, and cardiac activity then became normal again. Cardiac massage had been given in all for twenty-two minutes.

Post-operatively the patient was unconscious, her left arm was limp and paralysed, the right arm flexed and spastic and small jerking movements were present in the right leg. Ten days later the patient reacted slightly to noise, but no contact could be made with her. After one month an improvement could be seen. She was more awake, but was still unable to answer questions. She could say separate words, but they had no connexion with the question asked. Two months later the patient was talking complete nonsense and having hallucinations. After five months she was swearing like a trooper, but had become more rational and orientated. Six months after the operation the patient could walk, but the extremities were somewhat spastic and the range of movements limited. She now began to develop aggressive tendencies. The question of an operation for her mental condition was discussed, but the idea was abandoned as it was thought that nothing useful would be achieved. The patient was discharged home eight months after the operation.

Case II.—A 10-year-old girl with pulmonary stenosis underwent a transpulmonary valvotomy using a "by-pass" technique, by means of a catheter which takes the blood beyond the stenosed part of the artery, while the clamps are on and the valvotomy performed.

Anæsthesia was induced with nitrous oxide and maintained with cyclopropane utilizing a closed system (to-and-fro); 10 mg. Laudolissin was given for additional relaxation.

After the by-pass catheter had been inserted, clamps were placed on the pulmonary artery and three to four minutes later the pulmonary artery was opened and remained open for about two minutes. At this time the pupils were of medium size. Ten minutes after the artery had been clamped, cardiac arrest occurred. Treatment by cardiac massage was immediately commenced and the by-pass catheter was removed. The pupils were beginning to dilate and five minutes after the onset of cardiac arrest were maximally dilated. 10 ml. of calcium chloride were given for maintenance of cardiac tone. Now came the onset of ventricular fibrillation and the electric defibrillator (1·5 amp., 0·5 sec. ×2) was used four times, but without effect. 6 ml. of 1% lignocaine were now injected, followed by 4 mg. adrenaline, and then again 5 ml. of lignocaine; a further shock was given with the defibrillator using 1 amp. 0·15 sec., and the heart returned to normal rhythm.

Post-operatively, the patient had twitchings of the extremities, was unconscious, pale and cyanotic, but the corneal and pupillary reflexes were present and she reacted to pain. Cooling was instituted in an attempt to reduce the cerebral effects of the anoxia which had occurred during the operation and also in order to prevent a further rise in temperature. The lowering of the body temperature was accomplished by means of ice, cold water, and fans, supplemented with Phenergan and pethidine. When the temperature had been lowered to 29·9° C., the patient's condition was seen to have improved. During the night the temperature rose slowly to around 36°C., and at this level there came rhythmical twitchings in the patient's left arm and leg. This was controlled with barbiturates and pethidine intravenously. The following morning the patient was still unconscious but we were able to remove the tube. Only isolated twitching movements were occurring now in the leg, and these could be controlled with intramuscular pentobarbitone. Her condition continued to improve during the day until in the evening she could be contacted sufficiently to answer questions adequately including remembering her age and birthday. The twitching in the left hand ceased, but the child seemed dazed and slow to react, and complained somewhat. However, a closer examination revealed that she had been in a similar state before the operation. Her mother is mentally defective. A psychiatric examination was carried out on the child, but did not reveal anything of importance, and she was discharged in good condition.

I should like to say a few words relating to our experience with hypotension and hypothermia. Hypotension was used in 16 cases of patent ductus, in which prior to operation there was a high pressure in the pulmonary artery and also for 34 operations for coarctation. In the former group 3 deaths occurred, but in the latter only 1. There are two main indications for the use of hypotension in an operation for patent ductus arteriosus. Firstly, in order to reduce the pressure in the ductus itself, and so minimize the risk of bleeding or rupture during the course of the dissection and ligation or division; secondly, to reduce the pressure and improve blood flow in the pulmonary circulation. The results obtained have been very satisfactory to the surgeons, but as I have stated there were 3 deaths in this group.

Recently we have tried in 2 cases to combine the use of hypotension during operation with pre- and post-operative dehydration; this apparently has given good results. Out of a total of 12 deaths occurring in the patent ductus group of operations, 8 of the patients had pulmonary hypertension prior to operation. These cases are definitely a poor risk, and some of them are quite unable to tolerate clamping of the ductus, as it appears to act as a safety valve.

In coarctation of the aorta the systolic blood pressure is often 200 mm.Hg and during the operation it may rise even higher, to be followed by a sharp fall when the anastomosis is established.

Induced hypotension is of great value in these cases, and in a typical instance where it was employed the blood pressure remained around 100 mm.Hg during the whole of the operation, only rising slowly in the post-operative period. We have not seen a case of kidney complication arising from the use of hypotension, and in the series there was one death (Secher *et al.*, 1956).

Hypothermia has been used on 23 occasions but was reserved for the very poor risk cases of which the largest group — 10 — had atrial septal defects (Fig. 1). One-third of these patients died and almost as many developed ventricular fibrillation during operation.

We found this latter condition difficult to treat in the hypothermic patient, and achieved no success either with drugs or the defibrillator until the œsophageal temperature had been restored to 32°–34° C. This was achieved by pouring about 150 litres of warm saline into the open thorax (Fig. 2) (Husfeldt and Secher, 1956).

In our department we have virtually abandoned the use of hypothermia; it did not prove as successful as we had hoped and the production of bradycardia was the only real advantage. Operations upon atrial septal defects can be carried out with greater safety without the use of hypothermia and the results obtained by using the closed method are just as satisfactory.

Of the 1,005 cases reviewed here 105 died (about 10%) and the main factors relating to the cause of death are set out in Tables II–VII, which are largely self-explanatory.

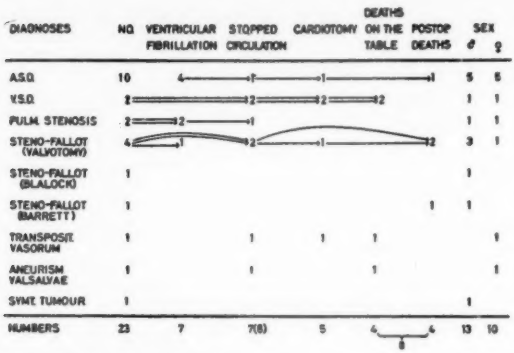

FIG. 1.—Records from the patients treated with hypothermia during operation. Each arrow represents one patient. By following the arrows the progress of each individual patient may be seen.

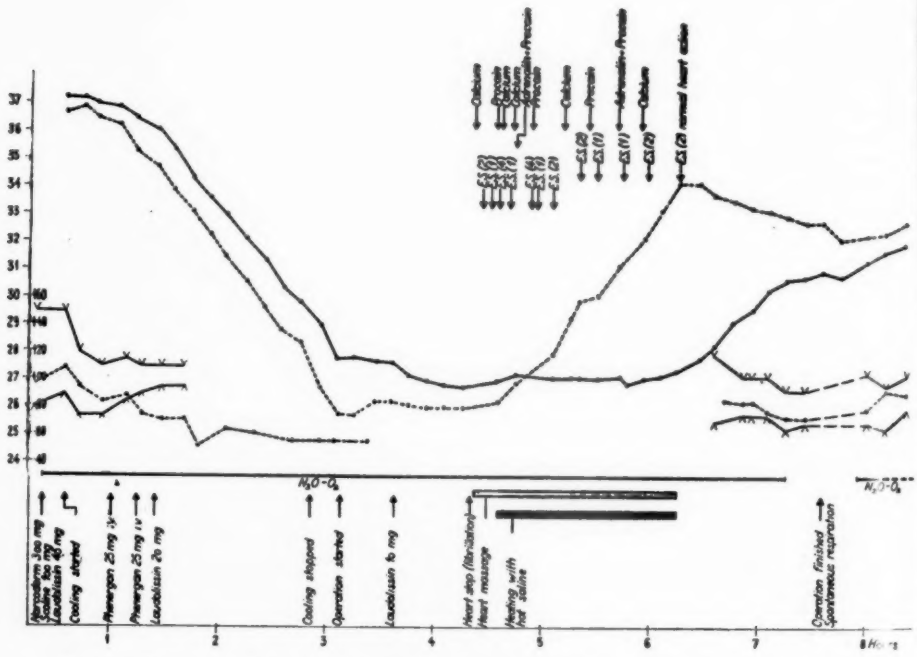

FIG. 2.—Temperature curve (continuous line, rectal; dotted line, œsophagus) blood pressure and pulse curve for one patient, a girl aged 17 with an atrial septal defect, who was operated on under hypothermia. Treatment of the ventricular fibrillation is shown on the figure.

(From: Husfeldt and Secher (1956) by kind permission.)

Table II shows the results in the patients who died, and it can be seen that the poorest results were obtained in those patients whose circulatory condition was little, if at all, improved by the operation. Furthermore the largest part of this group consisted of those cases of congenital heart disease operated upon during the first year of life, many of whom had multiple complicating malformations. In the mitral stenosis group the highest death-rate was found in those who had superimposed calcification of the valve; their average age at death was 45.

SHERRINGTON MEMORIAL LECTURE

Chairman—Sir CLEMENT PRICE THOMAS, K.C.V.O., F.R.C.S.
(President of the Royal Society of Medicine)

delivered on November 27, 1957

The Analysis of the Nervous System

By The Right Hon. LORD ADRIAN, O.M., F.R.S., M.D., F.R.C.P.

CHARLES SCOTT SHERRINGTON was born one hundred years ago and we meet to-night to honour his achievements by a commemorative lecture—the first of an annual or biennial series. I shall not try to express both the pride and the apprehension which I feel as the first of the long line of Sherrington lecturers who will exhibit some aspect of him to posterity. The picture that will be drawn of him may become more stereotyped and legendary as one generation of lecturers succeeds another and in the end there may be no more than a faint outline in black and white. For many of us here the picture is still full of colour and lively detail. No doubt much of it would dissolve if we tried to set it down; and our pictures would not all agree, their colours and outlines have been distorted already by our own prejudices. But at least it is our good fortune to have more than a legend to turn to: we can speak of a friend, not merely of an eminent figure in the scientific Pantheon. We must do what we can therefore to ensure that the legend does not leave out what should be remembered. It must do justice to the inspiration which Sherrington gave to Neurology. We are entitled to speak of it, for we were the younger generation who should have sat at his feet, if he had ever been willing to admit his seniority. Though we cannot go back to the period when his work took shape we have warm memories of the scientist we commemorate and of the way he lived when his work was in full swing.

He lived so long that I for one can claim to have known him for thirty years and to have known of his work for forty, although he had become a professor fifteen years before I became a medical student. He aged so little and seemed so much our contemporary that he would startle us at times by describing some episode which called up a picture of Victorian London with horse-drawn traffic and portly gentlemen with beards and top hats. One such occasion will be remembered by those members of the Physiological Society who were at a wartime meeting in Cambridge in 1940, for after the dinner at Trinity we asked him to speak to us about the meetings he had attended as a young man in the eighties. It is a pity that we had no tape recorder handy to take down his talk, but we can console ourselves by reading the letter, published in *Nature*, in which he described an emergency journey with the first samples of Diphtheria Antitoxin prepared in England to the bedside of a small boy at Lewes. It was in 1893 or '94 when he was Superintendent of The Brown Institution in London. There is no time to quote it all, though I should have

liked to do so, for it is a good example of the vivid word painting which illumina es his prose and his verse.

> "Dr. Fawssett of Lewes was waiting in a dog-cart at the station. I joined him carrying my awkward package of flasks, &c. He said nothing as I packed them in, but when I had climbed up beside him, he looked down, and said 'You can do what you like with the boy. He will not be alive at tea time.' We drove out to the old house; a bright, frosty morning. Tragedy was over the place, the servants scared and silent. The boy was very weak; breathing with difficulty; he did not seem to know me. Fawssett and I injected the serum. The syringes were small and we emptied them time and again. The doctor left. I sat with the boy."

By the afternoon the boy was better and two days later Sherrington went back to London and he and his colleague Ruffer thought that Lister should be told. "The great surgeon (not Lord Lister then) had visitors, some Continental surgeons to dinner. 'You must tell my guests about it', he said, and insisted—and so we told them in the drawing-room at Park Crescent."

The bare record of his career shows us a man who rose to scientific eminence by the accustomed route. He was at school at Ipswich, started medicine at St. Thomas's Hospital in 1876 and then went to Cambridge in 1879. He entered Caius in 1880, finished his medical course at St. Thomas's and began physiological research in the Cambridge laboratory with Langley. He was made Superintendent of The Brown Institution in 1891, Holt Professor of Physiology at Liverpool in 1895, and Waynflete Professor at Oxford in 1913. He was President of the Royal Society from 1920–25, received the Order of Merit in 1924 and the Nobel Prize in 1932. He retired from Oxford in 1936, after the death of his wife and moved to a house at Ipswich. During the war, when he was homeless, he came back to Cambridge and stayed with the Master of Caius and Mrs. Cameron. He spent his final years in a nursing home at Eastbourne crippled to some extent with rheumatism but with no other serious infirmity. He died without warning in 1952.

The record of his scientific work runs parallel with that of his academic status. His earlier papers make valuable additions to the physiology and anatomy of the nervous system but do not reveal a general plan of attack. This became evident when he held the Chair at Liverpool and when he was 49 the publication of his Silliman Lectures at Yale established it as the key to a new outlook on nervous control. This book, "The Integrative Action of the Nervous System", sums up the general methods and ideas which guided him in all his later work. It led to wider implications and more detailed analysis, but what he did afterwards at Liverpool and Oxford supplied fresh evidence but did not demand any revision of the original design.

The Simple Reflex

Reduced to essentials his plan of attack was to explore the central nervous system by devising the time-honoured form of experiment in which only one influence at a time is allowed to vary. The central nervous system might have been expressly designed to baffle such experiments, for it is there to be influenced by every circumstance which can matter to the organism. It is continually receiving messages from many sense organs and sending orders to many muscles. Sherrington's plan was to reduce this complexity by studying some very simple response which could be made to occur in isolation. By eliminating all the higher controlling regions of the brain and brain-stem the spinal cord was left able to carry out particular limb movements in response to particular sensory stimuli. These simple reflexes were still further simplified by isolating single muscles and nervous pathways and in the end the experimenter was left with a preparation in which the response would follow the stimulus with mechanical precision Comparison of such a reflex response with the twitch of an isolated nerve-muscle preparation showed the differences introduced by the more elaborate pathway through the spinal cord.

He found that conduction across the junctional regions was more readily disturbed by adverse conditions, fatigue, oxygen lack, &c., and in reflex pathways in general there was a less exact correlation between the time of commencement and ending of the stimulus and of the response. These differences were shown to depend on the synaptic junctions in the spinal cord and not on the quality of the nerve fibres leading to or from them. In this way the characteristic properties of the reflex pathway could be established and it was then possible to build up from the simple reflex contraction of the muscle towards the whole pattern of behaviour in the intact animal.

Excitation and Inhibition

One of the most important differences which Sherrington found between conduction in the reflex arc and in the nerve-muscle preparation was that a volley of sensory impulses could arrest activity in some of the motor nerve cells of the cord besides arousing it in others. It could inhibit as well as excite and in general the reflex contraction of one muscle would always involve the relaxation of those opposing the movement. It was this "Principle of Reciprocal Innervation" which opened the way to the further advance from the simple to the complex. It was the clue to the whole system of traffic control in the spinal cord and throughout the central pathways.

Sherrington's attack was bound to leave some strong points still holding out and the nature of the inhibitory effect had to be left until more was known about the properties of the synapse. There was then no clear evidence about the physical and chemical events which take place when the afferent impulses reach the end of their own pathway and cause the rise or fall in the activity of the pathways leading from it. Sherrington could safely leave these molecular problems to the younger generation who could use the latest techniques of biophysics and biochemistry. His own interests were more with the problems of integrated activity and he was content to leave excitation and inhibition where he found it.

It is encouraging, however, to know that the attack on the synapse has already reached a new position thanks to Sir Henry Dale and his colleagues and recently to one who was a pupil of Sherrington at Oxford. By the use of micro-electrodes Eccles has recorded the potential changes in the motor nerve cells of the cord. He finds that whereas excitation involves the expected decrease in the polarization of the cell membrane—the change which leads to activity—inhibition involves an increased polarization and so a higher threshold. How this change is brought about by the afferent neurones is still uncertain, but the chemistry of the junctional region may soon provide the answer.

The Control of Posture

When he passed from the simplest responses to the more elaborate, Sherrington was faced with a wide choice and had to select particular examples which would be favourable to analysis. Those which proved most illuminating were the scratch reflex of the spinal animal and the postural reactions of the decerebrate. The former was an example of a reaction which could be carried out by the spinal cord alone, but involved widespread excitations and inhibitions at many levels and great variety in the action of the limb muscles. But it was his investigation of decerebrate rigidity which led him farthest. It revealed the factors operating to give a smooth control of the muscular system and we are still finding fresh evidence of its importance.

His early work on neuro-anatomy had prepared the way and when he was established at Oxford the attack was concentrated on this theme. It was pressed home with improved techniques and enthusiastic pupils and it was a fitting sequel to the wider surveys he had made before. It showed that the ideas set out in his book retained their value for the details of reflex co-ordination as well as for the general plan.

The Stretch Reflex

This work at Oxford on the stretch reflex is so well known that I need not describe it at length. The decerebrate animal extends its legs rigidly and they resist efforts to bend them, although the degree of rigidity can be modified by the position of the head and trunk in space. The animal, in fact, maintains the steady contraction of the extensor muscles which would keep it standing if the brain-stem had not been divided. Magnus had shown how the general pattern of rigidity was modified by the signals reaching the vestibular nucleus from the otolith organs and he had been led from this to a masterly analysis of the control of posture and locomotion in the intact animal. Sherrington turned to the individual muscles and studied the effect of varying the pull on the extensors of the thigh. In the decerebrate animal these maintain a persistent steady activity which adapts itself to a varying load, so that the muscle changes its length much less than it would do if the nervous control had been cut off. The control was found to depend on the sense organs in the muscle which Sherrington had studied long before, the muscle spindles in particular. These signal the tension at each moment and their signals set up the answering reflex by which the muscle resists the change in length.

A remarkable feature of this reflex was its extreme simplicity: it was confined to the stretched muscle, the motor response copied the sensory stimulus, with no long delay, no after-discharge and no fatigue, almost as though there was no break in the pathway from the sense organs recording the tension to the muscle fibres maintaining it. The motor neurones must be open to influences from other routes, for the muscle must play its part in all the movements and postures of the limb, but it can work efficiently because the mechanism of the stretch reflex ensures that its contraction will be precisely adjusted to the changing demand.

The importance of this mechanism for adjusting the flow of impulses sent out to each muscle or to each motor unit in it has become even more clearly established by recent work. Sherrington emphasized its value in assisting the smooth transition from one motor activity to another and he was ready to compare it with the feed-back devices used by engineers for controlling the movement of heavy machinery. The engineer, like the brain and brain-stem, must decide what ought to be done but it can be left to the local monitoring instruments and their associated circuits to ensure that the movements do not overshoot their mark or overstrain the structure of the machine. In the same way the stretch reflex mechanism plays an essential part in the execution of each movement, though it has little to do with the decision responsible for it.

When Sherrington was examining the stretch reflex the general theory of feed-back circuits had not risen to its present mathematical dignity. His treatment of the subject was on a physiological level. But recent work has shown that the physiological circuits are more highly organized than he supposed. The muscle spindle, the main source of information about the forces within the muscle, does not act merely as a passive strain gauge. Its sensitivity is under constant adjustment by the spinal centres, for there are special motor nerve fibres to the muscular part of the organ: these can vary the tension of the sensitive region independently of the variations of tension in the whole muscle. The operation of this additional control has been worked out in the laboratories of Granit and Kuffler and it can be regarded as yet another example of a general principle of sensory physiology, the principle that the sense organs would be of much less value to us if they were not constantly focused and adjusted by the central nervous system. They control its activity but they are themselves controlled by it and made more or less sensitive to suit the circumstances. The control may involve widespread movement: shading the eyes against too strong a light, turning the head to catch a sound, or sniffing to identify a smell: it may depend on special accessory muscles attached to the organ, and in some cases there is evidence of efferent nerve fibres running directly to the receptor apparatus. Even the flexion reflex of the spinal animal might be regarded as an example, for its aim is the removal of the pain receptors from the stimulus which has set them in action.

Researches on the Brain

Sherrington set out to analyse the integrative action of the nervous system. His analysis of the spinal reflexes revealed a mechanism of neurones and synapses, operating by signals with inhibitory as well as excitatory effects and adjusted by information from the muscles to give a smoothly-flowing pattern of movement. But his success at this basic level never encouraged him to feel that the same methods and ideas would do for every level of nervous activity. The simple reflex had been the key to the understanding of co-ordinated movement and posture but some other kind of key might well be needed for the understanding of what went on in the brain. At Oxford he had no time to look for it, there was still too much to be learnt about the reflex mechanism, the experiments which had to be done were always laborious and his eminence had given him other responsibilities which could not be set aside.

At an earlier period, however, he had made two excursions into the field of brain physiology. One was reported in his Silliman lectures and he referred to it again in his final summing up in "Man on his Nature". It dealt with the highest level of all, for it was concerned with the visual sensations aroused by flickering light. By arranging the light source so that the bright and dark phases could occur simultaneously or alternately in the two eyes, he hoped to reach decisions about the site and the nature of the process which gives binocular fusion. The results were clear enough but their interpretation was, and remains, puzzling, for there is too wide a gap, too much unexplored territory, between the physical stimulus and the mental experience. The other research on the brain was done at Liverpool when he was working with Graham Brown and Layton. It was a careful mapping of the motor area of the chimpanzee and an analysis of the factors which caused the map to vary in detail from one animal to another. It was found that in any one animal it was rarely possible to elicit more than a fraction of the whole range of movement encountered in a series of experiments. Apart from its anatomical aspect this research may be considered the forerunner of many later investigations on the response of the cortex to electrical stimuli. It showed the much greater plasticity of the cortical than of the spinal neurones, the deviation of the response to a pathway opened by previous use, the progressive recruitment, the varied latency, &c., but in those days, forty years ago, the present range of electrophysiological technique was far below the horizon. Sherrington had to relate stimulus to movement, as in his work on flicker he had tried to relate stimulus to sensation. Some of the intervening events can now be recorded but then they could only be inferred and there were too few data to check the inference.

Thus at the end of his active work in the laboratory the brain and its control of behaviour remained a major field for experiment. Its control of or by the mind remained what it had always been, a theme for philosophers to debate. Sherrington never reconciled himself to Pavlov's whole-hearted acceptance of brain physiology as a sufficient explanation of the mind, though he was ready to await the results of new methods of brain research.

It cannot be said that our new methods have made it much easier to follow the operations of the brain in detail. They have added a great many data concerning the activities which take place inside it, but we are still waiting for more light on the basic problem of habit formation and the related one of attention. Yet the general scheme which was so effective for the spinal reflexes is still our best guide to the factors controlling the direction of behaviour as well as its detailed integration, for there is a gradual increase in complexity as we pass from the spinal to the cerebral level and the brain-stem gives us a transitional region where general behaviour begins to show itself.

The Brain-stem Level

When the cerebrum is destroyed, leaving the brain-stem in control, the animal can stand and walk and run and if it is placed on its back it will regain the standing position. Its behaviour has no survival value. It is that of an automaton which

can do little else than stand and walk, but the standing and walking are both activities demanding a level of integration which involves the whole animal.

In fact Magnus and Rademaker were able to reduce most of these elaborate reactions to a sequence of simple reflexes. Each one is the immediate response to a particular sensory stimulus, though their combination shows an adaptation to circumstances which links them with cerebral rather than spinal reactions. Thus, in regaining the standing posture, if the normal sequence of actions cannot proceed, another sequence takes its place. An animal placed on its side will raise itself by a chain of reflexes starting by head movement controlled by the vestibular organs, but if the initial movement of the head is prevented, the body is righted by a different set of reflexes controlled by the receptors in the body wall.

The behaviour of the brain-stem animal certainly lacks all the variety and effectiveness of that of an animal with its central nervous system intact. This has survival value, for it is concerned with the activities by which the animal supports itself in its environment, the pursuit of food, the avoidance of danger, the adherence to the herd, &c. Sherrington spoke of the cerebrum as head ganglion of the distance receptors, signalling events beyond immediate contact with the body, and the difference is not merely in the sense organs which inform it. Operations carried out at this level differ not only in the kind of information which guides them but in the much greater plasticity of the structures which receive it. The cerebrum retains the mould of past activities, it can develop habitual patterns of action, so that skills can be acquired and the problem once solved can be solved again with less effort. Its reactions seem less like those of a machine because the relation between stimulus and response depends on the past as much as on the present.

Yet we can admit this great difference and still see an essential resemblance between the control of postural and of skilled behaviour. The animal without its cerebrum can rise to its feet and stand firmly on an unsteady platform. This requires a constant adjustment of the pattern of muscular contractions depending on the reflex linkage of afferent and efferent pathways with all the feed-back circuits for the individual muscles and the general control from the vestibular organs and the pressure and tension receptors. It could be imitated by an artificial controlling system working on the same principles: an elaborate design would be needed but once set up the machinery should work automatically. The setting up of the reflex system may well involve some gradual change in the synaptic pathways when the animal first acquires the power to stand, but once adjusted the nervous mechanism need not differ in essentials from that which gives the spinal animal the power to scratch itself.

The Cerebral Level

To ride a bicycle or drive a car involves the kind of skilled behaviour only possible at the cerebral level. It needs the distance receptors and the habits impressed on the cerebrum by previous activity. Some of it depends, like human walking, on acquired habits of movement. We have learnt to keep our balance on the bicycle by turning the front wheel towards one side or the other. At first we turned it through many degrees and pursued a zig-zag course. Our manipulation of the handle-bars was not linked closely enough with the signals from the vestibular organs, with a result like the shunting of an engine with an insensitive governor. But with practice the linkage has been improved and the balancing can be done by movements of the body as well as of the arms. It needs no conscious effort and we are seldom aware of what we are doing.

In riding a bicycle or driving a car, or in walking for that matter, we must avoid pedestrians and oncoming traffic and, when we have acquired a proper road sense, this too can be done almost unconsciously. Yet for these adjustments there is a far less immediate connexion between the sensory signals and the end response. Our course is guided by the patterns of light and shade on the retina. It would not be difficult to design an artificial system to guide a car along a white line in the middle of the road, to stop it at the red light and start it again at the green, but with the brain

to interpret the optical signals the control goes far beyond this. The car is steered to avoid a pedestrian, to give a wider berth to a child than to a grown up, to pass another car before the oncoming traffic makes passing unsafe. These operations demand the power of recognizing the special features in the pattern of light and shade which indicate an adult rather than a child, a fast car rather than a tractor, and the recognition must be linked with an immediate estimate of speeds and even of the probable intentions of other drivers.

Although our driving would certainly be dangerous if we gave it no thought at all, the movements we make to control the steering wheel and the accelerator pedal are seldom based on conscious judgments. A small car near at hand will give the same sized retinal image as a large car farther off, but we judge its size and assess its distance and speed without more than general awareness, certainly without deliberate thinking. Once the brain has acquired this skill or indeed any skill, most of the operations required in it seem to be carried out almost as unconsciously as breathing or walking, although they demand most of the powers of recognition, generalization and judgment that are often considered as properties of the mind.

To give the cerebrum this great extension of its field of control it has the great expansion of the cortical sheet and the great plasticity of the nervous structures in it. These at least are important differences between it and the rest of the nervous system. No doubt we shall find other less obvious factors and they may compel us to adopt some new kind of analysis, but it is important to realize that for a great deal of skilled behaviour we have no real need to consider the intervention of conscious processes. Thought is not a necessary accompaniment of intelligent action.

The Mental Level

Liddell's admirable obituary notice of Sherrington quotes him as saying "Some people think that thinking is all electric currents. Well!" He thought it something so different that it could not be fitted into the scheme of energy and matter which we use for the brain. "Thoughts", he said, ' lie outside Natural Science". In his Gifford Lectures "Man on His Nature" he is at pains to make it clear that this is a territory which neurophysiology cannot be supposed to reach.

The burden of these lectures, the final reflections of a scientist on what he had learnt, is that the reflex with all its elaborations is a conception to be used only for the material events which take place in the nervous system and that the neurologist has more than the material events to puzzle him. Yet the chapters in which he delivers this judgment are as inspiring as any in "The Integrative Action of the Nervous System". They bring no sense of failure before a goal which can never be reached. He gives full weight to our mental experiences but his discussion is constantly reminding us of how little we know yet about the material activity of the brain, of how much nearer we might come to the mental level if we knew more of the physical events linking our sense organs and our behaviour.

Some of these events are already clearer. He deals with the changes in the electrical activity of the "roof-brain" in sleeping and waking, attention and inattention. Since his book was written these have become one of the major fields of research in neurophysiology. There are new techniques which make it possible to study the activity of individual neurones in the brain during its normal working; their response to electrical stimulation has been followed with a new precision and there is a fair prospect of analysing the massive potential oscillations of the cortex in terms of dendrite and nerve cell activity. Some of this may turn out to be irrelevant, for we are still in the exploratory stage: there are a great many events in the brain which can now be recorded, beautiful instruments for doing it and a wealth of literature for reference. The difficulty is still that the conception of the reflex pathway loses its clarity when it has to be widened to include conditioned pathways; for one brain may look like another, but what it does in response to a given stimulus may be quite different because it depends on all the brain has done since it was first in action. Though we may be able to record them it will not be

easy to disentangle the physical events in the brain, so that we can tell how the analysis should proceed.

Yet there should be no insuperable difficulty, no need to go outside the framework of natural science, in analysing the cerebral activity which accompanies skilled behaviour. It is worth insisting again that actions which would certainly pass as intelligent and purposive are often done without the intervention of conscious processes. We can try therefore to reduce them to the Sherringtonian scheme without feeling that the most important link has been left out: when this has been done we shall at least be able to consider how we think with a knowledge of how the brain achieves so much when our thoughts are elsewhere. The final puzzle will still be there, but without Sherrington's insistence on it we might deny its importance and get no farther.

It is time to recall the man who faced the final puzzle so squarely. All his life he had faced problems honestly without letting his wishes dictate the answer. His honesty was for himself, it was not the kind that is used to assert superiority and justify bad manners; it gave him no pleasure to be discourteous. But more than anything else it was his honest acceptance of what he found in the world and in himself that made us look up to him.

In his old age he had many visitors at Eastbourne and it was a delight to see him and to feel that he was glad to be seen. He would talk of friends, of the books he was reading, of physiologists of the past that he had known and of his admiration for what the younger generation were doing. No one who visited him then can have left Eastbourne without renewed strength and peace of mind. Sherrington found Nature often cruel and senseless and Man no better, but he was content to face his destiny in the universal plan. He helped us by his fortitude as well as by his science. For he was a great scientist but we who knew him are fortunate in having more than his science to recall this evening.

Disturbances of Renal Physiology

By A. A. G. LEWIS, M.D.

THE kidneys are partly responsible for maintaining the volume and composition of the body fluids within narrow limits. They may fail in this task, even when perfectly healthy, when disturbances elsewhere in the body bring about changes in their function, and it is these changes that I propose to review for they properly constitute "Disturbances of Renal Physiology".

Some of the present views of the way in which the kidney elaborates urine are summarized in Fig. 1. Approximately one-fifth of the cardiac output flows through the glomeruli, where

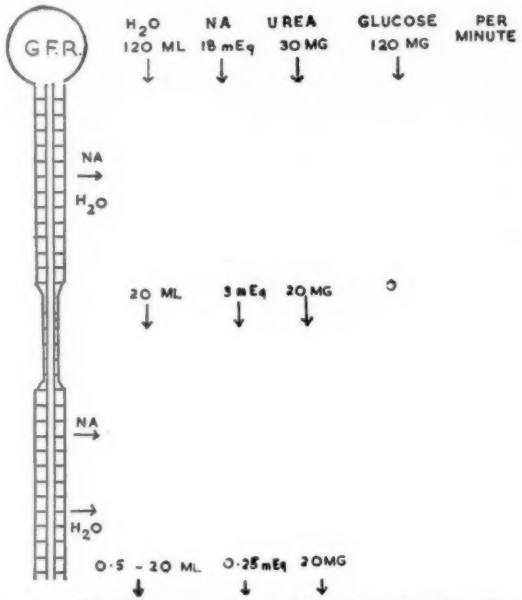

FIG. 1.—Schematic representation of filtration and reabsorption.
(*From* Lewis, 1953, by kind permission.)

roughly one-fifth of the plasma water is filtered off, with its dissolved solids. The approximate quantities of water, sodium, urea and glucose filtered per minute and ultimately excreted are shown. In the proximal tubule, seven-eighths of the filtered sodium is reabsorbed and all the glucose: as a consequence of this, it is thought, a corresponding volume of water is reabsorbed. The remarkable property of renal tubular cells of being impermeable to creatinine and almost so to urea should be noted. In the thin limb, final osmotic equilibration is thought to occur, so that the function of the glomerulus and the tubule down as far as the distal limb appears to be to supply the latter with a steady flow of some 20 ml./minute of isotonic, glucose-free, plasma filtrate. It is here that the final elaboration of the urine occurs, by a series of selective and almost independent processes of reabsorption. Sodium ions are reabsorbed and in the process partly exchanged for hydrogen or potassium ions. Sodium reabsorption can be greatly increased by the influence of aldosterone. In this part of the

tubule, water reabsorption occurs separately from that of sodium and can be varied independently of it by the activity of the antidiuretic hormone of the neurohypophysis. Two processes which, in the proximal tubule, occur together at a fixed rate, have become, in the distal tubule, independent and variable. The distal tubule also forms ammonia when extra base is needed for acid excretion.

These remarkably selective processes of reabsorption by the distal tubule may establish and maintain large gradients for the urinary constituents between urine and plasma. Urine osmolarity, for example, can be varied from less than a fourth to more than four times that of plasma; urinary sodium concentration can be reduced almost to zero, while a gradient for hydrogen ions of 800/1 can be established.

The two hormones that regulate the reabsorption of sodium and water independently by the distal tubule are aldosterone and anti-diuretic hormone (A.D.H.). Both are secreted in increased amounts in response to a fall in E.C.F. volume, and in the case of A.D.H. this has been shown to be mediated by stretch receptors in the wall of the left auricle responsive to the degree of its filling (Henry and Pearce, 1956). Both hormones, therefore, act so as to defend extra-cellular fluid (E.C.F.) volume, and, in addition, A.D.H. is secreted by the neuro-hypophysis in response to a rise of E.C.F. tonicity. An increase in the latter increases A.D.H. secretion so that distal tubular water reabsorption is increased.

Renal function may be disturbed by extra-renal influences in four ways:

(1) When renal blood flow is reduced; (2) when abnormal humoral or nervous influences modify renal function; (3) when the kidney, in carrying out one task, is prevented from performing another; (4) when there is urinary obstruction.

The renal blood flow and glomerular filtration rate are reduced when the cardiac output falls after hæmorrhage. They are reduced by pre-operative medication with morphine or pethidine and by anæsthesia, when fairly severe hæmorrhage, operative procedures or the reduction of blood pressure by ganglion blocking agents produce little further fall (Miles *et al.*, 1952; de Wardener *et al.*, 1953). Moderate falls of glomerular filtration do not have much effect on the composition of the urine. In Fig. 2, a reduction of venous return was

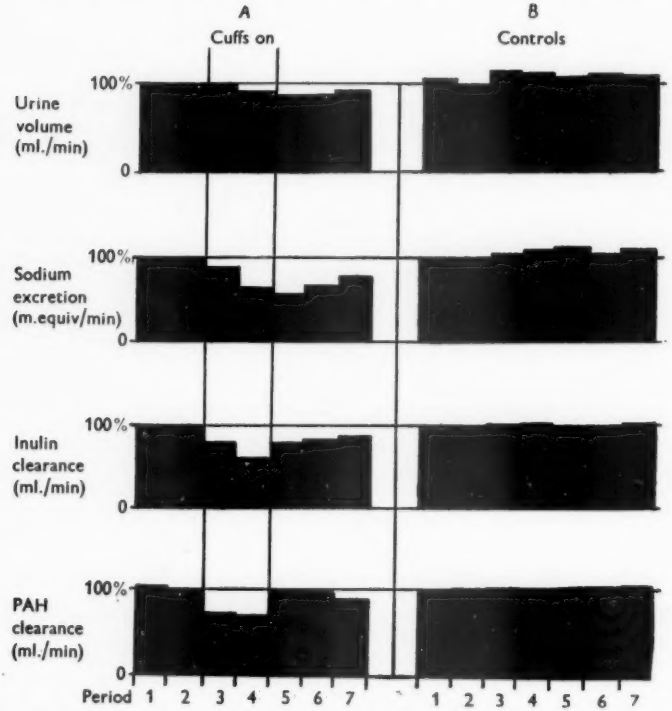

FIG. 2.—The effect of a moderate reduction of renal blood flow and glomerular filtration rate on urine volume and sodium excretion in man. (*From* Chalmers *et al.*, 1952, by kind permission.)

produced by the application of venous tourniquets to the thighs of normal subjects during sustained water diuresis. Some change in water and sodium output occurs, but this is in marked contrast to the dog, in which sodium output appears to be much more readily altered by changes in glomerular filtration rate.

Similar falls in glomerular filtration rate are produced by hypothermia, and it is significant that these are unaffected by high spinal anæsthesia. Tubular function and reabsorption may also be modified by hypothermia (Morales *et al.*, 1957).

Very severe hæmorrhage and shock produce intense renal vasoconstriction, the fraction of the cardiac output passing through the kidneys being greatly reduced (Lauson *et al.*, 1944). Though the capacity of the tubules to excrete substances such as para-amino-hippuric acid (P.A.H.) remains unaffected until the blood flow has fallen to about one-tenth of normal, distal tubular processes are suppressed and eventually no urine is formed. If intense renal ischæmia is prolonged, there is a delay in the recovery process, and if it lasts more than a few hours, tubular necrosis occurs. If this is to be prevented under these conditions, early and adequate transfusion is necessary. Where this has failed for any reason to restore the systolic blood pressure, the infusion of noradrenaline may restore renal function (Mattingly, 1957), provided that no tubular damage has occurred.

The importance of humoral and endocrine influences on renal function may be appreciated by a consideration of adrenal deficiency. Here, both glomerular filtration rate and selective distal tubular function are depressed, and can be restored by cortisone. Not only is sodium reabsorption reduced in the absence of aldosterone, but the ability of the tubule to handle sodium and water reabsorption separately is lost. Fig. 3 shows the effect of stimulating the

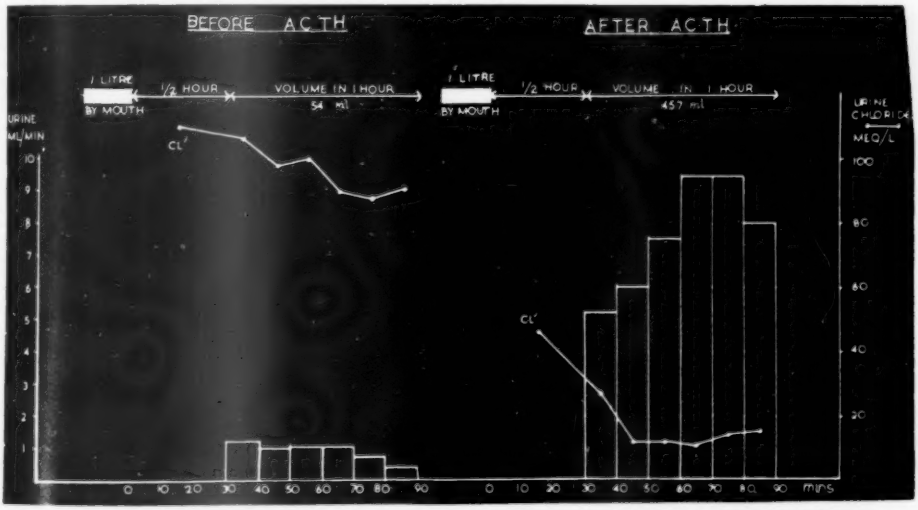

FIG. 3.—The diuretic response to a water load in panhypopituitarism before and after the administration of a course of ACTH.

adrenals with ACTH in panhypopituitarism: the ability of the kidney to produce a normal water diuresis, with dilution of the urinary solutes, in response to a water load is restored. In other words, distal tubular function has again become selective. A similar result is produced in adrenal deficiency by cortisone, but not by mineralocorticoids, which regulate sodium and potassium reabsorption only.

One interesting property of the distal tubule is its power of adaptation. On the whole, renal function in man is not greatly influenced by diet, again in contrast to the dog in which urea clearance can be greatly increased by high protein feeding. But it has recently been shown that the concentrating power of the kidney and the response of the distal tubule to vasopressin can be increased by a period of water deprivation or by a high protein or urea intake, while a period of high fluid intake reduces these responses (Epstein *et al.*, 1957).

Tubular reabsorption of sodium and water are normally related to body requirements by the varying rates of secretion of aldosterone and A.D.H. If anomalies in the production of these hormones occur, the kidney cannot make its normal contribution to homeostasis. A.D.H. will not be secreted if the posterior pituitary has been destroyed by secondary deposits,

by inflammatory changes or xanthomatosis. Distal tubular water reabsorption ceases and the patient experiences the constant water diuresis of diabetes insipidus. Occasionally, emotional disturbances lead to a suppression of A.D.H. secretion so that an emotional polyuria occurs: on the other hand, emotion, particularly that associated with fear and pain, often provokes A.D.H. secretion and emotional antidiuresis.

Both hypokalæmia and hypercalcæmia impair renal function, particularly, in the early stages, tubular function. Polyuria is a frequent early symptom of hypercalcæmia and may persist for long periods before other signs of renal failure occur. Actual deposition of calcium in the tubules and nephrocalcinosis appear to develop at a later stage, so that the condition is reversible at first. The polyuria and rising blood urea caused by hypercalcæmia may be the first signs of hyperparathyroidism, sarcoidosis, myelomatosis or of widespread secondary malignant deposits in bone.

A prolonged release of A.D.H. occurs after surgical procedures. The urine is concentrated and of low volume for many hours after operations (Fig. 4). Occasionally this

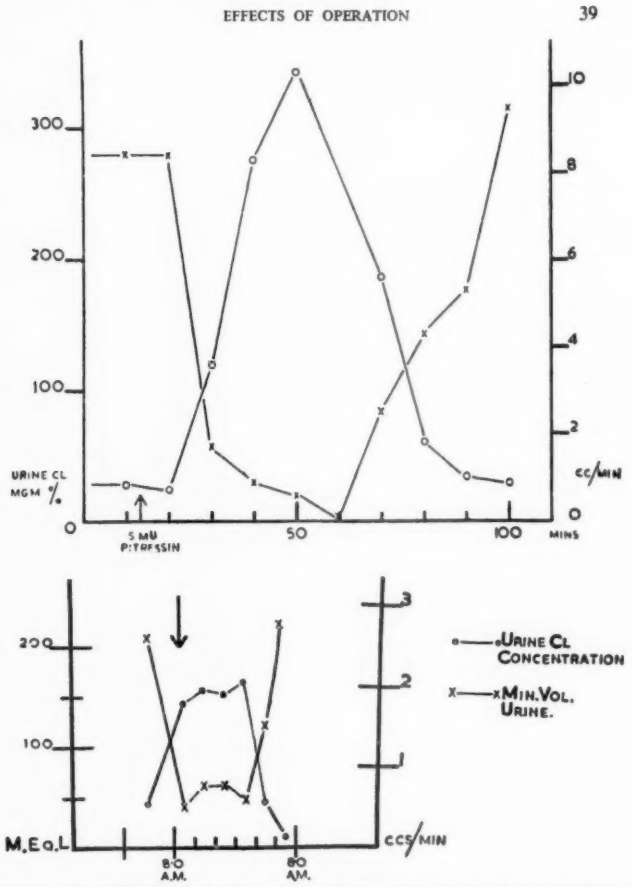

FIG. 4.—The lower graph illustrates the effect of operation (sigmoid colectomy) on the urine volume and chloride concentration, as shown by observations on four-hourly urine specimens obtained from an indwelling urethral catheter. For comparison, the upper graph shows the effect on urine volume and chloride concentration of an injection of pitressin (slightly modified from Lewis, 1953). Note that both graphs show similar changes, save that after operation these are much more prolonged.

Reproduced from Le Quesne, L. P. (1957). "Fluid Balance in Surgical Practice" (2nd edition). London: Lloyd-Luke (Medical Books) Ltd. By kind permission.

effect lasts for two or three days, when there is a risk of water intoxication if too much water is given (Fig. 5). This post-operative release of A.D.H. does not occur in response to the

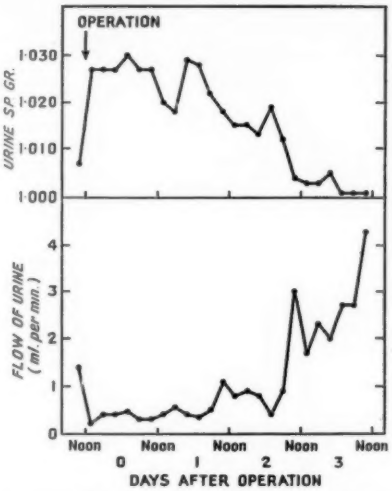

FIG. 5.—An example of prolonged post-operative antidiuresis. lasting seventy-two hours. Mild water intoxication occurred. (*From* Le Quesne, 1954, by kind permission.)

normal stimuli of changes in E.C.F. volume and tonicity. This is perhaps the outstanding example of a condition where the normal kidney is not a free agent: it is responding to an influence which is not under normal control. It follows that fluids should not be forced in the post-operative period: water should be given to replace losses occurring by the kidney, through the skin and into the gut until the abnormal secretion of A.D.H. ceases and the kidney can again excrete excess water.

Increased secretion of adrenocortical hormones also occurs after surgery. It has been reported that the urine contains increased amounts of aldosterone (Llaurado, 1955), but a recent study indicates that this only occurs when sodium intake is restricted (Hayes *et al.*, 1957). The sodium retention and potassium excretion that follow operations are usually the result of the secretion of compound F and of delay in its destruction by the liver, as well as of changes in the rate of the peripheral utilization of this hormone by the tissues.

Increased secretion of aldosterone is probably partly responsible for the renal sodium retention that causes the œdema of cardiac and hepatic failure. The production of this hormone may be increased when there is an adrenal cortical tumour, when the most striking electrolyte abnormality is the hypokalæmia produced by renal potassium loss. Hypokalæmia from any cause may produce disturbances in renal function, with low filtration rate and renal blood flow and loss of response to A.D.H. Histologically, vacuolation of tubular cells may be seen—the so-called hypokalæmic nephropathy. When the hypokalæmia is due to increased urinary loss of potassium brought about by aldosterone, the urine may be neutral since potassium and not hydrogen ions are replacing sodium ions in tubular reabsorption. But when extrarenal losses cause potassium deficiency, renal conservation of the ion occurs and hydrogen is exchanged for sodium, so that the urine is acid in spite of the systemic alkalosis of potassium deficiency.

This paradox is an example of what may occur if the kidney, having to perform one task, is thereby prevented from carrying out another. A more striking disturbance of this type is furnished by osmotic diuresis, when the kidney, called upon to excrete large quantities of osmotically active solute, fails to reabsorb sodium and water, so that dehydration results.

This is seen when the solute is glucose in diabetes mellitus, and when large quantities of urea are being excreted during high protein feeding or in the recovery stage of acute tubular necrosis. The characteristic of osmotic diuresis is the loss of the distinctive contribution

of the distal tubule, which is overwhelmed by the flood of filtrate unreabsorbed proximally: as the urine flow rises the specific gravity tends to approach that of plasma, 1010, and not, as in water diuresis, that of water.

Obstruction to the urinary outflow will obviously impose limitations upon renal function. One particular consequence, however, is worth special notice, and that is the tendency for the distal tubular response to A.D.H. to be reduced in some cases. Prostatic obstruction has been shown to be a possible cause of water-losing nephritis, the blood urea rising later, the loss of concentrating power and polyuria being corrected by removal of the obstruction (Roussak and Oleesky, 1954).

It is not easy to summarize the various instances of disturbed renal function that have been mentioned. One situation is particularly important—after a major operation the urine volume is found to be greatly reduced. Four main causes have to be considered. Pre-existing dehydration or blood loss may have been severe and not fully corrected, so that the urine is highly concentrated with high specific gravity and urea and low sodium, indicating good glomerular and tubular function. A very similar urine may be passed as a result of the usual endocrine response to surgery, and only clinical examination may differentiate this from the first situation; or severe blood loss and shock at the operation, perhaps temporarily masked by anæsthesia but becoming apparent later, may have led to urinary suppression from failure of renal blood flow and glomerular filtration rate. If this has been allowed to persist for long, acute tubular necrosis may have occurred, when the urine volume is very low—less than the minimum necessary for excretion of solutes—and, more important, the specific gravity is little raised and little modification of plasma concentration of solutes has occurred. The blood urea therefore rises rapidly. For practical purposes the kidney has now no excretory or regulatory function. I do not think that Strauss's (1948) analysis of the course of events in a 70 kg. man can be bettered. 70 grams of protein will be broken down daily as soon as carbohydrate stores are exhausted, when the combustion of 200 grams of fat will lead to the production of 470 ml. of water. Plasma potassium may rise at about 0·3 mEq./l./day if protein metabolism is halved by giving glucose, when 6 grams of N.P.N. will be formed per day, causing a rise of blood N.P.N. of 12 mg.% daily. In practice, protein destruction may be more rapid than this and is little affected by supplying further calories with exogenous fat—since this causes gastric disturbances it is better omitted. But recent work has shown that more water may be produced by metabolism than was at first realized, so that a considerable part of the daily insensible loss of 1 litre may be produced from this source. In conservative therapy, water intake should be so adjusted that a slight weight loss occurs daily.

Introduction to Western Influences in Pre-Meiji Japanese Medicine

By GORDON E. MESTLER

Department of Anatomy, State University of New York, Downstate Medical Center, Brooklyn, New York

IT is axiomatic that the early medical practice of old Japan was a traditional inheritance of classical Chinese medicine, brought back to Japan as a consequence of Japanese military invasions of Korea. But it is believed—erroneously—by many that Japan was "closed to foreigners" until the time of Commodore Matthew C. Perry, U.S. naval officer, whose fleet steamed into Tōkyō Bay in 1853 on the peaceful mission of establishing trade relations with the Mikado's empire. Before that time there had been, in fact, communication between Japan and the Western world for nearly 300 years, with occasional interruptions. Much of the intellectual and cultural exchange during that period was of a lasting quality. Indeed, the characteristic proclivity of the Japanese for the imitation of all that is good (and some that is bad) was to lead, ultimately, to the overthrow of the feudal system which had dominated Japan through a long succession of Shōgunate governments during the Edo period from 1615 to 1867.

The present paper will attempt to give a brief sketch of Western influences in pre-Meiji Japanese medicine. The emphasis will be on the major bibliographic aspects.

News of the "discovery" of Japan in 1543 spread rapidly to Europe, and in 1549 the first Christian missionary, St. Francis Xavier, landed at Kagoshima and for the next two years travelled in various parts of Japan, particularly to the capital at Kyōto. Following this, a steady stream of missionaries from Portugal, Spain and Italy came to Japan. For our purpose here, the important fact is that these religious men were accompanied by physicians and scientists, principally naturalists. Luís de Almeida, a Portuguese "brother-doctor", is described by Asobu or Yū FUJIKAWA (1865–1940) as the first European to practise medicine in Japan. Almeida came to Japan in 1555 or 1556, and at Oita he founded a school of surgery, annexed to which was a hospital especially for sick children. Beyond this fact, the nature of his influence and its spread among those who came into contact with him is not well known.

Probably the first Western physician to make a lasting literary impression on the medicine of Japan at that early time was one Christovão Ferreira, a Portuguese, who was associated with the *Nambanji* or "School of the Southern Barbarians" which had been established in the Province of Ōmi in southern Japan, where he taught surgery to the Japanese. Ferreira is not known to have been the author of any medical or surgical books prior to his coming to Japan, but about 1600, under the assumed name of Chūan SAWANO, he wrote directly in the Japanese language a surgical work entitled *Nambanryū geka-sho*, on the teachings of the Portuguese school of surgery.

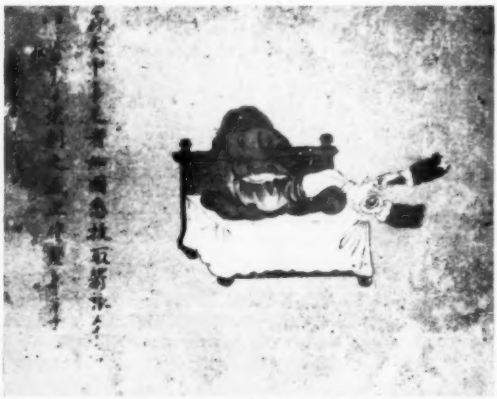
Western medicine and surgery first affected the thought and practice of Japanese physicians and surgeons by means of *oral* teachings, instructions and demonstrations provided by Western practitioners attached to various foreign missions to Japan or to foreign settlements established by permission of the Shōgunate. Such Western teachings were soon reflected in medical and surgical works composed by their Japanese pupils. Pre-eminent among these early Western physicians in Japan was Caspar Schambergen, who came to Japan in 1649 as a surgeon of the Dutch East India Company. His name identified what was perhaps the most influential Dutch school of surgery in Japan, known as "Caspar-ryū-Geka". Typical of the Japanese-written surgical works of that period was the *Geka ryōji-shu*, composed by Sōō NAKAMU, who had studied under Schambergen, a work published at Kyōto in the 2nd year of Jōykō (=1685).

Contemporary with Caspar Schambergen or immediately following his time were Willem Hoffmann, Hermanns Katz, "Danner", "Palm", "Stieven", Willem ten Rhyne, Andreas Cleyer and Engelbert Kaempfer. The clinical lectures of "Danner" and "Palm" were

preserved by one of their pupils, Hōan ARASHIYAMA (1633–1693), who wrote them out in his work entitled *Bankoku chihō tekiden* which appeared about 1675. The teachings of Schambergen were also incorporated in the *Caspar dempō*, composed by Ryōan KAWAGUCHI. In the *Almans hō-sho*, KAWAGUCHI gave an account also of the teachings of Hermanns Katz. Both of these Japanese-written surgical works appeared in 1661.

The most famous pupil of Willem Hoffmann was Chinzan or Eikyū or Shingohei or Tokitoshi NARABAYASHI (1648–1711), whose fame rests upon his translation of parts of Ambroïse Paré's *De chirurgie . . .*, from a Dutch translation by D. Carolum Battum (probably the Amsterdam edition of 1649 by I. I. Schipper). NARABAYASHI's classic work appeared in 1706 with several illustrations copied from Paré. It existed only in a manuscript (none of which is known to be extant at the present time). Fortunately, however, NARABAYASHI's manuscript, known as the *Geka sōden*, was copied by other Japanese, some parts even being stolen for that purpose. An independent semi-translation of Paré was also made by Gentetsu NISHI (1680–1760), in a manuscript work entitled *Kinsō tetsuboku ryōji* which appeared in the 20th year of Kyōhō (=1735).

Hōan ARASHIYAMA also made a copy of parts of Paré in a manuscript work known as the "Arashiyama text of Paré", probably equivalent to the *Kōi-geka sōden*. Although undated, that manuscript would predate the better known work of Chinzan NARABAYASHI in 1706, and the writer believes the ARASHIYAMA manuscript to be the earliest Japanese surgical writing which was based directly on an identifiable Western book on surgery . . . ARASHIYAMA's manuscript is still preserved in the Tōkyō University Library. Fig. 1 is a reproduction of one of the illustrations, with explanatory text, in the *Kōi-geka sōden*.



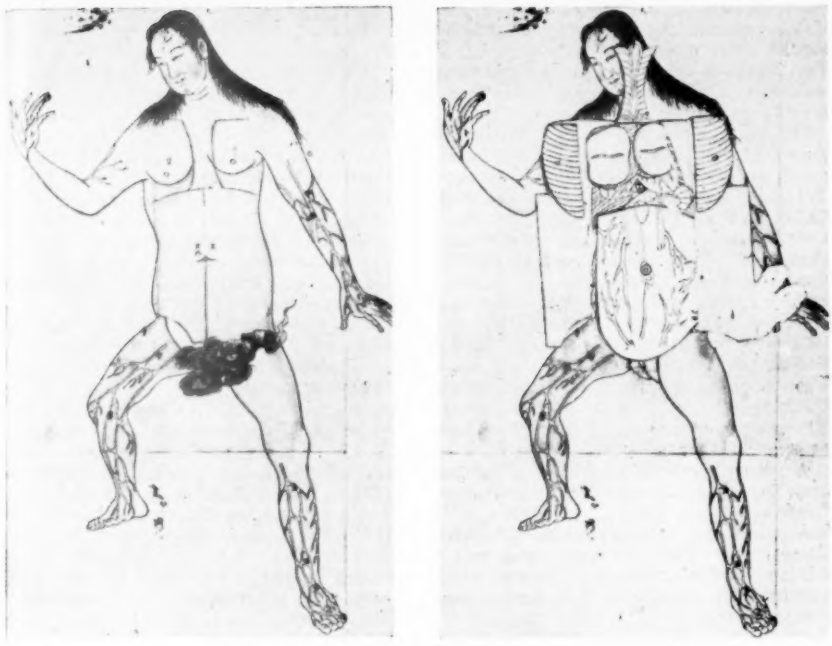


FIG. 1.—Illustration from the *Kōi-geka sōden* (n.d.), probably equivalent to the "*Arashiyama text of Paré*", manuscript by Hōan ARASHIYAMA (1633–1693). After NAGAYAMA.

The first *printed* version of the "Japanese Paré" copies was either the work known as *Geka kummō zu-i mokuroku*, by an obscure and unidentified writer, which appeared in 1764(?); or the work known as *Geka kummō zui*, by Kōhaku or Mitsuaki IRAKO (1737–1798), which was published at Kyōto in 1769 . . .

Since the dates of composition and/or publication are vague and uncertain, the distinction of being the very first Japanese medical writing to have been directly influenced by pre-existing Western medical books (as distinct from oral teachings) must be shared with the *Shokai naikei-shō*, which was a work on the nomenclature of the regions and organs of the human body that appeared in 1682, having been composed by Ryōi or Shōdau MOTOKI (1628–1697) from an unidentified Western book on anatomy. Or shared also with an anatomical atlas unique in the annals of Japanese medical works, a manuscript copy by MOTOKI based on Johann Remmelin's *Pinax microcosmographicus . . . Ontleding des menschelyke lichaems . . .* (Amsterdam, 1667), in which some of the wood-block illustrations were—like the original Western work—superimposed so that they could be folded back to reveal underlying structures. This work of MOTOKI unfortunately remained obscure following his death, until it was "rediscovered" by one Sōun SUZUKI who had it published in 1772 with the title *Oranda (or Waran) zenku naigai bungō-zu*. Fig. 2 shows a pair of the plates from this work, with the flaps in place (A) and folded back (B). MOTOKI chose to depict his figures with characteristic Oriental head and facial features.

The next important Japanese medical writing to reflect the influence of Western teaching appeared between 1742 and 1748 as the ***Oranda honzō wakai***, a work on pharmacology composed by Genjō NORO (1693–1760) who had studied under an unnamed Dutch physician at Tōkyō. The *Oranda honzō wakai* was probably the first of a series of Japanese pharmacological writings to bear the imprint of Western learning. The *Medicinae compendium* . . . (Lugd. Bat., 1731) of Johannes de Gorter is generally regarded as the first Western book on *clinical* medicine to be translated into Japanese. That work was accomplished by Genzui UDAGAWA (1755–1797) in his *Naika senyō*, which was published in 1793.

The first Japanese translation of European materia medica was made in 1828 by Genshin or Shinsai UDAGAWA (1769–1834) in his *Oranda* (*or Waran*) *yaku-kyō*, which was based upon the pharmacological writings of Adolphus Ypey, H. J. van Houte, J. Arnemann, and Christianus Ignatius Niewenhuis. Later on, the works of Karl Peter Thunberg, apparently a little-known Dutch edition entitled *Naamlyst van gewassen door den beroemden natuuronderzoeker* (n.p., n.d.); the work of Joannes Adrianus van de Water; and certain parts of an encyclopædia of medicine by Georg Friedrich Most were translated into Japanese. Also the pharmacopœias of Amsterdam, of Leyden, and of Batavia were abstracted into the Japanese language.

The anatomical atlas of MOTOKI, referred to above, was not considered important by the Japanese of that time . . . perhaps because it was overshadowed by the famous *Kaitai shinsho* in 1774, with its immediate precursor—a series of five sheets of anatomical drawings known as the *Kaitai yaku-zu* which appeared in 1773. The *Kaitai shinsho* was based principally upon Johan Adam Kulm's *Tabulæ anatomicæ* . . ., from the Dutch translation by Gerardus Dicten, *Ontleedkundige tafelen* . . . (Amsterdam, 1734). But Kulm is known to have copied the work of Philipp Verheyen, who, in turn, had imitated the plates of Andreas Vesalius' *De humani corporis fabrica*. Fig. 3 is a reproduction of the title-leaf of the atlas of the *Kaitai shinsho:* a redrawing, with alterations, of the title page of Christopher Plantin's ironical plagiarization of Juan Valverde's imitation of Vesalius, most probably the Dutch edition *Anatomie, oft levende beelden vande deelen des menschelicken lichaems* . . . (Antwerp, 1568). A set of wood-block illustrations in the *Kaitai shinsho* atlas is believed to have been copied from the Dutch edition, *Ontleding des menschelyken lichaems* (Amsterdam, 1690), of

Godfried Bidloo's *Anatomia humani corporis* . . . Certain of the works of Caspar Bauhinus, of Jan or Jean Palfyn, of Stephen Blancard, of Volcher Coiter, of Johann Vesling, and possibly of Albrecht von Haller were known to the Japanese, and each is supposed to have contributed in some way to their understanding of Western anatomical knowledge and to have been "read" in connexion with the composing of the *Kaitai shinsho*. Perhaps it is not without some truth that the *Kaitai shinsho* has been referred to as the "Japanese Vesalius".

The men responsible for the composing of the *Kaitai shinsho* were the core of a group who believed in and fostered the learning in Japan of Dutch medicine and science. This small group was headed by Ranka or Ryōtaku MAENO (1723–1803) and Gempaku SUGITA (1732–1817), and upon the latter ultimately devolved the credit for the publication of the *Kaitai shinsho* in its final form. The unique importance of the *Kaitai shinsho* was, first, that it immediately overthrew and made obsolete the Chinese conceptions of human anatomy which had dominated the medicine of Japan for many centuries; second, that it caused a renaissance in *all* fields of Japanese learning and culture; and, third, that it directed attention to the accuracy and superiority of Western knowledge as exemplified by Dutch books.

Within a few years the *Kaitai shinsho* was revised by Bansui or Gentaku ŌTSUKI (1757–1827) in a manuscript composed in 1798 and published in 1812 with the title *Jūtei kaitai shinsho*. An accompanying atlas followed in 1826(?) and shows the influence of still another Western anatomy, Bartholomaeus Eustachius' *Tabulæ anatomicæ* . . ., probably from the Dutch text by Andr. Bonn (Amsterdam, 1798) or as revised by J. C. Krauss (Amsterdam, 1800), with the plates of Eustachius re-engraved by Bernard Siegfried Albinus and copied by another hand for these Dutch editions.

Western obstetrics seems to have first made its appearance in Japan by means of Hendrik van Deventer's *Dageraat der Vroededvrouvven* (Leyden, 1696) and/or his *Manuale Operation Zijnde een Nieuw Light* . . . (Leyden, 1734 or 1746), influencing the work of Genshu or Kakuryō or Motochika or Shinhō KATAKURA (1750–1822) who copied many of Deventer's plates in the *Sanka hatsumō* which was published in 1799. KATAKURA also copied William Smellie's obstetrical forceps, which had been figured in the Dutch translation by Matthys van der Haage, *Verzameling van Ontleedkundige Afbeeldingen* . . . (Amsterdam, 1765). Earlier, in 1773, some influence of Western obstetrics had been felt in Japan, since certain extracts from unspecified Dutch and English books were incorporated in the *Sanikuhen* by Bumpaku YAMANOBE. This work, however, appears not to have had as much influence among the Japanese as did the later writing of KATAKURA . . . Later on, the obstetrical books of Gottlieb Salomon, of Alfred Meadows, and of Karl Ludwig Ernst Schroeder were translated, in whole or in part, into Japanese.

Boku or Kōki or Shōshū MITANI (1774–1823) composed in 1802, and first published in 1813, a description of the whole system of human anatomy in a work entitled *Kaitai hatsumō*. That work was distinctive as the first *printed* Japanese anatomy to use colour wood-block illustrations; it was based partly on original Japanese dissections and partly on an exposition of "new Dutch theories" (of human anatomy), the Western sources not specified by MITANI.

The Western sources used by Genshin or Shinsai UDAGAWA in his work, the *Ihan teikō* (1805), with its magnificent copper-plate atlas separately titled *Ihan teikō-zu* or *Naishō dōhan-zu* (1808), are more certain. Dutch editions of the works of Stephen Blancard, his *De nieuw hervormde anatomie* . . . (Amsterdam, 1686) and/or his *Anatomia reformata* . . . (Lugd. Bat., 1687); of Jan or Jean Palfyn, his *Heelkonstige ontleeding van's menschen lighaam* . . . (Leyden, 1718 or 1733) and/or his *Waare en zeer naauwkeurige beschrijving der beenderen van's menschen ligchaam* . . . (Amsterdam, 1758); and an unidentified work of Jakob Benignus Winslow are known to have been used by UDAGAWA. The title-leaf of the *Naishō dōhan-zu*, shown in Fig. 4, is a re-engraving of Blancard's title page with a medallion portrait of Blancard *supra*. This anatomical atlas is distinctive as representing the first copper-plate engravings to be used in Japan to illustrate a medical work.

One or both of the Dutch editions of Palfyn's books on anatomy was the basis for a later translation into Japanese, by Isaburō NAKAYA in his work known as *Kaibō-zu* which was published in the fifth year of the Bunsei period (=1822). The title-leaf of the *Kaibō-zu*, and an illustration from it, appear here as Fig. 5. It is interesting to note that the Japanese text describes Jan or Jean Palfyn as a Belgian specialist in cancer who himself died from that disease.

It was Genshin or Shinsai UDAGAWA who began the first Japanese translation of a Western work on ophthalmology, from an unidentified Dutch edition (1787) of Joseph Jakob von Plenck's *Doctrina de morbis oculorum*. UDAGAWA's abridged translation was expanded by Kinchō or Rikkyō SUGITA (1786–1846), who published it in 1815 as the *Ganka shinsho*. Dutch ophthalmology was compared with the classical Chinese ophthalmology then still used in Japan, by Fuichi or Shinichi or Toshiatsu HONJŌ (died 1846) in his *Ganka kinnō* (1831) and in his *Zoku ganka kinnō* (1837).

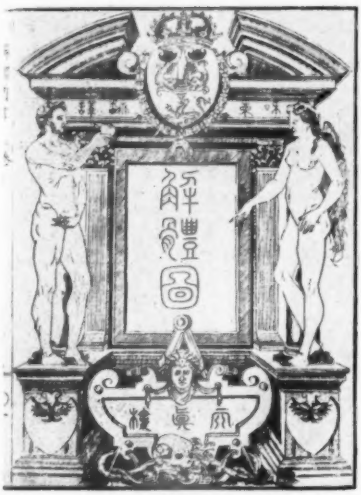

FIG. 3.—Title-leaf of the atlas of the *Kaitai shinsho* (1774).

FIG. 4.—Title-leaf of the *Ihan teikō-zu* or *Naishō dōhan-zu* (1808).

FIG. 5.—Title-leaf, and one of the anatomical plates of the *Kaibō-zu* (Bunsei period, 1818–1829). From *Meijizen Nippon igaku-shi*.

Most of the books by Joseph Jakob von Plenck appear to have been known in Japan, and the influence of his writings on Japanese medicine during the first third of the nineteenth century was great. The second edition in 1787 of Plenck's *Doctrina de morbis venereis* was, through the intermediary of a German translation by Franz Xaver August von Wasserburg and of the Dutch translation by Lambertus Nolst, *Verhandeling over de venusziekten* (Dordrecht, 1792), used by Kōgyū YOSHIO (1724–1800) to compose his work on syphilis, *Morenki baisō-ron* (n.d.). The Dutch translation was also used by Kinchō SUGITA in his *Baiso shinsho* (1820). Kinchō SUGITA wrote the first *complete* Japanese translation of a work on Western surgery in his *Yōka shinsen* (1830), which was based on Plenck's *Compendium institutionem chirurgicarum pro tironibus chirurgicae*. That same Western work was also used by Eihō YOSHIO (1785–1831) in his *Plenck geka-sho* (n.d.). The *Fujin byōron* (1850), a work on gynæcology by Takedō FUNABIKI or FUNANARI, was based on Plenck's *Doctrina de morbis sexus feminei*.

After the famous Japanese manuscripts and printed translations of parts of Paré, Western surgery made its greatest impact in Japan by means of a Dutch edition of Lorenz Heister's *Chirurgie*, identified as *Heelkundige onderwzingen* . . ., the second Dutch edition (Amsterdam, 1755). According to the account of this book as given in the *Rangaku kotohajime*, Gempaku

FIG. 6.—Illustration from the *Yōka seisen zukai* (1820).

FIG. 7.—The first Japanese stethoscope (1848). After NAGAYAMA.

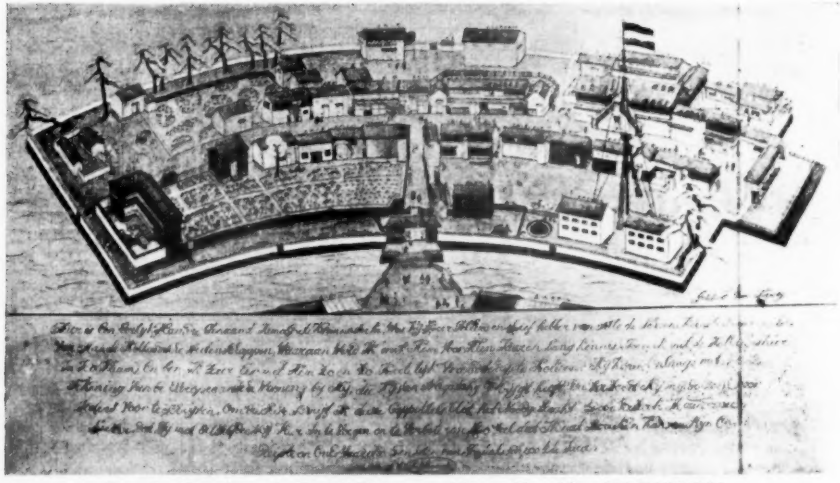

FIG. 8.—Deshima, the Dutch Factory at Nagasaki. After NAGAYAMA.

SUGITA borrowed it from Eishō or Kōgyū YOSHIO, who had traded 20 barrels of *sake* (rice wine) for the book which had been brought into Japan about the year 1767. SUGITA copied the illustrations, finished a translation of those parts of Heister concerned with bandaging, and started a translation apparently of the entire Dutch work. Bansui or Gentaku ŌTSUKI completed that translation in a manuscript dated 1792 known as the *Yōi shinsho*, some parts of which were later published. For example, Genkan ŌTSUKI, the son of Gentaku, revised that part of his father's work concerned with bandaging and in 1814 published the *Geka shūko* (sometimes referred to as *Taisei geka shūko*). Kōgyū YOSHIO also based at least his work on the treatment of wounds and bandaging, the *Kinsō-ron*, on Heister's book.

An independent translation of Lorenz Heister's *Heelkundige onderwzingen* . . . was made by Shinzō or Tokumoto KOSHIMURA in 1819 in an unpublished manuscript of 100 *hen* (=parts or volumes or books or sections or chapters). However, in 1820, KOSHIMURA

did publish a two-volume work entitled *Yōka seisen zukai*, illustrating various surgical operations and instruments—copied from Heister—with explanations and instructions. Fig. 6 is taken from a leaf of KOSHIMURA's atlas, showing an ophthalmic procedure with detail of the eye and some of the instruments used. The works of Tommaso Alghisi and of Ambroïse Paré, and perhaps also of François Tolet, are supposed to have contributed to KOSHIMURA's *Yōka seisen zukai*. It is not known, however, if that influence was directly from Dutch editions of their works (except for Alghisi, whose *Litotomia ovvero del cavar la pietra* appeared only in Italian editions) or indirectly through the intermediary of Heister who is known to have imitated the plates of those earlier writers. . . .

In the year 1818 an English book on Jennerian vaccination (possibly a copy of Jenner's *Inquiry . . .*) almost got into Japan, by being offered as a gift from a British sea captain to a Japanese physician to whom he had demonstrated the preparation of the smallpox vaccine. But the gift was refused, and fate was to decree that Western vaccination would be introduced to Japan by means of an obscure Russian writing, known in Japan by the title *Spop isbāwissha soueruseno wot was henoi saraza*[1] (St. Petersburg, 1803) which was translated into Japanese by Sadeyoshi or Sajūrō BABA (1786–1822) in a manuscript entitled *Tonka hiketsu* (1820), later to be published in 1850 with the title (*Wo*) *Roshia gyūtō zensho*. Opposed to this, however, is the generally accepted belief that Western vaccination first came into Japan with the arrival there in 1848 of Otto Theophil. Joh. Mohnike.

Philipp Franz von Siebold spent two separate periods in Japan, the first visit from 1823 to 1829 and the second visit from 1859 to 1861. His personal influence in the evolution of Japanese understanding of Western medicine in all of its varied aspects was perhaps greater than that of any other European who visited Japan. He was noted as a bibliophile and it is probable that he brought with him many Western works on medicine and surgery. Soon after his first visit Japanese translations of Western authors began to appear in ever-increasing numbers. We will content ourselves here with calling attention only to the most outstanding of such writings. In 1832 Kōan OGATA (1810–1863) wrote a work known by various titles, most commonly as *Jinshin kyūri shōkai* or as *Rasetsu jinshin kyūri*, which had been derived from the *Handboek der natuurkunde van den mensch* of Theodorus Georgius Augustus Roose and from the Dutch translation by Adolphus Ypey, *Handleiding tot de phijsiologie . . .* (Amsterdam, 1809) of Roose's *Handbuch der Physiologie des Menschen*. The publication in printed form of this work by OGATA is very much in doubt. The works of Roose, and of Johann Friedrich Blumenbach in Dutch translation, *Grondbeginselen der natuurkunde van den mensch* (Amsterdam, 1835), were also used later by Chōei TAKANO (1804–1850) when he composed the *Igen sūyō* and published it in 1836. This translation by TAKANO is generally regarded as having been the first physiological writing in Japan to be based on Western books.

The work of Christoph Wilhelm Hufeland, from the Dutch translation by H. H. Hageman, *Enchiridion medicum. Handleiding tot de geneeskündige praktijk . . .* (Amsterdam, 1838), proved to be very influential in Japan. Kōan OGATA translated the "Praxis" into Japanese in his book *Hushi kēikun ikun* which was published in 1843. Various other parts of Hufeland's book were also translated by Bairi or Seikai or Seikyō SUGITA (1817–1859) in his *Saisei sampō* (n.d.) and in his *I-kai* (n.d.). These Japanese translations were widely read. Except for only two earlier attempts by the Japanese to elucidate the philosophical aspects of human pathology, the *Byōgaku tsūron* by Kōan OGATA is regarded as the first Japanese writing on general pathology. It appeared in 1847 or 1849 and consisted, for the most part, of translated abstracts from the published works of Christian Wilhelm Hufeland, of Georg Wilhelm Christoph Consbruch, of Johann Wilhelm Heinrich Conradi, of Philipp Carl Hartmann, and of Kurt Polykarp Joachim Sprengel. Except for the Dutch edition of Hufeland's work, noted above, none of the Western original books used by OGATA is known.

Anthelme-Balthasar Richerand's *Nouveaux élèments de physiologie*, in the Dutch translation by A. van Erpecum, *Nieuw grondbeginselen der natuurkunde van den mensch* (Amsterdam, 1826), attracted the attention of several Japanese physicians. It was translated in 1844 as the *Iri-gaku gen* by Sodō HORIUCHI (1801–1854), Ryōan KUROKAWA and Kenzō AOKI; and in 1855 as the *Jinshin kyūri sho* by Genkyō HIROSE (1821–1870); and by Gempo MITSUKURI (1799–1863) in his *Jinsei kyōgen* (n.d.).

An interesting situation is presented by a Scottish (?) missionary-physician, Benjamin Hobson, who went to China in 1839 and spent the next twenty years in practice—and, with the help of a Chinese physician, CHIN Shū-dō, in the translation of European medical books into the Chinese language. One such collection of summaries or abstracts was further translated from Chinese into Japanese by CHIN, and in 1857 was published in Japan the remarkable work known as the *Zentai shinron*. The *Zentai shinron* contained extracts from several

[1]Transliterations into the Roman alphabet are not always easy, and this title may, more correctly, be *Sposob isbāvitsia sara (—) eniia ot (ospa) gnoinoi sarasai.*

Western medical books, notably English editions—for example, William Cheselden's *Anatomical tables . . .*—and this Japanese translation was destined to introduce much of Western medicine to the island empire.

An epidemic of cholera had ravaged parts of Japan in 1821–22, evidently for the first time, but the second epidemic in 1858 precipitated the first Japanese work on the subject—a book entitled *Korera byōron*, by Ryōkaku SHINGŪ, Ryōmin SHINGŪ and Tatsukichi OMURA. That work was, for the most part, a translation of an unidentified book on cholera which had been written by Georg Friedrich Most.

Medical instrumentation of the Western world was introduced into Japan by: microscopes (*c.* 1787), clinical thermometers (*c.* 1826), and stethoscopes (1848) which had been brought in by European physicians; models which were promptly imitated by the Japanese. The first Japanese stethoscope was made in wood by Eikyū or Umejirō SHINAGAWA (1808–1857), and is shown here as Fig. 7. This original model is—or was—preserved in the Nagasaki Medical College.

Nagasaki was the place in Japan through which most of the contacts with the Western world were made, by means of the Dutch Factory at Deshima. Fig. 8 is a reproduction showing the plan of Deshima from an old print. It was on a rock at a beach near Nagasaki that Jacobus L. C. Pompe van Meerdervoort, a Dutch physician and anatomist, performed, on June 9, 1859, the first dissection of a human body done by a Western person in Japan. Afterward, Pompe van Meerdervoort established several hospitals and popularized autopsies for teaching purposes.

This brief account of the principal Western influences in the development of pre-Meiji Japanese medicine, more especially from the bibliographic aspects, ends with the beginnings in 1857 of the present medical school of the University of Tōkyō. The Edo or Tokugawa period itself ended in 1867 with the overthrow of the Shōgunate and the "restoration" of the Emperor Meiji, and thus began the modern period in Japan.

Of equal interest is how knowledge of early Japanese medicine came to the Western world. Except for possible oral descriptions carried back to Europe by returning missionaries and physicians, the principal means were the writings of Willem ten Rhyne and of Engelbert Kaempfer. ten Rhyne's *Dissertatio de arthritide: mantissa schematica: de acupuncturа . . .* (London, 1683) was the first such writing. ten Rhyne followed that up with another account entitled "Der Chinesen und Japaner Weise, wie selbige allerley Kranckheiten durch das Brennen mit der Moxa, und Stechen einer gulden Nadel, völlig und gewiss curiren," which was obscured or even "lost" by being incorporated *in* Stephen Blankaart's *Accurate Abhandlung von dem Podagra . . .* (Leipzig, 1690). This title is sometimes given as *Verhandeling van het podagra en vliegende jigt*. Kaempfer's *Amoenitatum exoticarum politico-physico-medicarum, Fasciculi V. . .* (Lemgoviae, 1712) had the advantage of being a separate publication, and became even better known than ten Rhyne's earlier descriptions. Willem ten Rhyne (in Japan from 1674–77) and Engelbert Kaempfer (in Japan from 1690–92) were, then, the first to report to the West on early Japanese medicine. Except for Kaempfer's famous *History of Japan* (London, 1728), there were no descriptive writings by Western physicians for about one hundred years; not, indeed, until the time of Karl Peter Thunberg, who gave much information in his *Voyages de C. P. Thunberg, au Japon . . .* (Paris, 1796). Later on, Philipp Franz von Siebold gave some of the best accounts of the time in a series of publications beginning in 1824 and culminating in his *Nippon. Archiv zur Beschreibung von Japan . . .* (Leiden, 1832–52, 7 vols. 2nd edition, Wurzburg und Leipzig, 1897, 2 vols. New edition, Berlin, 1930–31, 3 vols.).

Since this paper is only an introduction to the subject and not an exhaustive account, a list of "selected references" is appended, chosen by the writer as giving the most useful information for an understanding of Western medical influences in Japan in pre-Meiji times.

Acknowledgment is made of the help given by Dr. Paul Akira MASHIMO, Research Fellow in the Department of Microbiology at Columbia University, College of Physicians and Surgeons, who clarified several obscurities in Japanese texts. Mrs. Taisa Scors, of the Library staff at the State University of New York, Downstate Medical Center (Brooklyn), kindly traced some of the even more obscure Russian literature bearing on this subject. The illustrations, from books and other materials in the writer's Japanese collection, were made by Mr. Philip Fleury and Mr. Jack Illari, of the Photographic Department in the State University of New York, Downstate Medical Center (Brooklyn). My thanks go to Miss Gertrude Annan, Librarian at the New York Academy of Medicine, for reading the manuscript and making helpful suggestions. Dr. Kenneth F. Russell, Professor of Anatomy in the University of Melbourne, has given constant encouragement and it is a pleasure to acknowledge this intangible—but very real—help.

Worms in History with Special Reference to Children

By JOHN RENDLE-SHORT, M.D., M.R.C.P., D.C.H.

Department of Child Health, University of Sheffield

IN the old London Bills of Mortality and in books on children's diseases in past centuries, three conditions recur again and again—teething, convulsions and worms. I have considered the first two of these in previous communications (Rendle-Short, 1955*a*, *b*). The present paper deals with the subject of worms.

There are probably three main reasons for the concept that worms cause disease. Firstly, as Grattan and Singer (1952, p. 99) wrote with regard to Anglo-Saxon medicine, "There is a constant association of ideas between the poison of the serpent and the supposed venom of the worm".

Secondly the presence of worms or maggots in a body after death has been known from antiquity. Meat left too long soon harbours maggots, and it was commonly supposed that they entered the body while the animal was still alive. Andry (1701, p. 24) mentioned that some people thought that if meat was kept in stoppered bottles protected from flies, maggots would not develop. He, however, rejected this idea without apparently trying the experiment himself. From the dead body with its grubs to the living body with its worms is obviously only a small step.

The third reason for the concept of the evils of worms is that they were so frequently found in sick people. Failing any other obvious cause for an illness, worms were apt to be incriminated.

In ancient oriental medicine worms figure prominently. From the Vedic period (1500–900 B.C.) we have the Atharva-Veda Samhita. In this there are incantations against worms.

> "O Indra, lord of riches, smite thou the worms of this boy; smitten are all niggards by thy formidable spell.
> "What one creeps about his eyes, what one creeps about his nostrils, what one goes to the midst of his teeth—that worm we grind up.
> "The worms that are white-sided, that are black with white arms, and whatever ones are of all forms—these worms we grind up" (Whitney, 1905).

Hippocrates (*c.* 440 B.C.) described worm infestation in some detail. He claimed that worms were formed while the child was still *in utero*. He advanced two arguments in support of his theory: Firstly that fæces never remain in the bowel long enough for an

animal of such size to be formed. It could not be produced even if there was no action of the bowel for several days. Secondly that when given a purge immediately after birth, children often passed a roundworm or a tapeworm with the first stool.

Chronologically far later, we come to the Anglo-Saxon period (around A.D. 1000) when medicine was a mixture of pagan magic and Christian teaching. According to Grattan and Singer (1952, p. 99), "There is hardly a symptom from toothache to fits that is not at one time or other ascribed to worms". In the Lacnunga, an Anglo-Saxon magico-medical common-place book dated around A.D. 1000 there is this spell:

> *In case a man or beast swallow a worm.*
>
> If it be of male kind sing this lay which is written hereafter into the right ear; if it be of female kind sing into the left ear" (Grattan and Singer, p. 107).

The spell itself was gibberish and unintelligible. It had to be sung nine times into the appropriate ear and then a single Paternoster. No instructions were given as to how the ingested worm should be sexed.

But to come down to more recent times. At the beginning of the eighteenth century Nicholas Andry produced his "Account of the breeding of worms in human bodies" (1701). According to him almost every ill was due to worms, so much so that he earned the nickname "Homo vermiculosus" (Still, 1931). He considered that all living creatures had their worms: vegetables, wood, coral, oysters, shell-fish, liver of sheep and "there is scarce any fish without them". Human worms he divided into two main types: those in the gut and those outside it. The latter included worms bred in the ears, teeth, lungs, liver and heart. (These could be seen in blood-letting and from the description may have been blood clots.) In addition there were "vesicular" worms (Plate I, Fig. 5), worms from sores

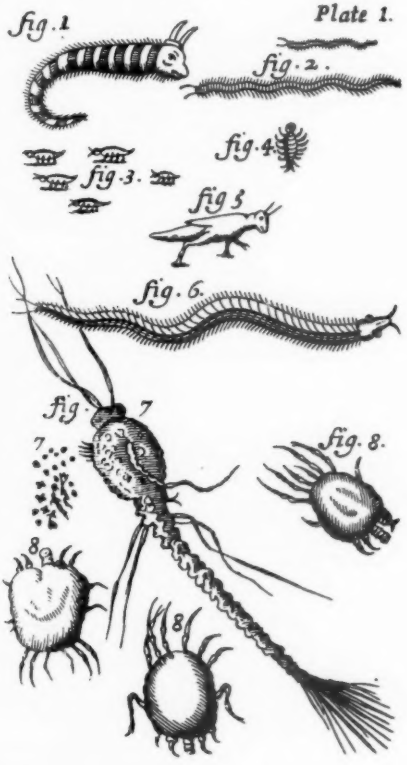

PLATE I.—Reproduced from Andry (1701).

and gangrene (Plate I, Fig. 6) and cutaneous worms (Plate I, Fig. 7) which appeared on the arms and legs and especially on the backs of breast-fed children. He acknowledged that some people considered these to be hairs not worms. Perhaps he was thinking of lanugo hairs, or more probably of blackheads. Ettmüller (1676) described a treatment for these worms which, "skulk under the skin especially about muscular places". The child was to be bathed in warm water in which chickens' dung had been boiled and then rubbed all over with honey to tempt the worms to come out in the form of black hairs. These could then be scraped off with a crust of bread "made sharp like the edge of a knife".

"Wax worms (Plate I, Fig. 8) lived under the skin creeping about and producing blisters which "occasion a vehement itching". It was possible to discover this worm when the blister was pricked. These worms, presumably *Sarcoptes scabiei*, were called "wax worms", "because stale wax is most apt to be eaten by them".

Andry (1701, p. 55) also mentioned umbilical worms which "breed in the navel of children and give 'em a great deal of trouble. They make 'em very lean and throw 'em into Universal Decay". He continued: "There is no other sign of this worm but this that if you fasten a gudgeon on the navel, next day part of the fish will be corroded." The gudgeon (Oxford English Dictionary) is a small fresh water fish which is easily caught. The word is now used to describe a person who is easily deluded. Perhaps Andry did not know this.

Ettmüller (1676), too, mentioned the umbilical worm and suggested treating the affliction by applying the gudgeon to the belly for a few nights and then substituting, "the inner shell of a walnut filled with powder of venice glass". Presumably the worm enjoyed eating the fish and returned for more, only to eat the glass by mistake and die.

Most authors described only four varieties of worm:

Old Name	Modern Name
Round and Short: Ascarides	*Enterobius* (or *Oxyuris*) *vermicularis;* threadworm; pinworm; seatworm
Round and long	*Ascaris lumbricoides;* roundworm
Flat and long; Tænia ..	*Tænia solium* (or perhaps *saginata*); tapeworm
Flat and short	Isolated proglottides of tænia

Bracken (1737), however, described three types: roundworms, broad worms and horrid worms. The latter had many feet, two heads and some a double forked tail.

We will now consider threadworms, tapeworms and roundworms in greater detail.

Threadworms.—Astruc (1746) wrote that ascarides caused the patient to feel "a troublesome sensation in the fundament", and Bracken (1737) described small worms which live "about the sphincter muscle of the anus". Armstrong (1777) mentioned that threadworms usually only appeared after the infant had been weaned, but occasionally they were seen in breast-fed babies if the mother had been subject to the same type of worm from infancy.

Specific treatment for threadworms was not often described but Rosen von Rosenstein (1776) suggested several forms of therapy, the most notable of which was a clyster (enema) of rats' dung and sugar in tepid milk to be administered six nights running. Alternatively, a clyster of tobacco smoke could be given. Another ingenious treatment he suggested was to tie a string to a piece of fresh pork which was then inserted into the rectum. The worms apparently bit the pork and could thus be removed. The pork had to be changed and the fishing continued for some time in order to evacuate all the worms.

Tapeworms.—As might be expected most descriptions of tapeworm infestation concern adults. However, Harris (1689) described the 3½-year-old daughter of an Earl (many of Harris's case histories refer to titled children) who had a slow fever, was sleepy and had twitching of the nerves and a dry cough. She was given clysters, purges and emetics for six days, which caused her to pass a worm "a span long, after which she was presently relieved from her whole disorder". Brouzet (1755) described flat-worm infection in older children who had continual spitting, paleness, weakness, pains in the liver and offensive breath. Slimy stools occurred in which small pieces of the worm were voided. He mentioned an irregular appetite, but Rosen von Rosenstein (1776) described a state of continual hunger and recorded that a woman who later passed 18 tapeworms, ate voraciously day and night.

The treatment of tapeworm infestation was long and arduous and consisted chiefly in starvation and purgatives. Sometimes worms lived to a great age—15 years is recorded.

Roundworms.—At the present time in this country these helminths are infrequent and

innocuous, but this was not so in the past, and even to-day in some parts of the world they are common and dangerous. The difference lies partly in the poor nutritional state of the victims—itself to some extent the result of the roundworms—but mainly because of the large number of infesting worms. de Silva (1956) records that in Ceylon the passage of 100–200 or even up to 1,000 worms is not uncommon.

Ascaris lumbricoides has only one host—man. The clue to the problem of worm infestation therefore lies in the method of disposal of fæces. This in the past was very casual. Norman castles had their garderobes placed in a corner with a wooden seat and a stone shaft which discharged at the base of the wall or into the moat (Quennell and Quennell, 1947). In 1596 Sir John Harrington, a poet and godson of Queen Elizabeth, invented the first water closet. In the pamphlet in which he described his invention, he gave a long account of the state of affairs which then existed. He wrote "Even in the goodliest and statliest palaces of this realme, notwithstanding all our provision of vaults, of sluces, of grates, of poore folkes in sweeping and scouring, yet still this same whorsom sourie stink though he were commanded on pain of death not to come within the gates yet would spite of our noses even prease to the faire ladies chamber."

But Harrington's closet did not become popular, and indeed it could not be of any great value until the introduction of main drainage which only occurred in London in 1865. Meanwhile in towns, privies were usually just a single bucket at the bottom of the stairs, and the newer part of London was built over cesspools. According to Creighton (1894) the soil of London "was full of organic impurities including the decomposition of many generations of the dead. A hot summer raised an effluvia from the ground such as the modern residents have no experience of". Parson Woodforde (1799) was probably as well situated as anyone in his day with his "Jericho" as he called it. This consisted of a seat in the garden which discharged directly into a pit which projected at the back so that it could be emptied. This refuse would then have to be disposed of, probably by strewing it on the land. Obviously there was ample opportunity for the contamination of food.

Most later writers believed that worms came from eggs. Some remarked that they did not know where the eggs came from (Brouzet, 1755; Astruc, 1746). Ettmüller (1676) incriminated corn or bread, but the majority of writers believed that fruit and vegetables were the offending articles of diet (Pechet, 1697; Boerhaave, *c.* 1724; Underwood, 1784). It was for this reason that these foods were usually forbidden to children, which may have saved them from worms, but almost certainly resulted in their contracting scurvy. One of the few writers who was willing to brave the dangers of fruit eating was Cadogan (1748), who wrote: "Some may think they (fruit and vegetables) carry into the stomach the eggs of future worms; but of this I am not very apprehensive: for I believe there are few things we eat or drink that do not convey them."

The signs and symptoms of roundworm infestation can be divided into medical and surgical. Many writers describe the former. Thus Pechet (1697) listed: a mouth full of spittle, teeth grinding, dreams, scratching the nose, chewing, dry cough, nausea, vomiting, "kickops", thirst, swollen belly, cold sweats, flushing, fits and fevers. Tissot (1765) gave a similar list but added that the belly was "larger than ordinary, the rest of the body meagre". He also included palsies of hands, arms or legs, "gums in bad state as though gnawed or corrupted and even loss of sight or speech". Andry (1701, p. 90) described the case of a "young girl that was dumb eight days and recovered her speech after she had voided 40 worms by stool". Plate II shows a roundworm illustrated by Andry.

fig. 11

PLATE II.—Reproduced from Andry (1701).

The mention of fever is interesting. It was the frequent appearance of worms in fever-ridden patients which led to the idea that the worms caused the fever. Harris (1689) went so far as to write a section in his book entitled, "Of worms producing the smallpox" and

gave a case record. Butter in 1782 published "A treatise on the infantile remittent fever", which he said is, "Commonly but very unjustly called the worm-fever". He continued, "the patients generally pass worms in the course of this fever even when they were never known to void any before".

Surgical ascariasis is virtually unknown in this country to-day, but in those parts of the world where the standard of hygiene is low, the condition occurs quite frequently. In 1955, 53 cases of partial and 10 cases of complete intestinal obstruction, and 10 cases of acute peritonitis all due to surgical ascariasis were admitted to the Surgical Unit of Colombo Children's Hospital (de Silva, 1956). In times past, owing to heavy infestation and the frequent use of violent purges and vermifuges surgical complications were common.

Many old writers considered that worms could obstruct the gut and compress and irritate the bowel (Tissot, 1765). They also caused trouble by gnawing them (Boerhaave, *c.* 1724). Pechet (1697) wrote that, "white worms are better than yellow, livid red or blackish". They were better evacuated by stool than upwards, "and worst of all when they eat their way out". Andry (1701, p. 92) described the case of a young man of 15 who was very sick. He was made to take "a certain powder" which "caused him to void downward above 100 worms. But after all the belly continuing hard and stretched toward the navel (a plaster was applied) and twenty-four hours after several worms of good length began to come out from his navel". Later the lad ate some strawberries and "the grains or seeds" also came out. Andry concluded, "this will not permit us to question but that the bowels and the containing parts were pierced by the worms". Presumably the lad had intestinal obstruction with perforation of the gut and peritonitis which discharged through the umbilicus.

The most famous case of intestinal obstruction associated with worm infestation was that of Herod Agrippa. St. Luke tells us (Acts, xii, 22) that after the King had made an oration, the people, wishing to curry favour with him, cried out that it was the voice of a god not a man. "Immediately an angel of the Lord smote him, because he did not give God the glory; and he was eaten of worms and died." From Josephus (*c.* 93) we can learn more about the same incident. He tells us that after the shout of the people, the King did not "rebuke them, nor reject their impious flattery". But he looked up and "saw an owl sitting on a certain rope over his head, and immediately understood that this bird was the messenger of evil tidings, and fell into the deepest sorrow. A severe pain also arose in his belly and began in a most violent manner". Herod lingered on, the pain becoming more severe for five days, and then he died. Josephus did not mention the worms nor St. Luke the pain, but putting the two accounts together we almost certainly have a case of acute intestinal obstruction with perforation of the intestine and death caused by, or in association with, worms.

Returning to more recent times, a few writers even in the eighteenth century rejected the theory that worms pierced the gut. Brouzet (1755) remarked that even though he had seen worms and fæcal matter spread over the intestine, he considered it was caused by "the inflammatory and gangrenous contractions and twisting of the gut", not by the worms.

Treatment

Irrespective of their views on ætiology or symptomatology, all writers had definite views on the treatment of roundworms. These consisted mainly of purges. Calomel (Bracken, 1737), or syrup of wormwood, rhubarb or senna (Harris, 1689) was prescribed. Underwood (1784) suggested pewter filings and treacle, "of which children of 4–5 years old may take several teaspoonfuls in a day almost at pleasure". This treatment probably killed both worms and children by lead poisoning. Naturally enemas were not neglected. Pechet (1697) suggested giving the child bitter things to take by mouth. This was to drive the worms into the lower gut. Sweet things were then injected as an enema to tempt them farther down. The same method was advised by Astruc (1746), but after attracting the worms with a sweet enema he advised a bitter one to kill them. He wrote with evident glee, "I like very much this practice".

Rosen von Rosenstein (1776) gave various rules for ridding a child of roundworms. Any medicine, he wrote, must be swallowed at the time the patient would normally be having breakfast, for as "worms are accustomed to feed at that time, one may more easily cause them to suck or feed on that which is given to kill them". It was most important that the remedy be attempted only when the moon was waning. Lastly he advised that the patient must not be allowed to smell the medicine before it was given as then the worms would hide.

Teething, convulsions, and worms; these three were regarded as the great diseases of children before the advent of scientific medicine. Of the trio worm infestation was certainly not the least important.

Summary.—The concept that worms cause disease goes back to antiquity. It probably arose partly from fear of serpents, partly because maggots could be found in dead or putrefying material and partly because worms were known to inhabit the gut of man and animals.

Owing to poor sanitation worm infestation was far commoner in the past than it is in civilized communities to-day. Many medical symptoms including fevers were ascribed to ascariasis in children. Intestinal obstruction with perforation was not uncommon when large numbers of worms were present. Treatment was crude, it consisted mainly of bitters to drive the worms to the lower intestine, or sometimes sweet enemas to encourage them there. It was hoped that they would then be easily voided.

Acknowledgments.—I would like to thank the librarians of the following libraries for their unfailing help: The Royal College of Physicians, The Royal Society of Medicine, The University of Sheffield and the Wellcome Historical Medical Library. Finally, my thanks are due to Professor R. S. Illingworth for his kindly criticism.

[*May* 16, 1957]

Papulonecrotic Tuberculides with Miliary Tuberculosis.—I. S. Hodgson-Jones, M.D., M.R.C.P.

Mrs. E. M. F., aged 49. Three years ago this patient had a severe pyrexial illness which was not diagnosed. Eighteen months ago she started to develop crops of papules on her legs, which, having broken down centrally, were very slow to heal and left scars. These have been recurring ever since and have become worse lately.

Apart from a slight cough in recent weeks, her general health has been good. General physical examination revealed no abnormality except the necrotic and scarred lesions on her legs which appeared to be papulonecrotic tuberculides.

Investigations.—X-ray of the chest revealed a fine reticular mottling throughout the whole of both lung fields, with a diffuse hilar flare but without obvious glandular enlargement, which was thought to be miliary tuberculosis. X-ray of the abdomen showed no calcified glands. The blood picture and erythrocyte sedimentation rate were normal, as were the plasma protein estimation and the cerebrospinal fluid. Biopsy of a skin lesion taken from the leg showed central caseation with a surrounding tuberculous reaction. No tubercle bacilli were found in the sputum or in gastric washings. The Mantoux test was negative 1 : 10,000 but positive 1 : 1,000.

Treatment.—Following bed rest, together with streptomycin 1 gram i.m., PAS 15 grams, and prednisolone 15 mg. daily, the lung lesions cleared up in six weeks and no new tuberculides have appeared on the legs.

Comment.—Opinion has been divided as to the nature of the changes in the lung fields, particularly as to whether they are early or late miliary tuberculosis. The patient's relatively good health, normal erythrocyte sedimentation rate and the long history of lesions on the legs, make one feel that this might be chronic healed miliary tuberculosis, as described by Hoyle and Vaisey (1937, Chronic Miliary Tuberculosis, London), the original dissemination having taken place three years ago when she had her severe pyrexial illness. Against this, however, is the fact that no calcification has taken place, and the response to antitubercular therapy has been rapid, indicating perhaps, changes of a more recent origin.

Dr. B. C. Tate: I wonder if Dr. Hodgson-Jones looked for tubercle bacilli in the sections?

Dr. Hodgson-Jones: No, we did not look for bacilli in the sections because one so seldom finds them in papulonecrotic tuberculides. They were looked for in the sputum and gastric washings but were not found.

Dr. C. H. Whittle: One can have a completely silent tuberculosis which is both active and widespread. I once saw a hernial sac, removed from a boy aged 4, which was studded with tubercles in which were found acid-fast bacilli and the histology showed miliary tuberculosis. The patient was perfectly well, but similar tubercles were present and were felt by the surgeon's finger over the abdominal peritoneal surface.

Incontinentia Pigmenti.—W. Frain-Bell, M.D., M.R.C.P.Ed. (for R. T. Brain, M.D.).

E. B., female, aged 5 months.

History.—This child was born on 19.12.56 as a full-term normal delivery, birth-weight 5 lb. 8 oz. On the first day of life reddish marks appeared on the skin of the forehead and scalp, similar lesions being noticed the following day on the arms and legs. Blisters were seen for the first time on the third day and recurrent extensive blister formation continued until the age of 9 weeks, when they gradually reduced in number, hyperkeratosis forming at the sites of the blisters associated with development of dark brown pigmentation, which was linear in some areas. During the last six weeks the hyperkeratotic areas have gradually cleared, the main abnormality now being the residual pigmentation. The child's progress since birth has been normal, except for retarded weight gain during the early months; the parents are not related and there is no history of other familial abnormalities.

On examination.—There is a widespread greyish-brown pigmentation, linear in arrangement in some areas, involving extensive areas of the skin of all parts of the body. There is in addition some residual hyperkeratosis on the fingers and left lower leg.

Dr. Henry Haber: Asboe-Hansen (1953) described 4 cases of bullous keratogenous and pigmentary dermatitis with blood eosinophilia in newborn girls. All 4 cases had severe eosinophilia combined with an acute eruption of papules, vesicles, bullæ and pustules localized on the limbs. In all cases the lesions healed with formation of thick warty keratoses, which on subsiding left scars and pigmentation. The pigmentation was not slate grey and showed more the character of ordinary pigmentation and not the pattern seen in Bloch-Sulzberger syndrome. Other ectodermal defects were absent. I have seen a similar case recently shown to me by Dr. T. Morgan. I wonder whether the case shown to-day does not belong to this group.

Necrobiosis Lipoidica Diabeticorum and Granuloma Annulare.—W. FRAIN-BELL, M.D., M.R.C.P.Ed.

C. T., female, aged 16 years.

History.—This girl has suffered from diabetes mellitus for the last three years, which is at the moment reasonably well controlled with 65 units of NPH insulin daily and a diet of 1,800 calories; her maternal uncle also suffers from diabetes. Except for the skin lesions the diabetes is otherwise uncomplicated. Three years ago, a nodular eruption was noticed on the dorsum of the left foot; a biopsy was carried out but no firm diagnosis was arrived at. She was first seen by us in February 1956 and at that time she presented with grouped subcutaneous nodules on the dorsum of the left foot and ankle, some of which were noticed to be coloured; the clinical picture was that of granuloma annulare which was subsequently confirmed histologically. One month later a few fresh nodules were noted on the skin of both lower legs. She did not attend again until a year later (February 1957) at which time it was noticed that she had a number of reddish nodules on the front of the right leg and a few similar lesions on the left leg, the original nodules on the dorsum of the left foot being much smaller. In addition she had developed a plaque on the outer aspect of the left lower leg with a well-defined pigmented edge and a yellowish centre and telangiectasia, suggestive of necrobiosis lipoidica which was subsequently confirmed histologically. Further regression of the granuloma annulare lesions on the dorsum of the foot has occurred during the last six weeks.

On examination.—There are a number of firm reddish nodules on the front of both lower legs, more on the right side than on the left. There appears to be also some central scarring. One or two skin-coloured palpable nodules are still present on the dorsum of the left foot with thickening of the biopsy scar. On the outer aspect of the left leg above the ankle there is a firm well-defined plaque with a brownish periphery and yellow centre with telangiectasia.

Investigations.—Serum cholesterol 250 mg.%, lipids 1,300 mg.% (fasting normal 400–800 mg.%).

Histology (Dr. H. Haber).—23.11.56: There is one focus of change within the corium showing partial degeneration of collagen permeated by typical histiocytes and giving it a characteristic picture. Diagnosis: Granuloma annulare.

29.4.57: The epidermis does not show any diagnostic changes. The corium exhibits widespread areas of collagenous change exemplified by broadening and homogenization of their bundles. The inflammatory reaction envelops blood vessels and seems also to penetrate the tissue spaces of the collagen. Diagnosis: Necrobiosis lipoidica.

Comment.—From time to time it has been suggested that granuloma annulare and necrobiosis lipoidica may be variants of the same disease, especially as all the clinical, histological and histochemical findings in necrobiosis lipoidica have at times been associated with granuloma annulare. This existence of common features may be significant despite the ease of differentiation between classical examples of each condition. In this patient, it may be that the collagen change has been modified by the associated diabetic condition into giving rise to two extremes of the same basic condition, granuloma annulare on the one hand and necrobiosis lipoidica on the other.

The following cases were also shown:

[*June* 20, 1957]

Macular Atrophy of the Skin.—R. G. HOWELL, M.R.C.P.

B. F., girl, aged 14 years.

History.—For thirteen months she had been developing lesions scattered on the trunk and legs. These begin as small, red, non-scaly papules which gradually heal at the centre, producing a dead white scar with slightly raised erythematous edge. Later the edge disappears.

On examination.—General health good. No serious illness in the past. Mild ichthyosis and keratosis pilaris. No adenopathy. Liver and spleen not palpable. C.V.S., abdomen and C.N.S. normal. Blood pressure 110/80.

Investigations.—Mantoux 1 : 10,000 positive. W.R. and Kahn negative. Hb 94% (14·4 g./100 ml.), W.B.C. 8,000 (polys. 44%, eosinos. 2%, lymphos. 50%, monos. 4%). E.S.R. 2 mm. in one hour (Westergren). Urine normal.

Histology (Dr. H. Haber).—The centre of the lesion shows marked atrophy of the epidermis, and there is a marked perivascular and periacinous lymphocytic infiltration in the dermis.

Comment.—The macular atrophic lesions in this case do not resemble the anetoderma of Jadassohn or the similar condition described by Schweninger and Buzzi in which the atrophic areas are flaccid and can be herniated on pressure. The clinical appearance in this case is similar to that described by Degos (1954) under the title "Papulose Atrophiante Maligne". This condition eventually involves the gastro-intestinal tract causing hæmorrhage and perforation. However, the histological picture described by Degos shows thromboses of vessels and necrosis without cellular reaction in the dermis. In a recent case described by Ingram and Sutherland (1957) the lesions were also necrotic.

Ehlers-Danlos Syndrome.—E. WILSON JONES, M.R.C.P. (for H. J. WALLACE, F.R.C.P.).

Mrs. S. M., aged 19, gave a history that she had shown excessive liability to bruising from early childhood. In addition, cuts or abrasions tended to heal very slowly, leaving abnormal scars.

There was no family history suggestive of the Ehlers-Danlos syndrome. The parents and five siblings were stated to have a normal skin. It was, however, not possible to confirm this since our patient lives away from home.

On examination.—The patient was thin and looked generally undernourished. The striking abnormality of the skin was the presence of mottled pigmented scars over both knees and down the greater extent of both tibia. There were similar smaller scars over the points of both elbows. In parts the scars were baggy and papyraceous. Her skin was thin, but in no part demonstrated hyperelasticity. Her hands showed a mild degree of arachnodactyly. No hyperextensibility of the joints was found.

On general medical examination, the only other feature of note was the presence of faintly bluish sclerotics and on examining the heart a soft systolic murmur was heard in the pulmonary area without any other abnormal cardiac signs.

Investigations.—Plasma calcium 9·4, phosphorus 4·6 mg./100 ml. Clotting and bleeding time normal. Chest X-ray normal. Hb 70%, W.B.C. 7,400. Normal differential count. Platelets 494,000. Hess test negative. Electrocardiogram: Clockwise rotation, otherwise physiological.

Ehlers-Danlos Syndrome, with Spondylolisthesis and Malformation of the Terminal Digit.—LOUIS FORMAN, M.D., F.R.C.P.

Miss A. P., aged 23.

Family history.—Only child; her mother and maternal grandmother had abnormal elasticity of skin.

History.—Since birth there has been abnormal mobility of all joints and her skin bruised easily. At the age of 8, following an injury to the right leg, an ulcer developed which healed after a considerable period of time. It relapsed after another injury and again healed slowly. This sequence has been repeated. The present ulcer has been present for two years and attempts at suturing following excision have failed. Eighteen months ago some of her finger nails became yellow and flat, and the distal phalanges shortened.

Present status.—The skin is of fine texture, smooth and supple. It is hyperelastic over the cheeks, the neck and backs of the hands. Over the right shin there is a clean superficial ulcer 1¼ in. × 1 in. There is increased range of movement of all the limb joints, bilateral pes cavus and marked lumbosacral deformity. Five of the finger nails are flat, spooned, longitudinally striated.

Investigations.—Normal blood picture, normal proteins and serum calcium, normal clotting mechanism. Hess test negative.

X-rays: (1) Lumbosacral region: gross spondylolisthesis at the L.5–S.1 level.

(2) Numerous areas of subcutaneous calcification anterior to lower half of each tibia.

(3) The terminal phalanges of the 1st, 2nd and 5th fingers of the left hand and the 2nd finger of the right are malformed. Some show absence of the distal part of the phalanx. The intracapsular rim of bone is retained.

"The above findings are consistent with the findings in Ehlers-Danlos syndrome" (Dr. P. J. Hurley).

Skin biopsy.—From abdomen, connective tissue thin loose poorly-formed and poorly-stained bundles.

Elastic tissue, increased, thick and coiled.

Comment.—The two characteristic signs of Ehlers-Danlos syndrome are exhibited to some degree in this patient:

(1) Increased elasticity of the skin due to greater content of fibres which have been shown to be elastic fibres under the electron microscope (Tunbridge quoted by Rothman).

(2) A lowered tensile strength of the skin so that it splits with injury. The connective tissue fibres are thin with fewer cross connexions and, according to Rothman, slide more readily on each other when stretched.

Rollhauser (quoted by Rothman) states that differences of tensile strength of the skin are paralleled by the tensile strength of tendons and other fibrillary structures. This explains the associated laxity of joint capsules and tendons. The delay in healing may be due to this increased elasticity of the skin keeping the wound apart, the thin loose collagen that is reformed being of low tensile strength. The tensile strength of the skin, according to Rothman, is less in infancy than in old age, the fibres becoming thicker and more matted together with time. It may be, therefore, that the disability in Ehlers-Danlos syndrome, of splitting of the skin with trauma, will become less obvious with time. This inherited abnormality affects other mesoblastic tissues such as bone and ligaments and explains the dystrophy of the spinal bones and phalanges which this patient presents.

The Changing Ætiology of Erythema Nodosum in Children

[*Summary*]

By JOHN LORBER, B.A., M.D., M.R.C.P., and T. COLVER, M.D.

IN a consecutive series of 106 children with erythema nodosum seen in Sheffield between January 1951 and December 1956, 66 (62%) were tuberculin positive as a result of tuberculous infection, 5 (5%) followed BCG vaccination and 35 (33%) were tuberculin negative. These figures contrast with an 88% incidence of tuberculous infection among 100 children reported by Doxiadis partly from the same unit in 1949.

There was a progressively falling proportion of children with a positive tuberculin reaction. 73% of 49 children with erythema nodosum seen in 1951/53, and only 53% of 57 seen in 1954/56, were tuberculin positive.

A positive tuberculin reaction is not necessarily an indication that tuberculosis was the only or the main predisposing factor unless there is evidence of recent tuberculin conversion, the presence of an active tuberculous lesion and other possible causes having been excluded. An active primary tuberculous lesion was seen in 46 children (43%) in the whole series. The proportion was 55% in children seen during 1951/53 and 33% in 1954/56. Even among these there were 7 with a severe preceding sore throat and 4 had beta-hæmolytic streptococci in their throat swabs. 10 of the 46 children developed various forms of tuberculous diseases (apart from the erythema nodosum and the primary complex) during observation. For this reason it is suggested that children with active primary tuberculosis associated with erythema nodosum should be given anti-tuberculous chemotherapy. In 20 children (19%) the only evidence of tuberculosis was a positive skin test. This proportion was about the expected incidence of positive reactors in the child population of the appropriate age groups during the years of this study. None developed tuberculous complications. 9 had evidence of preceding throat infection. Tuberculosis probably played an ætiological role in only a few, if any, in this group of 20.

5 children developed erythema nodosum after BCG vaccination, and in 4 this occurred at the time of tuberculin conversion. Nevertheless, other factors were present in 3 of them.

Among 35 tuberculin-negative children 17 complained of a preceding pharyngitis and in 10 laboratory evidence of a beta-hæmolytic streptococcal infection was obtained.

It is probable that multiple simultaneous factors are often responsible for the eruption of erythema nodosum.

Relapse of the erythema nodosum occurred in 6 cases and multiple cases occurred in 3 families.

Cine-angiocardiography in Acyanotic Heart Disease of Infancy

By R. ASTLEY, M.D., D.M.R.

The Children's Hospital, Birmingham

THE various forms of congenital heart disease that are associated with a shunt of blood from the systemic to the pulmonary circulation—commonly, isolated septal defects and patency of the ductus arteriosus—are important causes of death in small children, particularly in the first year of life. Oldham (1957) analysed a series of 100 consecutive infants in whom congenital heart disease was causing disability. There were 39 with a defect causing a left-to-right shunt, including 9 with an isolated patent ductus; 19 (including 5 with a patent ductus) died within their first year.

Thus diagnosis in this group and, in particular, the localization of the site of the left-to-right shunt, is important since a patent ductus is so readily treatable surgically. However, this localization may be a difficult problem as the physical signs are often atypical in the very young; for instance, the continuous murmur of a patent ductus is often absent. Cardiac catheterization has its technical difficulties at this age and angiocardiography with simple methods at one to two pictures per second has proved disappointing. Therefore a series of small children has been investigated by cine-angiocardiography, to determine whether this method gave improved or simplified diagnosis.

The radiographic technique employed was that described previously (Astley and Oldham, 1956), using a Philips image intensifier and a 16 mm. cine camera. The camera was linked to a General Radiological Electronic generator so that each cine frame was exposed for 0·002 second as an individual high-speed radiograph, thus reducing radiation dosage and eliminating movement blurring.

Cine-angiocardiograms were obtained in 35 small children with a left-to-right shunt; there was a patent ductus in 7, an aortic-pulmonary fistula in one and atrial or ventricular septal defects in 27. These 35 formed part of a larger series of 136 cine-angiocardiograms containing all forms of congenital heart disease and part of a series of 405 angiocardiograms when examinations by full-sized films were included.

The radiographic signs that proved useful in patency of the ductus arteriosus (or aortic pulmonary fistula) were a dilution filling defect in the pulmonary artery and persistence of pulmonary artery filling (or re-filling) after the right heart chambers had emptied. These two signs were seen in all instances. With an uncomplicated septal defect, the most important feature was persistent filling or re-filling of the right atrium and/or right ventricle. A dilution filling defect in one of these chambers was often seen. In a number of children there was also a small reverse (right-to-left) shunt seen in the early stages of the angiocardiogram.

Initially, the interpretation proved less straightforward than in cyanotic heart disease. At the outset a number of false interpretations were made but with increasing experience it was found that a very definite distinction could be drawn between a patent ductus and a septal defect. The exact localization of a septal defect was less definite but often possible.

At first, when the venous angiocardiogram indicated a patent ductus, this was confirmed by counter-current cine-aortography. With increasing experience this confirmation became unnecessary and sole reliance could usually be placed on the cine-angiocardiogram, a simpler procedure that also had the advantage of indicating any associated cardiac defects.

An incidental advantage of the technique was the need for less anæsthesia. Complete cessation of movement was not necessary to obtain still pictures since each cine frame was exposed for a much shorter duration that is usually possible on full-sized films. With sedation by the Toronto modification of the "lytic cocktail" (Rowe, Vlad and Keith, 1956) the disturbance to the patient was usually slight and sometimes his general condition even appeared to be improved by the procedure.

A cine film was shown to demonstrate the cine-angiocardiographic evidence of patent ductus arteriosus, aortic-pulmonary fistula and uncomplicated septal defects.

Grateful acknowledgments are due to Dr. Clifford Parsons, who has been very closely associated with this study. The technique and evaluation of the radiographic signs will be described more fully elsewhere.

The Association of Acute Appendicitis with Infective Diarrhœa

By K. B. Rogers, M.D.

The Children's Hospital, Birmingham

This is a preliminary report of the work of the pathology departments and the surgeons of the Birmingham Children's Hospital and it will be reported more fully later by all those concerned.

At this hospital the routine bacteriological examinations are designed to ensure that all non-lactose fermenting bacilli, from any site, are fully examined to ensure that any salmonellæ or shigellæ are identified. These methods allowed both *Shig. sonnei* and salmonellæ to be identified in the pus from the peritoneal cavities of cases of perforated appendicitis: it was also noted that some children, who had been admitted for appendicectomy, developed dysentery due to the same organisms a few days after operation.

In 1956 the proximal third of every appendix was examined bacteriologically whilst the distal portion was used for histological examinations. There were 250 appendicectomies: 170 appendices were cultured and 12 yielded *Shig. sonnei*. All of the appendices from which these strains of *Shig. sonnei* were isolated showed histological evidence of acute inflammation: *Salm. heidelberg* was isolated from one appendix which also showed histological evidence of inflammation.

Eleven of the strains of *Shig. sonnei*, and the strain of salmonella, were identified by slide agglutinations of emulsions made from colonies picked off desoxycholate citrate medium, the morning after each of these appendicectomies had been performed. The twelfth strain of *Shig. sonnei* was isolated a day later from a subculture made on to a desoxycholate citrate plate, from selenite fluid enrichment medium in which the specimen had been growing for eighteen hours. The identity of each strain was verified by tube agglutination and biochemical testing (Rogers, 1954*a*): each strain was also tested for its sensitivity to antibiotics and sulphonamides.

As soon as a strain was identified the patient was transferred to the isolation ward and was given appropriate chemotherapy. The rapid identification of all these strains, at a time when the intestines of the patient were quiet following the operative interference, allowed all the infected children to be removed to the isolation ward before any post-operative diarrhœa developed. The introduction of chemotherapy, within a day of operation, may have aborted any attacks of diarrhœa or the patients may have only been carriers, but none of these patients developed diarrhœa: chemoprophylaxis was given to all the other children in the ward to which the infectious case had been originally admitted (Rogers, 1954*b*). It is noteworthy that during the dysentery pandemic of 1956 no surgical ward had to be closed to admissions because of the spread of dysentery.

The appendices were also cultured to demonstrate the presence of other organisms, including clostridia, by the techniques previously described (Rogers and Heslop, 1948). Except for the anaerobic cultures, and the incubation of the MacConkey and desoxycholate citrate plates, all these cultures were incubated in an atmosphere of 10% carbon dioxide: this probably accounted for the finding of Lancefield group F hæmolytic streptococci in 11% of the appendices, as Liu (1954) has shown that these "minute" group F streptococci grow better in an increased concentration of carbon dioxide. A few of the appendices provided heavy growths of pneumococci and *H. influenzæ*, and 34% grew *Cl. welchii*.

It is not suggested that salmonellæ or shigellæ are the cause of acute appendicitis but that sometimes acute appendicitis is associated with an enteral infection and that if cultures are made to demonstrate the presence of these intestinal pathogens it is possible to remove an infectious case from a ward before cross-infection occurs. It must be emphasized that there was a pandemic of Sonne dysentery in the year in which the above investigation was made and this may account for the relatively large proportion of the appendices from which *Shig. sonnei* was isolated.

The Treatment of Juvenile Thyrotoxicosis with Potassium Perchlorate

By Professor J. M. Smellie
The Children's Hospital, Birmingham

The infrequency of hyperthyroidism in children renders knowledge and experience of its treatment limited and the merits and demerits of various therapeutic procedures are controversial. 6 children, aged from 6 years to 13 years have been treated with 200–300 mg. of potassium perchlorate daily. The duration of treatment has been from nine months to three years. In all, satisfactory clinical progress has been achieved and the children are now euthyroid. The only undesirable side-effect encountered has been a minor degree of hypothyroidism in two instances; none has had any gastro-intestinal upset. Iodine must not be given during perchlorate treatment.

Experience to date would appear to indicate that treatment will be required for a period of two to three years and perhaps even up to puberty.

It is not yet possible to say whether potassium perchlorate will restore all hyperthyroid children to a euthyroid state and thus render surgery unnecessary, but it does at least delay consideration of any operative procedures without detriment to the patient.

[This paper is published in full in the *Lancet* (1957) ii, 1035.]

Duodenal Obstruction in the New-born

By A. Gourevitch, F.R.C.S.
United Birmingham Hospitals

(In presenting this paper, I wish to record that Mr. Michael Lord has participated in the work of its preparation.)

Congenital abnormalities are responsible for the hard core of neonatal deaths. Notable among these are congenital abnormalities of the bowel, and, in particular, obstruction.

The results of operative treatment particularly in the intrinsic group, have been disappointing and a number of factors, which I shall examine here, have contributed to this.

This paper concerns a series of 58 babies with duodenal obstruction admitted to the Birmingham Children's Hospital between the years 1939 and 1956. 49 were operated on: of the remainder 7 were considered too ill for surgery, a mongol was left, and in another, a malrotation, operation was not indicated.

I have separated duodenal obstruction from the rest of neonatal intestinal obstruction to compare conditions having a similar clinical and radiological picture. Furthermore, I believe that duodenal obstruction is ætiologically and in its natural history a different condition from jejuno-ileal atresia.

I have divided this series into intrinsic and extrinsic groups (Fig. 1).
3 types of intrinsic obstruction have been encountered (Fig. 2).

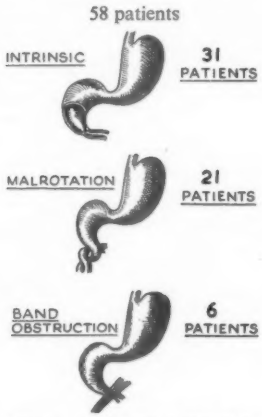

FIG. 1.—Duodenal obstruction.
Three main groups.

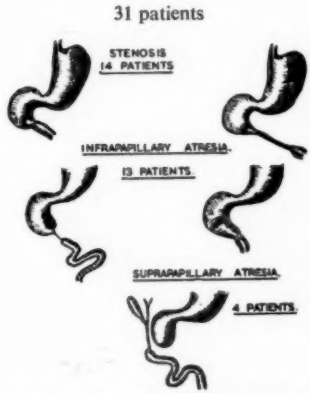

FIG. 2.—Types of intrinsic duodenal obstruction.

MULTIPLE LESIONS

These lesions can occur together in any combination (Fig. 3).
Excluding malrotation + bands, we have had 10 cases of multiple lesions in 49 operated patients.

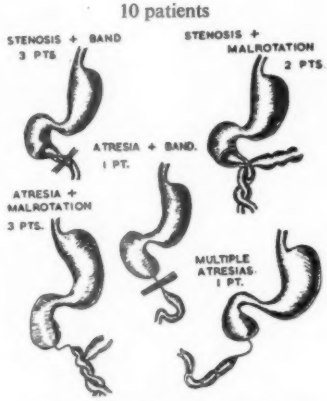

FIG. 3.—Duodenal obstruction.
Multiple lesions.

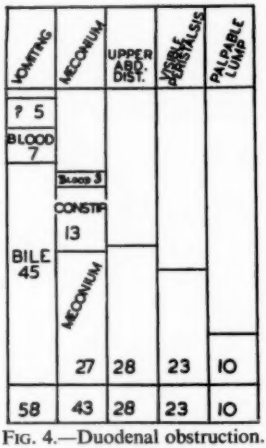

FIG. 4.—Duodenal obstruction.
Clinical findings.

The association of malrotation and bands being well known is unlikely to be missed. The chief danger lies in the co-existence of duodenal stenosis with another lesion. In 5 such patients, the intrinsic lesion was overlooked with fatal results. Clearly, it is not enough just to divide a band that crosses the duodenum, or merely to untwist a volvulus. Even if the distal bowel fills, this is no proof of the absence of stenosis. Where doubt exists, a short-circuiting operation should be done.

There were 7 mongols among these babies. 4 of these had cardiac anomalies, 1 other had congenital hydronephrosis and hydro-ureters. There were no other such gross developmental abnormalities in the series. Operation is, therefore, well worth while.

Clinical Picture (Fig. 4)

Sustained vomiting soon after birth is the sheet-anchor of diagnosis. Every child in the series vomited, the majority vomited copious amounts of bile. 13 only were constipated; the passage of meconium is therefore misleading.

Diagnosis

The value of the plain X-ray film can hardly be over-emphasized. We X-ray every child in whom obstruction is suspected. In most cases there is no need for barium which has obvious disadvantages.

Dr. R. Astley, Radiologist to the Birmingham Children's Hospital, screens the baby, who lies in the left lateral position, which favours the entry of gas into the duodenum; 2 X-ray films (Figs. 5 and 6).

Fig. 5.—Plain A.P. film of abdomen. Intrinsic duodenal obstruction.

Fig. 6.—Plain lateral film of abdomen. Intrinsic duodenal obstruction.

The features in duodenal obstruction are:

(1) Considerable dilatation of the duodenum.

(2) The presence of a small amount of gas in the distal bowel in stenoses and malrotations.

Pre-operative Preparation

It is advisable to allow a delay of several hours after X-ray. The child gets chilled as a result of the examination. It is unusual for these children to be severely dehydrated. We nearly always introduce a needle into a vein, and give fluid and electrolyte, if necessary. The stomach is emptied by Ryle's tube.

Anæsthetic

This is usually gas and oxygen in equal proportions, supplemented by scoline. The relaxant has made the operation technically much simpler. An endotracheal tube is quite essential: its introduction into a tiny larynx needs a lot of practice.

Operation

The incision should be a long one; there must be room for a careful but rapid inspection of the whole abdomen. As soon as the peritoneal cavity is opened, the whole of the mid-gut is exteriorized. This manœuvre is essential, without it one is literally working in the dark. The cæcum is identified, if it is not in the right iliac fossa, a malrotation is present. A finger and thumb are then passed round the root of the mesentery. If there is a volvulus there is a sensation as if a knot had been tied in the root of the mesentery. The volvulus, which is usually clockwise, is untwisted.

The duodenum is then inspected throughout its length, and if there is imperfect rotation of the bowel, its whole length may very well be visible; and it will be unnaturally long and convoluted. All bands are divided as stressed by Ladd of Boston many years ago. Furthermore, there may be a large colic vein compressing the duodenum and so requiring division.

The jejunum must be seen to fill. The stomach tube should be fed on into the jejunum to demonstrate its patency (not always an easy manœuvre).

If an intrinsic obstruction is present, the duodenum will be seen to be dilated and hypertrophied, it may be as large as the stomach. It may end as a blind sac. Even if this appearance is not seen, *no useful purpose is served in trying to locate a diaphragm.*

Preliminary X-rays, and the appearances at operation will have made the diagnosis certain. If a diagnosis of duodenal obstruction has been made it is never safe merely to divide bands, assuming them to be the sole cause of the obstruction. *There is almost always an intrinsic obstruction as well.* I perform a duodeno-jejunostomy, using 3–0 chromic atraumatic suture mounted on a 30 mm. hand needle, and the anastomosis is done in 2 layers. After operation 20–60 ml. of blood (depending on weight and blood loss) are injected by syringe.

Results

During the years 1952 and 1953, I noticed that babies with intrinsic obstruction were dying anything up to three weeks after operation, with continuing bile aspiration or vomiting, indicating that obstruction was unrelieved; and yet at autopsy the anastomosis was intact and patent. Clearly, the anastomosis was not functioning. I knew that others had had the same experience.

The stomach and duodenum seemed incapable of transferring fluid to the collapsed jejunum. It seemed rational, therefore, to introduce fluid directly into the jejunum via a Ryle's tube passed down the œsophagus and to force the fluid in with a syringe. I used this method for over a year, but it had several disadvantages:

(1) It meant a tube in contact with the stoma for anything up to three weeks.
(2) A second tube had to be introduced for gastric aspiration.
(3) There was no certainty that the jejunal tube would not slip back into the duodenum.

At this stage Mr. Peter Bevan suggested a feeding jejunostomy in addition to the anastomosis. Accordingly in November 1954 for the first time, I sewed a fine soft polythene tube into the jejunum in a case of duodenal atresia. The child was fed down the tube. The tube was taken out on the ninth day, after it had been demonstrated that carmine introduced orally was passed *per anum.* The child thrived and was ready to go home on the twenty-first day, when he aspirated vomit and died. I used this technique on 4 subsequent occasions with 3 recoveries and 1 death. The death was in a premature infant, and peritonitis was found at autopsy with an intact anastomosis, presumably due to soiling of the peritoneum at operation.

I have since then, in babies subsequent to this series, performed a feeding jejunostomy as a routine using a very fine soft rubber catheter, rubber being softer than polythene. Usually it is possible to do a formal Witzel procedure which obviates the danger of leakage. There is no doubt that after an interval of time, the bowel, receiving its normal stimulus, starts to work spontaneously.

The method is not foolproof, but it does introduce fluid directly into bowel which lacks the normal stimulus to contraction, and it has one other advantage, it spares veins and offers a ready avenue for the introduction of fluid, electrolyte and calories, so that everyone gets more sleep.

Post-operative Management

These babies have generally been under the combined care of a surgeon and a pædiatrician. They are the particular care of a senior resident officer who checks their intravenous schedules twice a day and cares for them most diligently. Assessment of the child's state has been almost entirely clinical, using serum analyses as an occasional check; this method has proved quite adequate. Daily serum electrolyte estimations means constantly withdrawing blood from a small baby with a diminishing supply of veins. Contrary to what I used to believe, these babies do not present a complex biochemical problem, not to be compared, for example, with that of a severe gastro-enteritis.

Mortality

There have been 49 operations and 26 deaths—a formidable operative mortality of 52%. In trying to assess the causes of death after operation in a small series such as this, spread over seventeen years, it has to be remembered that any lessening in mortality may merely reflect the increasing effectiveness of surgery and anæsthesia, rather than the virtue of any particular device or manœuvre. Looking at the series as a whole, it is clear that in a fair

proportion of these babies, operation for one reason and another has been technically ineffective.

Out of the 26 deaths:

(1) The anastomosis has leaked three times.
(2) There has been an unreduced volvulus on two occasions.
(3) A stenosis has been overlooked three times.
(4) Multiple atresias have been overlooked once.
(5) Frank general peritonitis has occurred twice, presumably due to peritoneal soiling.

It does seem, therefore, that advances can be made by scrupulous attention to every detail of the technical conduct of the operation.

I have arbitrarily divided the whole series into three groups of 19, 19 and 20 patients in chronological order, to see whether there has been any noticeable improvement over the years.

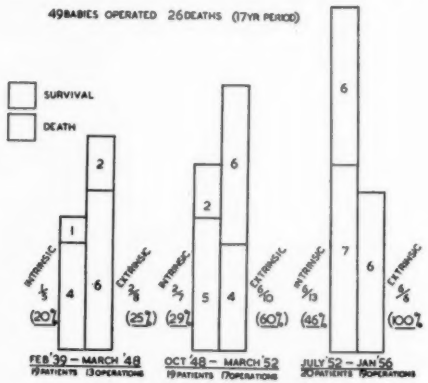

FIG. 7.—Duodenal obstruction.
Survivals.

A number of features stand out (Fig. 7):

(1) *The high death-rate and low operability rate in* series 1.—Actually the first 11 babies admitted, died, 6 with operation, 5 without. At this stage, I think it fair to say that surgeons were unfamiliar with the problem of the neonatal belly.

(2) In series 2, the death-rate has fallen, but is still high in both intrinsic and extrinsic obstruction.

(3) In series 3, there is no mortality in extrinsic obstruction, but still a high one in intrinsic obstruction due probably to technical faults, but also to the non-functioning though intact anastomosis.

Of the last 4 intrinsic obstructions, all of whom had a jejunostomy, 3 survived. Whereas three or four years ago it was an event to salvage an intrinsic obstruction, I should now be disappointed if we did not save 3 out of 4, or even 4 out of 5.

All extrinsic obstructions should be recovered.

I should like to express my thanks to my medical and surgical colleagues at the Birmingham Children's Hospital for allowing me access to case records. To the resident staff for all their help. To my registrar, Mr. M. Lord, for helping me to collect clinical information. To the nursing staff of the Birmingham Children's Hospital, for caring for these babies. To Dr. R. Astley, radiologist at the Birmingham Children's Hospital. To Dr. H. S. Baar, lately pathologist at the Birmingham Children's Hospital.

DISCUSSION ON MAJOR SURGERY IN CARCINOMA OF THE RECTUM WITH OR WITHOUT COLOSTOMY, EXCLUDING THE ANAL CANAL AND INCLUDING THE RECTOSIGMOID

Dr. Cuthbert E. Dukes:

General Results of Surgical Treatment

Our discussion is concerned chiefly with comparisons of alternative methods in the surgical treatment of rectal cancer, and my function as opener is to present a picture of the general overall results.

The St. Mark's Hospital statistics for the twenty-five years 1928–52 inclusive may be summarized as follows:

A total of 3,596 rectal cancer patients were admitted to hospital or seen in the Outpatient Department.

2,447 of these were treated by a surgical operation which removed the primary tumour.

The overall operation mortality of these surgically treated cases was 9·4%.

Every possible endeavour was made to keep in touch with operation survivors and only 28 have not been traced. These are assumed to be dead. Since they constitute only 1·1% of all cases they exert no appreciable effect on the statistics.

The crude five-year survival rate of all patients treated by surgical removal of the primary tumour (after excluding operation deaths) was 48·3%.

When allowance was made for deaths due to intercurrent diseases the corrected five-year survival rate was found to be 57·4% (Table I).

TABLE I.—SURGICAL TREATMENT OF RECTAL CANCER AT ST. MARK'S HOSPITAL 1928–1952

Total cases of C.R. admitted to St. Mark's or seen in out-patients' department	3,596
Number treated by surgical removal of primary tumour ..	2,447
Overall operative mortality ..	9·4%
Crude five-year survival rate of patients in whom primary tumour was removed (operation deaths excluded)	48·3%
Corrected five-year survival rate	57·4%

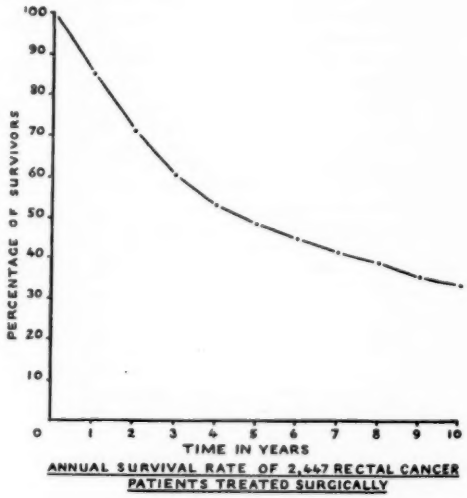

FIG. 1.

All survival rates have been calculated by actuarial methods and the crude survival rate curve for a period of ten years is shown in Fig. 1.

During the period I have reviewed (1928–1952) several different operations have been employed in the surgical treatment of rectal cancer, and subsequent speakers will point

out their advantages and disadvantages. During the last few months with the help of my research assistant, Mr. H. J. R. Bussey, I have been analysing the results of every form of surgical treatment at St. Mark's and have been impressed by the importance of ensuring that any groups compared should be of similar constitution with respect to age and sex and that the operations compared should date from approximately the same period of time.

Influence of Age of Patient on Survival Rates

The crude five-year survival rate merely states the percentage of individuals still living after five years. Some of those who failed to live for five years died of cancer and some from other causes, but the crude five-year survival rate makes no distinction between deaths due to cancer and deaths due to intercurrent diseases. Obviously therefore the crude five-year survival rate must be much affected by the average age of patients at the time of treatment: for example, the percentage of five-year survivors is likely to be considerably less from a group of patients with an average age of 70 than for another group with an average age of 60. This point is of special importance in relation to rectal cancer because the risk of dying from other causes increases rapidly just at the time of life when many patients receive surgical treatment.

It might be possible in a small series of patients to ascertain the cause of death in each one and then exclude from calculation all deaths not due to cancer within the five-year period, but in a big series this direct method is impracticable and it is easier and probably more accurate to proceed indirectly and make allowance for intercurrent deaths by making use of data provided by life tables. When a correction is made for the estimated probability of dying from causes other than cancer the term "corrected survival rate" is used.

There is more than one statistical device for producing a corrected survival rate, and I consulted Dr. Percy Stocks as to the best to adopt for our records at St. Mark's, and he recommended that described by Paterson, Tod and Russell in their book "The Results of Radium and X-ray Therapy in Malignant Disease" (Christie Hospital, 1950).

The principle is that one calculates from the standard death-rate appropriate to each age group the probability of survival in each age group for a further period of five years. This gives a factor known as Po. The crude survival rate experienced is then divided by this factor, and this corrects for deaths due to intercurrent diseases in the specified period. Dr. Stocks (1957) very kindly supplied additional statistical tables to cover the years 1931 and 1950 and my research assistant, Mr. Bussey, has calculated the correction factor separately for each of the five-year periods included in this review (1928–1952), because standard death-rates have not remained stationary throughout the twenty-five years.

The corrected survival rate gives a much more accurate picture of what is actually accomplished by surgical treatment than does the crude survival rate, and is therefore of special value when comparisons are being made between different surgical operations, especially if there is any difference in age and sex distribution of patients.

So far we have been considering the age of a group of rectal cancer patients only because of its obvious effect on the risk of dying from intercurrent diseases, but age is of importance also because the rate of growth of a rectal cancer tends to slow down with advancing years. There has long been a general clinical impression that this is so, though it has been difficult to prove by statistical evidence (Lees and Park, 1949).

The simplest way of demonstrating the effect of advancing years on rate of growth is to group rectal cancer patients according to age and then compare the percentage of cases with metastases in each age group. This information is set out in Table II, from which it

Table II.—Relation of Age of Patient to Incidence of Lymphatic Metastases

	Males			Females		
Age group	No. of patients	No. with metastases	Percentage with metastases	No. of patients	No. with metastases	Percentage with metastases
Under 40	84	61	72·6	67	50	74·6
40–49	176	93	52·8	112	75	67·0
50–59	414	209	50·5	218	114	52·3
60–69	544	245	45·0	243	132	54·3
70 and over	270	109	40·4	128	62	48·4
Total	1,488	717	48·2	768	433	56·4

will be seen that in patients under 40 years of age the incidence of lymphatic metastases was over 70%, and that it decreased steadily in middle age.

Another way of demonstrating that the growth potential of rectal cancer slows down

with advancing years is by comparison of the average age of patients at successive stages in the development of malignancy. This brings to light the somewhat paradoxical fact that the average age of early stage patients is older than the average age of later stage patients, which seems at first to be contrary to expectations, because we might have anticipated that the average age of A cases would be younger than B, and the B cases would be younger than the C. The exact opposite was found to be the case. The actual figures for this series were as follows: For males the average age for A cases was 61·97, for B cases 61·23, and for C cases 58·50 years. The corresponding figures for females were A cases 60·10, B cases 59·54, and C cases 56·62 years (Table III). This point is worth mentioning because

TABLE III.—CANCER OF RECTUM
Average Age in Years of A, B *and* C *Cases at Time of Surgical Treatment*

Cases	Men	Women
A	61·97	60·10
B	61·23	59·54
C	58·50	56·62

it is often assumed that if comparisons are made of survival rates of tumours which have been classified according to stages of development then the average age of the patients need not be considered, but this would only be justified if the average age at each stage was the same. In rectal cancer this is not so. Stage I or A cases are on the average about three and a half years older than the Stage III or C cases.

We gain a truer picture of what is actually accomplished by surgery if we take the age of patients into consideration when comparing survival rates of A, B and C cases and apply a correction factor to make allowance for deaths from intercurrent diseases. The effect of this is greatly to improve the survival rate of A cases, because this being the oldest group is the one in which the greatest number of intercurrent deaths might be expected. The application of the correction factor has less effect on the crude survival rate of B cases and still less on C cases (Table IV).

TABLE IV.—CANCER OF RECTUM
Five-year Survival for A, B *and* C *Cases*
(Operation deaths excluded)

MEN				WOMEN			
No. of cases	Stage	Crude five-year survival rate %	Corrected five-year survival rate %	No. of cases	Stage	Crude five-year survival rate %	Corrected five-year survival rate %
206	A	80·4	99·9	129	A	81·8	93·8
565	B	61·3	76·0	206	B	71·6	82·0
717	C	26·1	31·3	433	C	29·1	32·7

INFLUENCE OF SEX ON SURVIVAL RATES

When considering the effect of sex on survival after rectal cancer we should first recall that the natural expectation of life after middle age is not so good for men as for women. The extent of this sex difference varies with locality, but here in London now the death-rate for men between the ages of 45 and 64 is actually twice as high as for women in this same age group (Scott, 1955). Moreover at the age of 65 (when so many cases of rectal cancer receive surgical treatment) the natural expectation of life for men is twelve years but fifteen for women.

The fact that rectal cancer is commoner in men than in women points to the probability of some innate constitutional sex difference. This certainly exists and I will mention some ways in which it may affect survival rates after surgical treatment.

In the first place women patients on the average are two to three years younger than men at the time of diagnosis. Secondly, at the time of surgical treatment the disease tends to be at an earlier stage of development in women than in men, as proved by the fact that A cases are relatively more numerous. Thirdly, rectal cancer tends to metastasize earlier and more frequently in women than in men.

Fourthly, in all types of major surgery for rectal cancer the operative mortality has tended to be lower for women than for men. Finally, the sex ratio in combined excisions at St. Mark's has been 33% women to 67% men, but in restorative resections the proportions have been 43% women and 57% men.

Since there are so many ways in which sex may influence survival after rectal cancer it is always desirable to calculate survival rates separately for men and women, when comparisons are being made between different operations.

Effect on Survival Rate of Decline in Operative Mortality and Rise in Resectability Rate

During the twenty-five years under review there have been many improvements in anæsthetics and in the pre- and post-operative treatment of patients, and these have resulted in a considerable decline in operative mortality and an astonishing rise in the resectability rate. The average operative mortality for this whole series was 9·4%, but it was as high as 12·8% in 1928–32 and it declined progressively to 6·8% in the period 1948–52 (Table V).

The average resectability rate for the whole period was 72·5%. It was only 46·5% in the first five-year period but it rose steadily to reach 92·7% in the last (Table VI).

Table V

St. Mark's Hospital, 1928–1952

Operative Mortality of Rectal Cancer

Period	Operations	Deaths	% Operative mortality rate
1928–32	484	62	12·8
1933–37	601	66	11·0
1938–42	595	66	11·1
1943–47	775	61	7·9
1948–52	918	62	6·8
1928–52	3,373	317	9·4

Table VI

Resectability Rate of Rectal Cancer

Total No. of cases assessed for operation	No. of cases in which growth was removed	% Resectability rate
484	225	46·5
601	346	57·6
595	413	69·4
775	612	79·0
918	851	92·7
3,373	2,447	72·5

The combined effect of these notable advances has been to enlarge the scope of surgery and to increase the total number of patients cured thereby, but it is important to notice that these improvements in the total overall results of surgery are not reflected in post-operative survival rates, because these are based on operation survivors only and not on the total cases seen or diagnosed. In fact, survival rates after surgical treatment tend to be adversely affected by both a decline in operative mortality and by a rise in the resectability rate for reasons which I will endeavour to explain.

A decline in operative mortality from 12·8% to 6·8%, such as occurred between the beginning and the end of this series, means that out of every 100 patients 6 more survived the ordeal of surgery and joined the ranks of post-operative survivors. But these 6 recruits are unlikely to be as physically fit as the rest of the group they have joined, as suggested by the fact that they would have succumbed had they undergone the ordeal of their operation when it was more severe and only survive now because it has been made easier. Their inclusion in the group of post-operation survivors tends to lower the average level of fitness and to lessen the percentage who will reach the five-year goal.

A rise in resectability rate has a similar effect. Patients who formerly were considered unfit for surgery are now placed on the operation list. Such patients must have a poorer expectation of life and in some cases an increased liability to recurrence. A lowering of the average level of health in the group of operation survivors will tend to add to the number who fall by the wayside and to lower the percentage of those who live to celebrate the fifth anniversary of their operation.

This process of dilution with relatively unfavourable material has continued progressively throughout the whole period covered by this review, yet in spite of this the five-year survival rate has not declined (Table VII). This means that surgeons to-day are as successful in

Table VII.—Five-year Post-operative Survival Rates after Surgical Treatment of Rectal Cancer at St. Mark's Hospital, 1928–1952

All Operable Cases (3,373)

Period	Crude five-year survival rate %	Corrected five-year survival rate %
1928–32	49·3	56·5
1933–37	46·2	54·5
1938–42	46·8	54·9
1943–47	53·7	63·9
1948–52	46·2	56·1
1928–52	48·3	57·4

dealing with relatively poor material as their predecessors were in selected cases twenty-five years ago.

The stationary character of the five-year survival rate naturally raises the question as to whether or not surgery has reached the limit of human achievement. There must be a limit somewhere, at any rate with existing resources. Of course the five-year survival rate is a far from delicate indicator of progress, and we know that many refinements and improvements are constantly being introduced which it fails to register. Its chief merit is that it is a convenient and easily understood way of assessing the results of surgery.

I will conclude by recalling an experience I had recently in New York, where I had been invited to participate in a panel discussion on the pathology and treatment of rectal cancer. Questions were sent up by the audience, and one concerned the relative merits of the four operations we are discussing. This provoked a lively discussion amongst the surgical members of the panel and finally the Question Master turned to me saying, "Now tell us, Dr. Dukes, which of these operations would *you* choose if you needed one yourself or for a close relative or friend?" This was the last question of the day and time was getting short, so I replied briefly as follows. "I should not choose the *operation*, but I should choose the *surgeon* who was to do it, and I should choose him with *very great care*. Then I should say to him, 'Do the operation just when and where you think best, but please promise to go to bed early the night before and to get up in good time and have a good breakfast!' It would be a relief also to be assured that the operation would not be filmed or televised!"

Mr. A. Lawrence Abel:

The Abdomino-perineal Operation for Cancer of the Rectum

This is the fiftieth anniversary of the introduction by W. Ernest Miles of the abdomino-perineal operation for cancer of the rectum. As an old Registrar, assistant and colleague of Ernest Miles I am highly honoured to be invited to speak on this important subject in this Jubilee year.

History.—I would remind you that in 1826 Lisfranc, and later Verneuil (1873), carried out small perineal excisions for this disease with a mortality of 80% and a recurrence rate of 100%. In 1875 Kocher introduced the use of antiseptics and closed the anus before performing a perineal excision, and reduced the mortality to about 20%, though the recurrence rate remained high at 84%. In 1885 Kraske excised part of the sacrum to attain easier access and the mortality of his operation varied in different hands from 20% to 11%, but still had a recurrence rate of between 70% and 80%. So for nearly a hundred years although many surgeons attempted to cure this disease (with poor anæsthesia and no antibiotics) the mortality remained around 80% and there was over 80% recurrence.

The Miles abdomino-perineal operation.—In 1907 Ernest Miles, as a result of his researches into the lymphatic spread of the disease, introduced the attack starting high up in the abdominal cavity so as to include the maximum upward, lateral and downward spread. Ever since I became associated with him some thirty-four years ago I have used the abdomino-perineal operation for the majority of cases. During recent years the resection rate has been 94%. Less radical treatment is given only in 6% of patients with cancer of the rectum.

For example:

(1) Occasionally cases are sent to the Royal Marsden Hospital and Institute of Cancer Research, Royal Cancer Hospital, who have such extensive abdominal complications that they have obviously only a few days to live and in whom no surgical treatment is called for.

(2) In the very old and feeble, surgical diathermy is occasionally utilized to keep the rectal lumen patent. The performance of a colostomy as the only remedy is hardly ever undertaken.

(3) If at laparotomy the liver is found to be heavily affected with metastases I sometimes carry out an extended Hartmann's operation, resecting the pelvic colon and rectum to anal canal without incising the perineum.

(4) The remainder of the 6% of advanced cases have an anterior conservative resection with restoration of intestinal continuity. I would emphasize that I do not perform this

operation in any case of cancer of the rectum which appears curable, because out of 11 cases which one of my colleagues and I operated on some years ago, 7 recurred within eighteen months.

The remaining 94% of cases are treated by the radical abdomino-perineal operation. This is always preceded by a biopsy of the lesion and a few days of bowel preparation by washouts and intestinal antibiotics.

The anæsthetic.—The patient is put to sleep in bed by an injection of Omnopon 1/3 grain and scopolamine 1/150 grain. One hour later the anæsthetist gives Pentothal, and the patient is brought to the theatre unconscious. Then an intrathecal injection of 1 : 1,500 Nupercaine is given and general anæsthesia continued with nitrous oxide and oxygen only. These techniques made a great difference to the mortality. For over thirty years we have avoided ether and chloroform.

The bladder.—It is very important to empty the bladder and to keep up steady suprapubic pressure until the catheter is withdrawn, otherwise the bladder fills with air which, in pelvic operations, is worse than a bladder full of urine.

The operation.—This was demonstrated by a colour film with a commentary as follows:

A long right paramedian incision is made extending from 2·5 cm. above the umbilicus to the pubis. The fat of the abdominal wall is protected by attaching cloths to the anterior rectus sheath on both sides.

When the abdomen is open the liver is always felt to see if metastases are present. It used to be said that cases which at the time of laparotomy were found to have obvious hepatic metastases should be treated by colostomy alone. However, in 1931 I had the privilege of meeting Dr. Daniel Fiske Jones of Boston. He told me of the great benefit and prolongation of life that these patients received if a full abdomino-perineal excision was carried out. Since then the majority of my cases with hepatic metastases have been treated by the radical operation. They are of course incurable, but they die at a later date than if the primary lesion is left in situ. The majority live free of pelvic complications and have a painless death. I have seen many live over five years, one for eight and a half, and one over twelve years.

The exploration made, a wide self-retaining retractor is inserted, the intestines are packed into the upper abdomen and the table is tipped into a high Trendelenburg tilt.

Mobilizing the pelvic colon.—The pelvic colon is drawn to the right revealing the bloodless white line where the hindgut rotated and joined the parietal peritoneum—the zygotic plane. The first step is to divide the adhesions which always exist between the left side of the pelvic mesocolon and the left iliac parietal peritoneum. The peritoneal incision is carried downwards obliquely towards the recto-vesical pouch, still in the zygotic plane. Blunt dissection with a small gauze swab on a long forceps (the use of which I learned from Dr. Frank Lahey in Boston in 1931) is very satisfactory for performing a bloodless dissection of the tissues whereby the ureter is immediately seen with the spermatic (or ovarian) vessels to the outer side. Behind the ureter, the bifurcation of the common iliac artery and its two branches are quickly defined.

The internal iliac arteries.—The anterior division of the internal iliac artery is separated from the big internal iliac vein behind it by a little blunt dissection (the posterior division has, of course, come off at the bifurcation of the common iliac and gone backwards through the great sacro-sciatic notch). The next step is to pass a ligature around the anterior division of the internal iliac artery and ligate it in continuity.

Now an incision is made in the right leaf of the pelvic mesocolon with the pelvic colon drawn to the left. The bifurcation of the aorta, the right common iliac artery and its bifurcation are defined. The right ureter is seen a little to the right of the bifurcation. Blunt dissection again separates the anterior division of the internal iliac artery from the underlying vein. A catgut or thread ligature is passed round it, and it is ligated in continuity. In an average case I do not think this is an essential step, but it certainly prevents bleeding from the middle hæmorrhoidal arteries. However, if the uterus or bladder has to be removed at the same time it is a most valuable step. Miles used it invariably for a Wertheim's hysterectomy. I have done it for many years, both for a standard abdomino-perineal excision and when an abdomino-perineal and a Wertheim have to be carried out together.

The inferior mesenteric artery.—The next key point in the operation is ligature of the root of the pelvic mesocolon with its contained inferior mesenteric artery, vein and lymphatics. With the assistant pulling the pelvic colon well down, a stout ligature is passed by means of a Reverdin needle around the root of the pelvic mesocolon just above the level of the bifurcation of the abdominal aorta and firmly tied. This is at the "site of election", or "pointe critique" and is called the "Rubicon ligature" because once it is tied

there is no turning back, for the blood supply to the lower sigmoid and rectum is now cut off. A second ligature is passed and tied 2·5 cm. below the first ligature to prevent back-flow.

Before these two ligatures are tied, care is taken not to manipulate the rectum with its contained growth because there is evidence that cancer cells may be forced into the blood stream. This is one reason why I do not have another surgeon working in the perineum.

The pelvic peritoneum.—The peritoneum is now divided farther down on each side of the rectum till the incisions meet in the recto-vesical or recto-vaginal pouch. This completes the division of the peritoneum around the pelvis and the rectum is thus entirely free of peritoneal attachments.

Following this the fingers are passed into the hollow of the sacrum to strip the rectum and all the retro-rectal fat and lymphatic glands contained in the fascia propria of the rectum from the front of the sacrum down to the coccyx. The clean shining periosteum of the sacrum is the indication that the stripping is in the correct plane.

The lateral rectal ligaments.—Now the lateral ligaments of the rectum become apparent and they are divided with 14-inch scissors. Care is taken not to damage the big vessels lying to the outer side on the lateral pelvic wall. This incision is carried downwards to the fascia of the obturator internus and upper surface of the levatores ani muscles. Thus the rectum is freed on both sides down to the levatores ani. The rectum is now mobilized anteriorly with blunt or sharp dissection keeping between the fascia of the rectum and the fascia enclosing the seminal vesicles (or vagina). Thus the rectum is now free right down to the prostate in front, to the levatores ani laterally and to the coccyx posteriorly.

Division of the colon and mesocolon.—The pelvic mesocolon is now divided at right angles to the main or "Rubicon" ligature. For the first time since the abdomen was opened, one or two vessels will be seen to bleed showing that there is a good collateral circulation to the part of the bowel which is to form a terminal colostomy or artificial anus. These vessels are ligated. The incision is at right angles to the bowel so that as much as possible of the dangerous pelvic mesocolon and the greatest possible length of pelvic colon with its paracolic glands are removed.

Division of the bowel.—I use the Zachary Cope modification of the Martell three-bladed clamp—a most valuable instrument; it sterilizes the bowel by crushing it; the middle of the three blades is removed; the bowel is divided between the two remaining blades with the cautery or diathermy. Cultures taken from upwards of two hundred of these incised surfaces have remained sterile. Nevertheless, to be quite safe a plastic cap is applied over each end of the Cope–Martell clamp or a cover may be made from rubber sheeting.

The whole mass of pelvic colon, mesocolon and rectum is tucked downwards into the hollow of the sacrum. At this stage another useful step is to pass a ligature around the median sacral artery where it may be seen or felt lying on the sacral promontory. This often prevents difficult bleeding in those cases in which the coccyx has to be excised in the perineal part of the operation.

The new pelvic floor.—This is made by stripping up the peritoneum from the dorsum and base of the bladder and from the side walls of the pelvis. By gently separating and teasing with blunt dissection a nice thick, firm sheet of peritoneum with which to close the lower abdominal cavity is obtained. This is known as the "strip-tease" part of the operation. On each side wall the vas deferens is seen and the suspensory ligament of each is dissected free. In elderly subjects each vas is divided for the same reasons as when performing prostatectomy.

This newly-formed peritoneal flap is sutured by a continuous interlocking catgut stitch, first by bringing its centre or apex to the peritoneum in the region of the Rubicon ligature and then extending to the wall of the pelvis on both sides. The rough edge of the peritoneum should be carefully extroverted towards the pelvis so that on the abdominal side the peritoneum is smooth. Care is necessary on the left, where the suturing goes round the root of the bowel which is going to form the artificial anus in order to avoid including blood vessels in the stitch. When this suture is finished the pelvic cavity is completely separated by the new peritoneal flap from the abdominal cavity.

The artificial anus.—The self-retaining retractor and packs are removed. The bowel end must be brought through the anterior abdominal wall. This is effected thus: at a point one-third of the distance between the left anterior superior iliac spine and the umbilicus a circle of skin 2·5 cm. in diameter is excised. A stab wound is made through all layers of the wall and stretched. Through this the termination of the colon with its attached clamp and cap is drawn and should be found to project about 2·5 cm.

Inside the abdomen one further suture is needed. This is to close the gap between the

last 8–10 cm. of the pelvic colon and the wall of the abdomen and left iliac fossa, otherwise a knuckle of bowel may pass into it and strangulate. It is interesting that if a knuckle of small intestine does pass through such a gap it usually goes from below upwards and not from above downwards. In a case which has not had this lateral paracolic gutter closed and which develops acute obstruction a surgeon should know that three times out of four, the small intestine has passed from below upwards.

Closure of the abdomen.—The abdomen is closed: the peritoneum with catgut; the rest of the abdominal wall with stainless steel wire. The latter was brought to my attention by Dr. Thomas E. Jones of Cleveland, Ohio, twenty years ago, and I have used nothing else since for closing major abdominal wounds. If the patient is thin interrupted stitches are used; if fat, continuous. In either case the far-and-near stitch which Alan Hunt and I described nine years ago is used; the far stitch takes a bite of the linea alba and about 2·5 cm. of rectus muscle; then the near stitch the two adjacent edges of the anterior rectus sheath, making a figure of 8. It has been shown that in general abdominal work using other suture materials a little over 1% of wounds disrupt; of these 43% die. The proper use of stainless steel therefore saves nearly one-half of 1% of cases. As it is preferable not to have stitches through skin, Michel clips are used to appose the skin edges.

Fashioning the artificial anus.—The final stage in the abdominal portion of the operation is the important treatment of the last few centimetres of the colon in order to prevent peri-colostomic herniation. In my young days, a large proportion of these cases developed peri-colostomic hernias, sometimes big, sometimes small. Miles used to place one stitch above and one below between the skin and the bowel: herniations were common. For many years now a catgut suture has been inserted—first between the wall of the bowel and the peritoneum of the abdominal wall—second, another continuous interlocking layer between the anterior aponeurosis and the wall of the bowel, and finally just before the patient leaves the table, 8 or 12 stitches are placed accurately apposing the mucosa and the skin: to-day, herniations are rare. Years ago, stenosis and contraction of the opening were frequent; with this care the artificial anus retains its wide opening. I prefer to call it "artificial anus" and not "colostomy". Many people have had a grandfather or someone who had a colostomy in the old days, when a loop of bowel was brought out and when the primary disease was not removed. If the word "colostomy" is used for to-day's operation, which is curative in a large proportion of cases, the relations are apt to imagine that the patient is going to be worse with this "colostomy" than before. So to call it "artificial anus" is good psychology.

The perineal portion of the operation.—This is carried out in the right lateral position. The skin is carefully cleansed, not only because of pyogenic organisms but also because of the possibility of cancer cells having oozed out. A lotion of mercury, which Miles taught for many years will destroy cancer cells, is used. The anus is closed with a purse-string suture and the area again treated with 1 : 500 perchloride of mercury.

The incision.—A figure-of-6 incision—Miles' original incision—starts to one side of the sacro-coccygeal joint and includes a wide area of peri-anal skin and deepens vertically upwards to divide the ischiorectal fat close to the ischia and inner borders of gluteus maximus muscles. The knife is insinuated, in the male usually between the coccyx and sacrum, but in the female often below the coccyx. A deeper sweep cuts the levatores ani close to the wall of the pelvis starting on either side of the sacro-coccygeal junction. The displaced colon is now drawn out through the wound from the sacral hollow and, owing to the extent of the dissection which has been carried out from the abdominal aspect, all that remains is to dissect the lower third of the rectum and anal canal from the prostate and base of the triangular ligament avoiding damage to the bulb of the urethra which should not have an indwelling catheter. All bleeding points are carefully secured.

The toilet and closure.—The pelvic cavity remaining is relatively septic because of the disruption of innumerable lymphatics potentially bearing organisms and cancer cells. Because of this it is swabbed with 1 : 500 perchloride of mercury and then this is washed away with normal saline. The wound is covered with a layer of oil-silk into which is packed about 1–2 yards of gauze impregnated with sulphonamide. The end of the pack is left protruding and the remainder of the wound closed by some deep and some more superficial interrupted catgut sutures to draw the subcutaneous tissues together. The most comfortable stitch for the skin is subcuticular. Two or three of these are required, each 5–7·5 cm. long, and the patient can sit up the next day because the wound is comfortable. Blood transfusion is given at or towards the end of the operation.

[End of film commentary.]

The scope of the standard combined abdomino-perineal operation is shown in Fig. 1. It can easily be extended if the disease is more widespread (Figs. 2–6).

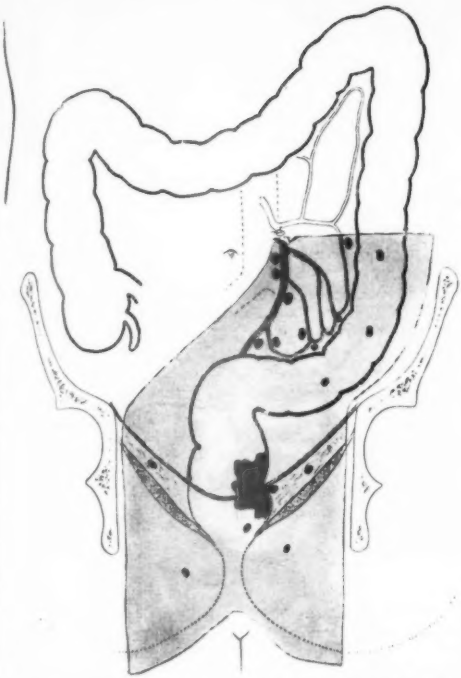

FIG. 1.—The standard combined abdomino-perineal operation.

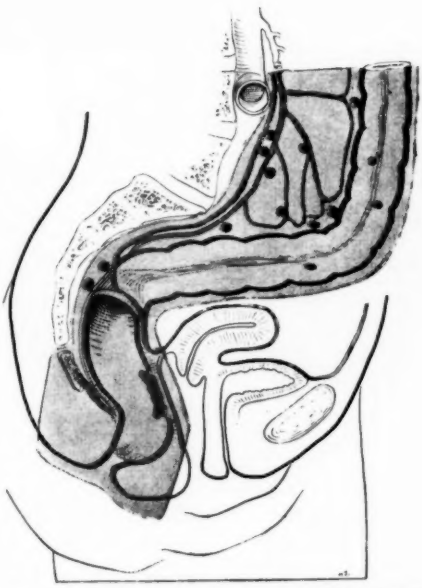

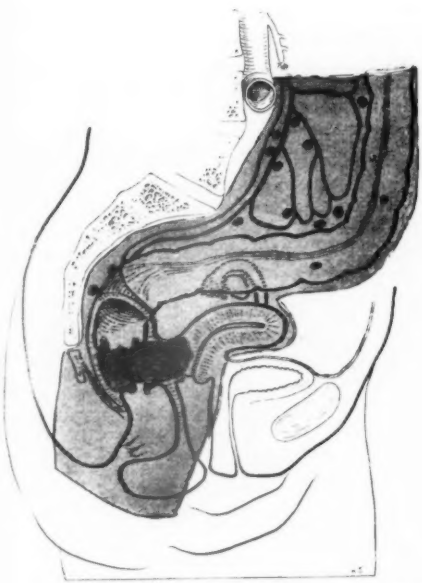

FIG. 2.—The abdomino-perineal operation extended to include the posterior wall of the vagina.

IG. 3.—The abdomino-perineal operation plus Wertheim's hysterectomy.

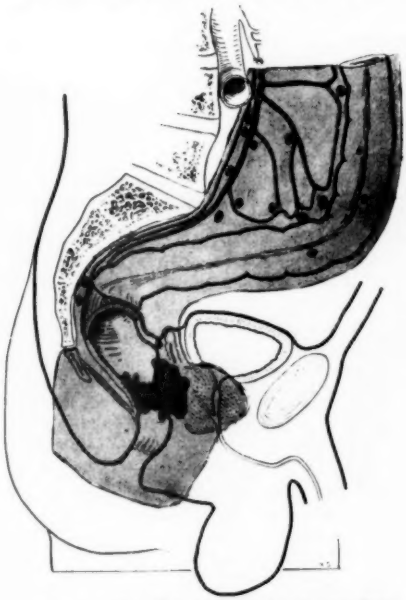

FIG. 4.—The abdomino-perineal operation plus removal of the affected prostate.

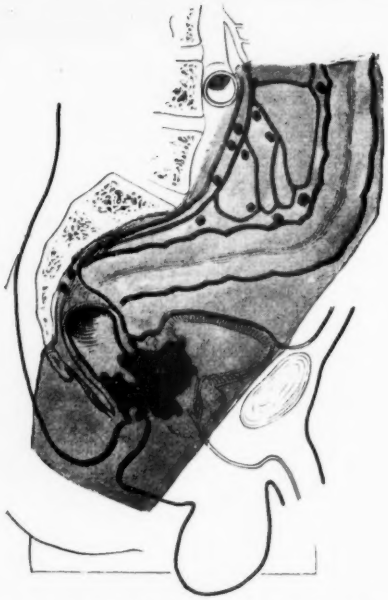

FIG. 5.—The abdomino-perineal operation plus total cystoprostatectomy.

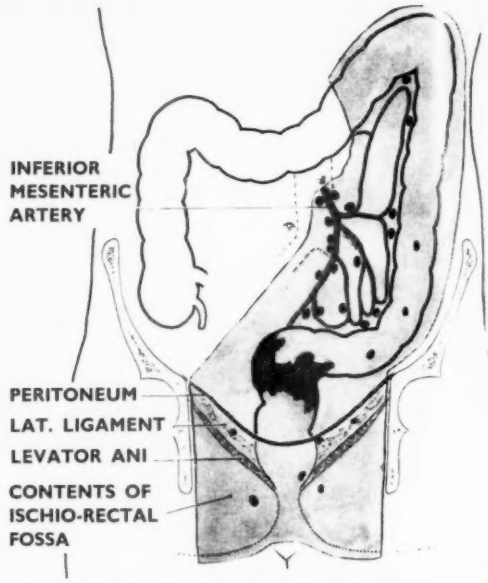

Fig. 6 shows the scope of operation for an advanced lesion at the pelvi-rectal junction. The ideal area of resection is from the left half of the transverse colon down to and including the whole rectum including ligature of the inferior mesenteric artery at its origin from the aorta. However, some patients are unable to withstand such an extensive resection as compared with the standard abdomino-perineal excision. The advantage gained, however, is the removal of the lymph nodes lying on the first 3–4 cm. of the inferior mesenteric artery. Therefore for these advanced cases the extensive operation is carried out whenever possible but the standard operation is used for a poorer risk case.

Before the days of antibiotics and modern anæsthesia the operative mortality was due to infection, pulmonary complications, peritonitis, paralytic ileus and urinary infection. Shock in those days was a big factor. To-day the majority, if not all of these, have been eliminated, and the mortality is almost limited to diseases which are as yet difficult to avoid, such as coronary catastrophe, pulmonary embolism, and only rarely infection.

With regard to results, the statistician at the Royal Marsden Hospital and Institute of Cancer Research, Royal Cancer Hospital, Mr. P. M. Paine, and my senior Registrars, Mr. Cyril Cooling and Mr. Allan Clain, have analysed 200 consecutive cases seen during 1947–1951. Of these cases 94% had the radical operation. The mortality was 5·3%. Of the survivors the five-year crude survival rates are shown by stages in Table I.

TABLE I.—CANCER OF THE RECTUM

Abdomino-perineal Excision

5-year crude survival rates by stages

(Overall resectability 94%)

Stage A	87%
Stage B	60%
Stage C	43%
All Stages	53%

Lastly, it is heartening to recall that, out of more than 1,300 operated cases, very many who appeared to be in an advanced stage of the disease and whose pathological report indicated a grave prognosis, after an abdomino-perineal excision, still attend for follow-up inspections twenty, twenty-five and even thirty years later.

Mr. W. B. Gabriel:

Perineo-abdominal Excision

My first one-stage perineo-abdominal excision of the rectum for malignant disease (that is, without a preliminary colostomy) was done in April 1932, so that in reporting my experience for this operation to the end of 1956 I am covering a period of close on twenty-five years. The total number is 1,223. These operations were all for established malignant tumours proved by section, and perineo-abdominal excisions done for benign lesions such as polyposis or large villous tumours have been excluded from this total.

In addition there is a relatively small number of cases in which a perineo-abdominal excision was done as a second-stage procedure after a colostomy had been established. Most of these were in my early days, some before 1932. I regard these cases (39 in all) as separate from the main group. There have been only 9 in the last ten years and they have not been included in the gross figure of 1,223 given above.

GUIDING PRINCIPLES IN THE CHOICE OF TREATMENT

I favour a straight radical excision of the rectum and pelvic colon when a malignant growth develops at any level of the rectum or rectosigmoid, for the following reasons:

(1) It is generally reckoned that about 80% of intestinal cancers develop in the rectum, rectosigmoid or pelvic colon, and if one malignant growth forms in the rectum or rectosigmoid it would seem to be a mistake to conserve any part of this dangerous area.

(2) Related benign tumours are found in at least 30% of specimens removed by radical excision; some are below but more usually they are found above the main tumour and a radical excision of the rectum and pelvic colon up to a left iliac colostomy enables the risk of later malignant growths in this segment to be excluded. In a number of my cases after radical excision a pedunculated adenoma has presented at the colostomy and has easily been removed after ligation of the pedicle.

(3) Multiple malignant tumours have been found in approximately 50 cases in my series (4%). Usually the upper growth has not been diagnosed either before or during operation and only the subsequent pathological examination has shown the need for and the wisdom of a combined radical operation.

(4) The complete removal of the upward zone of spread must pay dividends in the long run and I defy any surgeon to assess accurately the extent of lymphatic spread at the time of operation. Some turn out to be better than expected, some worse, and discontinuous upward lymphatic spread is common.

(5) My opposition to restorative operations for rectosigmoid cancers is that these operations must be more lengthy and more dangerous especially in old subjects with arteriosclerosis, diverticulitis, or a short pelvic colon, and may place a greater strain on their healing capacity than a straight radical excision. Also in these days of shortage of hospital beds and expense of private wards the question of hospital morbidity is an important one. I get most of my patients with perineo-abdominal excisions out of hospital on or about the twenty-third post-operative day and some go earlier than this if it fits in with arrangements for convalescence.

(6) The great majority of patients after a radical operation have a trouble-free life and assure me that they are not worried or troubled by their colostomy. Once the perineal wound is healed only a six-monthly visit is advisable and I like these patients to appreciate that there is no need for close hospital supervision and that they can resume their normal activities. Reconstruction of a colostomy for stenosis is perhaps the most common subsequent minor procedure, and a repair operation for a sacral or perineal bulge is needed rarely. One common problem is to persuade these patients not to put on too much weight.

Selection of Cases and Preliminary Investigations

The chance of cure or relief must be given to the largest possible number of cases and, as we grow in experience and the confidence that is engendered by team work, operation is extended to late cases, bad surgical risks and what in general I call the "bad starters". Many of them do unexpectedly well but if we aim at a resectability rate of 90% or over, there is bound to be a high proportion of late cases; this is shown in my series by the fact that the C cases considerably outnumber the A and B cases combined (Table III).

Even the Stage IV cases with secondaries in the liver do well for a variable number of months and no statistics can measure the relief that we give to these cases. In my series of perineo-abdominal excisions there have been 53 Stage IV cases in the last ten years, with only 1 operative death, and 11 have survived for two years or more.

Estimation of operability.—I hesitate to label any case of cancer of the rectum as inoperable except when the patient is moribund from old age, severe general disease or massive liver metastases with jaundice. The term "borderline operability" is a better one to use, and after preparation many turn out to be more mobile and better subjects for operation than the first estimate would suggest.

Age.—Advanced age does not in itself contra-indicate a radical operation and in the last ten years I have done a perineo-abdominal excision in 171 patients of 70 or over, in fact they constitute more than one-quarter of the total operated upon during this period (Table I). 14 patients were 80 or over, the three oldest being 84, 85 and 86, and all 3 recovered.

Table I.—One-stage Perineo-abdominal Excision for Malignant Disease of the Rectum and Anal Canal

Operation Mortality Since 1932

Total Series = 1,223 Cases

Period	No. of cases	Operative deaths	Operation mortality %
1932–36	81	21	26
1937–46	517	58	11
1947–56	625	33	5·3
Total	1,223	112	9·2

This is my total series since 1932 comprising all hospitals and clinics. Both radical and palliative cases are included.

In the last ten-year period, 1947–56, the operation mortality in 625 cases has been 5·3%. Included in these 625 cases are 422 done at St. Mark's Hospital with 11 deaths =2·6%. The operation mortality in the remainder (203 cases) done elsewhere than at St. Mark's was 22 deaths = 10·8%.

Nutritional state.—Since the end of the last war we have all become accustomed to operate on obese subjects and with modern care they usually do well. The grossly obese subject, by which I mean the patient weighing 16 st. or more, should have special consideration and occasionally it may be advisable to postpone operation for four to six weeks while the patient is put on to a drastic slimming regime: a biopsy report of an average or low grade malignancy would favour such a course.

Full medical investigation.—This is now routine in all cases and involves investigation of the blood picture, blood urea, X-ray of chest, ECG and medical opinion; it should be carried out in good as well as in bad risk subjects. An X-ray of the chest which proves lung metastases to be present is sometimes the deciding factor against laparotomy in an advanced case of doubtful operability or one with clinical evidence of secondaries in the liver.

I used to be apprehensive about patients with calcified aortic disease but as long as all the facts are known and the surgical team appreciates the importance of maintaining the blood pressure at operation these cases can be brought to a successful conclusion.

In the bad-risk patient the physician's opinion as to preliminary and subsequent supportive treatment is of great importance in reducing the surgical risk. I and all my colleagues at St. Mark's are grateful for the help and guidance we have received for many years from Dr. Courtenay Evans. If he advises me to pause for a week or two before embarking on a major operation I take his advice and the patient eventually comes to operation in a much better state.

Biopsy.—I attach the greatest importance to a preliminary biopsy and regard this as essential. Biopsy enables the granulomatous lesions, such as those due to amœbic dysentery and tuberculosis, to be differentiated from carcinoma. Lately I have had a case of generalized lymphosarcoma with ulcerated rectal lesions which exactly resembled a carcinoma clinically, but this was correctly identified by biopsy thus enabling the patient to be referred for deep X-ray therapy. Biopsy usually enables the high-grade and colloid lesions to be diagnosed. I think it is correct to say that biopsy is reliable in close on 100%; in the paper published by Dukes, Bussey and myself (Gabriel *et al.*, 1951) in a series of 670 cases we proved biopsy to be correct in 97%. It is only in the case of large villous tumours covering many square inches that one cannot expect a biopsy infallibly to reveal a small focus of carcinoma and then the clinical signs of friability, ulceration and induration are the decisive factors.

Examination under anæsthesia (E.U.A.).—This is a good line to adopt in the case of a deeply ulcerated carcinoma of the lower third of the rectum especially when it involves the anal canal, for if it is situated posteriorly it may be impossible otherwise to get fragments for biopsy. E.U.A. is useful when a male patient has a deeply ulcerated growth anteriorly and it is important to decide if the prostate is invaded or not. A stricture of the rectum or anal canal may also be an important indication for examination under anæsthesia if symptoms suspicious of a rectal carcinoma develop.

Barium enema.—This is not necessary or routine practice in the average rectal carcinoma and, in fact, a barium enema given to a patient with a stenosing rectosigmoid growth might precipitate an attack of obstruction. I quite frequently see patients who have had a barium enema when there is a growth within easy reach of the finger and sigmoidoscope; however, sometimes these films show points of interest such as a short pelvic colon or advanced diverticulitis.

Points in Operative Technique

The operation has been described elsewhere (Gabriel, 1948) and I need only mention a few special points. Sulphonamide preparation is not given as a routine and is reserved for the occasional patient with noticeably offensive diarrhœa and those with a deeply ulcerated growth which might perhaps become perforated in the course of the operation.

A right paramedian incision is used for the preliminary exploration and is, I think, better than a left-sided incision because it will be farther from the colostomy.

After opening the peritoneal cavity a quick infiltration of the abdominal wall is done with 1% procaine. The liver, the rest of the colon and the pelvis are examined. If the growth is advanced anteriorly it is often helpful in the male to make a transverse incision with a long-handled scalpel at the bottom of the rectovesical pouch and a tentative separation can be made in the plane of cleavage between the rectum and the base of the bladder. The same manœuvre is useful in the female especially when a hysterectomy has been done previously and it might be difficult to find the peritoneal cavity from below.

After deciding that the growth is operable the pelvic colon is held out by an assistant and the base of the pelvic mesocolon is injected with 10 c.c. of 1% procaine without adrenaline. This effects a block of the inferior mesenteric plexus and must be to the patient's advantage in preventing ascending impulses. Many of these patients leave the table with a pulse-rate of 70 to 80.

The abdominal wound is closed temporarily with 4 or 5 through-and-through sutures tied over gauze and the perineal phase is then carried out in the left lateral position. The dissection is done with straight scissors exactly as it used to be done by my old chief, J. P. Lockhart-Mummery. The peritoneum is opened widely and is cut upwards on each side as far as can be reached with long blunt-ended scissors. The lateral ligaments are cut and ligated if necessary. If there is any suggestion of lateral spread the middle hæmorrhoidal pedicle can be dissected laterally for a short distance and can be divided if thought advisable by cutting diathermy.

The fully mobilized rectum encased in a sterile glove is washed with saline and pushed up into the abdomen. Sometimes in the case of a large growth in a small pelvis the mobilized rectum has to be left in the pelvis and is brought upwards when the abdomen is reopened. The stitch closing the pelvic floor is usually started from below as suggested by F. W. Connaughton many years ago and the needle is passed up into the abdominal cavity on a piece of gauze with the excess catgut wrapped round it.

The main pedicle is usually ligated above the first sigmoid branch. I do not believe in the "high tie" technique unless there is some specific indication for this which in my experience is rare.

A left iliac colostomy is established, with closure of the lateral space as an invariable routine. The pelvic floor is easily closed by bringing up and then carrying on the stitch

which has been started from below. A steep Trendelenburg tilt is not required and in fact a 15-degree tilt is seldom exceeded. The internal oblique is sutured to the side of the mesocolon and colon to prevent prolapse of small intestine. A snip with scissors through the fibrous margins of the external oblique serves to prevent any undue compression of the colon. The bowel is divided with a cautery about 4 cm. external to the abdominal wall and is decompressed by a soft catheter. Dry gauze dressings are anchored round the colostomy with Michel clips.

Results

When one meets with an ulcerated flat malignant growth at or about the level of the ano-rectal ring it is impossible, I think, on clinical grounds alone to say if it is a carcinoma of the rectum invading the anal canal, or a carcinoma of the anal canal extending up to or beneath the rectal mucosa. In any case the histology of these tumours is extremely difficult, they may be of mixed histology, part squamous and part adenocarcinoma, so that a biopsy is not absolutely final. The one fact that usually applies is that in this situation a carcinoma is of a high grade of malignancy and the outlook is fairly bad whatever the histology shows. I think these tumours, speaking generally, should be ranked as carcinomas of the rectum (Fig. 1A, B, C, D).

The problem is obvious and it would be a pity to split up a series of cases into small sections on a basis of histology. I cannot see that the surgical risk differs at all and from the point of view of statistics the larger they are the more accurate and informative they are likely to be.

The figures which I present include 15 squamous carcinomas of the anal canal, 1 squamous carcinoma of the rectal ampulla, 5 sarcomas of the rectum (one being in conjunction with an adenocarcinoma), 1 melanoma, 3 mixed adenocarcinoma and squamous carcinoma, and 1 malignant carcinoid with liver secondaries. These cases are included in my mortality figures and 20 that were operated upon before December 31, 1951, are shown in the survival rate (Table III).

Table I shows the steady drop in mortality and in the last ten years my overall mortality has been 5·3%. During this time the death-rate in my patients at St. Mark's Hospital has dropped in the five-year period 1947–51 to 3·6%, and from 1952–56 to 1·5%. At one time I had 168 cases without a death, and during the ten years 1947–1956 my mortality at St. Mark's in 422 cases has been 11 deaths = 2·6% (Table II).

Table II.—St. Mark's Hospital

One-Stage Perineo-abdominal Excision of the Rectum for Malignant Disease of the Rectum and Anal Canal, Radical and Palliative

For the ten-year period, 1947–1956 inclusive (W. B. Gabriel)

Period	No. of cases	Operative deaths	Operation mortality %
1947–51	223	8	3·6
1952–56	199	3	1·5
Total	422	11	2·6

In the last five years 73 patients were 70 or over, 5 being over 80. At one time there were 168 consecutive cases without a death. The 3 operative fatalities since 1952 were: (1) a frail old man aged 80 who died on the second day after operation from cerebral thrombosis and coronary disease; (2) a frail senile man aged 77 who died of cardiac failure on the fifth post-operative day; and (3) an immensely broad short man aged 65 who died from hæmorrhage, shock and coronary disease three hours after operation.

The mortality rate of my patients outside St. Mark's has been much higher, amounting to 22 deaths in 203 operations (10·8%). The majority of these were done in the Royal Northern Hospital, there being 183 perineo-abdominal excisions with 21 deaths = 11·5%. This is more than four times the death-rate in St. Mark's Hospital in the corresponding period and is a serious and significant difference. There are probably a number of factors which account for this: on the one hand we have St. Mark's with its highly specialized team and the intake of carcinomas is increased by the patients admitted to our private wards; these usually provide earlier cases and better operative risks, whereas in a big general hospital I believe we see a higher proportion of older and advanced cases. This is borne out by the fact that 1 in 10 of my Royal Northern cases (18 out of 183) have been

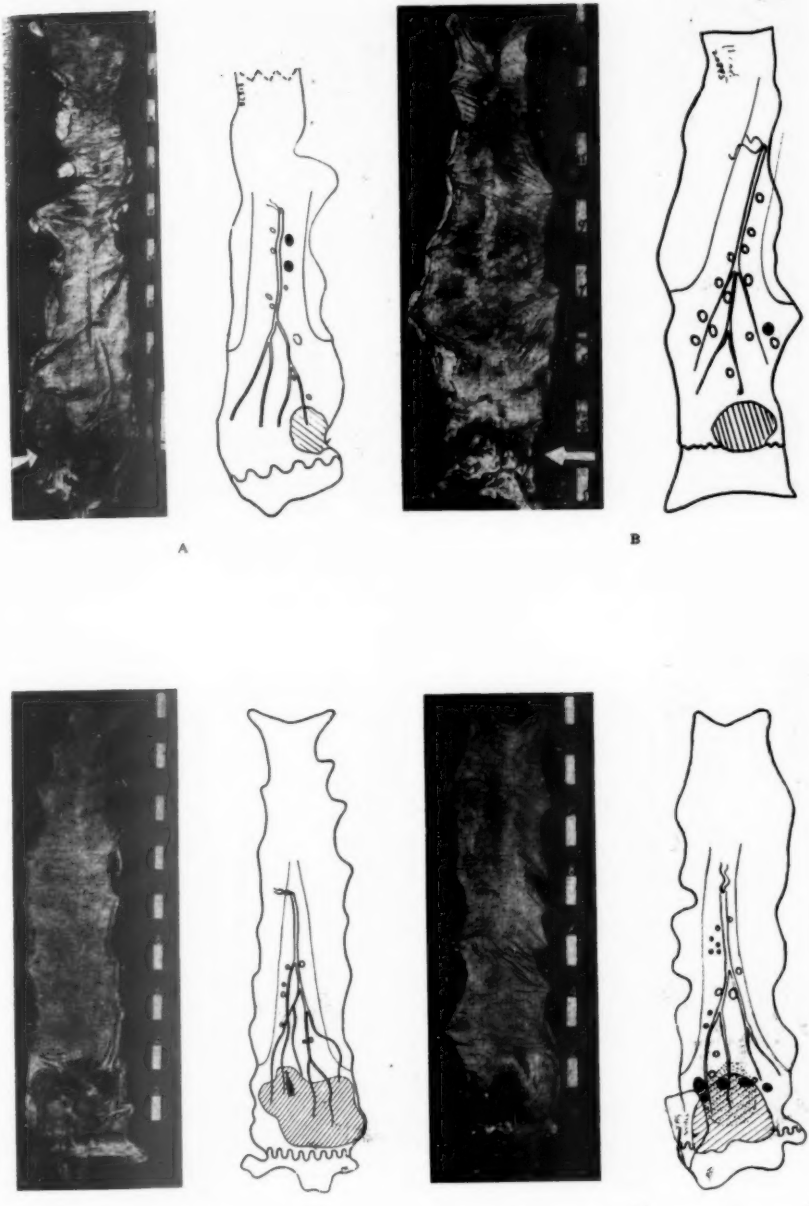

FIG. 1.—Figure showing lesions of different histological types involving the lower third of the rectum and anal canal. A, Adenocarcinoma of lower third of rectum invading anal canal. B, High-grade squamous carcinoma of anal canal extending up into the rectum with metastases in one hæmorrhoidal lymph node. C, Mixed adenocarcinoma of rectum and anaplastic squamous carcinoma of anal canal. This patient has survived for twelve years after a perineo-abdominal excision. D, Anaplastic carcinoma of anal canal. This was originally considered to be anaplastic squamous, but on review it is now believed to be anaplastic adenocarcinoma.

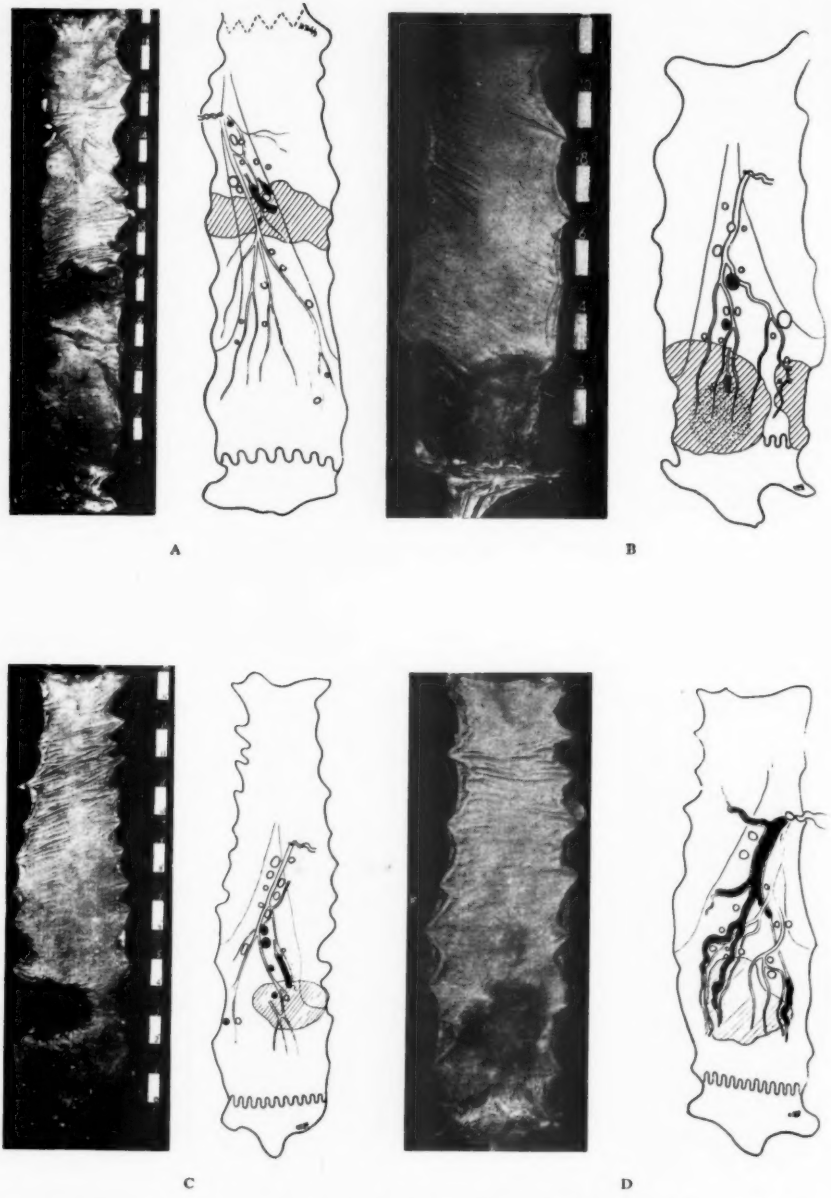

FIG. 2.—Four cases of cancer of the rectum with proved venous involvement followed by long survival after perineo-abdominal excision of the rectum.

A.—C2 case survived 8 years.
B.—C1 case survives 12¾ years.
C.—C1 colloid case survives 17 years.
D.—B case with extensive venous involvement to the point of ligation of the pedicle. This patient is alive and well 20 years after operation.

Stage IV cases with secondaries in the liver and of the C cases more than one-quarter (23 out of 88) proved to be C2 cases.

Furthermore I have formed the opinion that these patients do not do so well when nursed in big busy general wards. At St. Mark's we have, I believe, a higher ratio of nurses to patients than in most London hospitals. My figures indicate the advantage of doing these operations in special clinics or wards.

Survival Rate

This is shown in Table III which includes all operation survivors from 1932 to December 31, 1951, so that a clear period of five years has elapsed. Both radical and palliative cases are included and the difference in survival rate in the A, B and C groups follows the usual pattern.

Table III.—Five-year Survival Rate Following Perineo-abdominal Excision of the Rectum for Malignant Disease of the Rectum and Anal Canal
(Comprising all cases operated upon from January 1932 to December 31, 1951)

Group	No. of operation survivors	Untraced	Died of other causes in less than five years	Died of cancer in less than five years	Alive at five years	Percentage of five-year survivors
A	117	1	9	7	100	85
B	281	0	29	72	180	64
C	453	1	26	276	150	33
Total	851	2	64	355	430	50·5

Note.—This list includes 5 B cases and 27 C cases who were proved at operation to have liver metastases, that is, they were Stage IV cases. Other palliative operations due to irremovable local spread are also included in this series.

If the Stage IV cases are deleted the survival rate in B cases is improved to 65% and in C cases to 35%.

Of the 2 untraced cases 1 was operated upon in Spain and the other has emigrated to Southern Rhodesia.

If the Stage IV cases with secondaries in the liver at the time of operation are excluded (5 B cases and 27 C cases) the survival rate in B and C cases is slightly improved to 65% and 35% respectively.

Before concluding there is one point to which I must refer. I have heard the perineo-abdominal method criticized on the score that venous embolism is more likely to take place than in the other methods of combined excision.

I do not think this is a just or valid argument. My series is bound to contain the average number of cases of venous involvement and my survival rate figures speak for themselves. This operation depends for success, like any other, on the operator's technique and gentleness. The method of dissection of excised specimens which has been employed at St. Mark's for many years enables the cases of venous involvement to be detected with fair certainty and the examples of venous involvement followed by long survival (Fig. 2A, B, C, D) show that this does not necessarily imply that embolism to the liver must take place either before or during operation.

This series is probably unique in that of the 1,223 cases reported, all except one were examined and classified by Dr. C. Dukes at St. Mark's Hospital, and to him and his department I am supremely grateful.

Mr. O. V. Lloyd-Davies:

Synchronous Combined Excision

The operation of synchronous combined excision, requiring as it does two surgeons, can only be carried out in the lithotomy-Trendelenburg position. Bloodgood in 1906 described the use of Halsted's perineal board or table (*see* Halsted, 1924), upon which the patient was moved during the operation from Trendelenburg to lithotomy position and Clogg in 1923 described a rather similar procedure. Mayo in 1910 advocated the lithotomy position for perineal excision and there is little doubt that the even spread of the buttocks and the four-square approach to perineum facilitates the dissection from this aspect.

The position more or less as used to-day was first described by Kirschner in 1934 and Devine in 1937.

We first used the position at St. Mark's in 1936 for abdomino-anal resections and in 1938 Naunton Morgan and I did the first synchronous combined excision. It was a case I well remember with extensive involvement of the iliac and obturator lymph nodes but unfortunately our efforts were of no lasting benefit to the patient. It did, however, reveal to us what could be done in those days without increasing the operative mortality.

Since that time as the result of team work the positioning of the patient has been gradually perfected.

The Goligher sacral rest to elevate the perineum has replaced the sand-bag. A small lumbar air cushion made by Lilo eliminates undue kyphosis. The Frankis Evans epaulette shoulder-rests have removed any danger of a brachial palsy and the angled leg-rests have been modified to extend the thighs more fully to give an even better access to the abdomen.

The lithotomy-Trendelenburg position has many advantages. *In the first place* the choice of several operations is available without change in the patient's position. The single surgeon may carry out either an abdomino-perineal or perineo-abdominal type of excision according to his inclination. Between a quarter and a third of the cases seen may be suitable for some form of restorative resection—either an abdomino-anal or anterior resection. This position is essential for these operations in order to carry out the special rectal toilet before rectal division to eliminate the possibility of transplantation of free cancer cells in the lumen.

Briefly, it consists of irrigation through the anus of the portion of rectum to be retained after an exclusion clamp has been placed across the rectum at a minimum distance of 5 cm. below the lower margin of the tumour. The solution used is 1 : 500 perchloride of mercury. The proximal colon is also very carefully swabbed out with the same solution and suture-line recurrences have been virtually eliminated by this method.

In Hartmann's operation, now less commonly used than in the past, this rectal toilet is also very necessary and can only be accomplished in the lithotomy-Trendelenburg position.

Secondly, in restorative operations a second assistant can be very conveniently placed between the extended legs.

Thirdly, where the bladder may be incompletely emptied by preliminary decompression, complete emptying can be readily obtained with virtually no disturbance to the general towel arrangement.

Fourthly, any further examination such as cystoscopy, ureteric catheterization or a sigmoidoscopy when searching for colon polyps, may all be accomplished during a laparotomy with the minimum of disturbance.

Regarding the virtues of the synchronous method, there can be no doubt that it has influenced the resectability rate although other factors such as advancements in anæsthesia and the fuller understanding of the pre- and post-operative care of the patient together with an increase in our knowledge of electrolytic balance have also played a considerable part.

At St. Mark's Hospital the resectability rate has increased from 60% to over 90% since 1938 and from information I have obtained from hospitals elsewhere in the country where this method is used the resectability rate has in many instances been doubled.

In the straightforward case the operation is of course time-saving but it also allows those patients with large bulky tumours or with a frozen pelvis—frozen as often as not by inflammatory tissue—to be given a chance. They are often the cases in which removal of the rectum can only be accomplished by a dual approach and the end-results of operations of such magnitude are often very gratifying and certainly worth while.

In 14·6% of our cases other adherent organs have been removed with the rectum, such as loops of ileum, the uterus and adnexa, the vesicles and portions of the prostate and bladder—again with considerable time saving when these additional structures require removal. In these advanced cases the crude five-year survival rate is 25%—a low figure—but it does indicate that these extended operations have been worth while.

The figure of 14·6% does not include the removal of the posterior vaginal wall which has for some years been a routine procedure for any tumour in the lower half of the rectum whether clinically adherent to the vagina or not—with the result that a vaginal recurrence is now a rarity. Where even more extensive excisions such as pelvic exenteration are necessary most surgeons agree that the synchronous operation using the lithotomy-Trendelenburg position is the method of choice.

The C2 case, that is the case with glandular spread up to the highest point of ligature, presents a problem. If it were possible to convert a C2 case into a C1 case by doing a higher ligation—that is by tying the inferior mesenteric trunk at its origin—it might eventually be possible to show that there was an actual prolongation of life as the result of this step. There are, however, many other factors.

Although high ligation is an almost routine procedure at St. Mark's for upper-third, rectosigmoid and left colon tumours, in this series which mainly concerns tumours of the lower and middle thirds it was not done as a routine, but it should certainly be considered in those cases with palpable glands reaching the promontory. In poor-risk cases or those with marked arteriosclerosis or those where fat obscures the vascular anatomy, this extended operation would be unwise and might well increase the operative mortality.

There are other useful features in the synchronous operation which should be mentioned—such as the dual control of hæmostasis. Ligatures may be very conveniently passed up or down the empty pelvis and tied by the surgeon most conveniently placed. The pelvic peritoneal floor closure over an empty pelvis is a great advantage in itself and allows a wider removal of peritoneum and subperitoneal tissues.

Finally the synchronous operation is ideally suited for the training of the young surgeon in rectal dissection—since one part of the operation can be completed by a trained surgeon whilst the other instructs a junior. In this way there is the minimum loss of time and the safety of the patient is not impaired.

From 1938 to 1955—1,090 synchronous combined excisions have been carried out at St. Mark's Hospital. These have been operated upon by the beginners and the experienced.

The resectability rate which for some years now has been well over 90% obviously includes an increased number of poor-risk cases—but despite this the overall operative mortality for the series which includes both palliative and radical cases is 8·6%.

There has been a steady decline in this rate from 11·5% in the first five-year period to 4·4% in the last period. The crude five-year survival rate for radical cases is 53·4% but this figure cannot be compared with any other combined series for, since 1948, one-quarter of the cases presented for this operation have had restorative resections. This quarter represents the cream of the tumours in the upper half of the rectum and analysis of this group shows an increased proportion of early cases with a reduced operation mortality rate, and a much increased survival rate.

From another aspect they are not comparable even with Mr. Gabriel's perineo-abdominal figures at St. Mark's since more patients of the older age groups are included in this series, the average age of both males and females is nearly two years older. This makes quite a difference when the crude five-year rate is statistically corrected for age.

Some comparisons can be made with the perineo-abdominal method, and of those that are important urinary retention and infection should be mentioned. This is two and a half times more common in synchronous excisions and the cause in the majority of cases is due to varying degrees of damage to the nervi erigentes.

Watson and Innes Williams (1952) were of the opinion that this damage resulted from a failure to divide Waldeyer's fascia posteriorly. I find this explanation difficult to accept since the division of this fascia at the bony pelvic outlet is a formal and defined step in the perineal dissection. A truer explanation probably lies in the comparison of these two operations. When the major part of the dissection is carried out from above as in the synchronous or abdomino-perineal method, the ureters can be seen and, if necessary, exposed throughout their course. This enables the surgeon to remove the lateral ligaments widely out upon the pelvic walls and this I think is where the nerve damage occurs. When the major part of the dissection is carried out from below, as in the perineo-abdominal method, the surgeon has no accurate knowledge of the position of the ureters and takes a course closer to the bowel.

Goligher in 1951 reported upon the sex function after combined excision and found one-quarter to be totally impotent. There was no statistical difference between the synchronous and perineo-abdominal operations but the series was really not large enough to evaluate.

When dealing with malignant disease it is very necessary to be as radical as possible but one should balance the effects of any complication in terms of the length of the patient's life. At present there are no figures to give us any decision in this matter.

From a practical viewpoint I think the perineo-abdominal method of dissection is the operation of choice for the case of colitis where the patient is often young and any increased

risk of the destruction of sex function or a urinary disability would be totally unwarrante[d]. It may also well be the method of choice for the very elderly man with prostatic symptom[s].

One final comparison relating to pulmonary embolism. It has been suggested that th[e] position of the calves of the patient in the leg rests might induce increased venous stasi[s]. The legs are, of course, well elevated during periods of the synchronous operation and th[e] St. Mark's statistics show no difference in the incidence of embolism between the perineo-abdominal and synchronous methods.

I have tried to give a fair assessment of the synchronous combined excision method bu[t] there is undoubtedly a place for all these operations in the hands of those well skilled i[n] the various methods.

The synchronous operation has now a well-established position in the surgery of rectal cancer and is becoming increasingly the method of choice. In the average case there can be no difference between the results of the three established methods of rectal excision. However, in the advanced cases, bulky and adherent to the pelvis or to other organs, this may often be the only method by which excision is possible and some good results can be obtained.

Mr. C. Naunton Morgan:

Restorative Resection

In considering the subject of carcinoma of the rectum re-evaluation of the mode of lymphatic spread has shown that although the upward pathway is by far the most constant and frequent, downward spread is uncommon. Dukes has shown that retrograde lymphatic involvement was present in 6·5% of 1,500 operation specimens, but in only 2% did this occur for more than 2 cm. It was also noted in those specimens exhibiting downward extension that about three-quarters of the growths were of a high grade of malignancy. Lateral spread in the pelvic fascia and musculature is also unusual when the rectal carcinoma lies above the pelvic peritoneal pouch (Wood and Wilkie, 1933; Sauer and Bacon, 1951). In fact, local recurrence following combined excision of growths with lymphatic involvement, situated above the peritoneal cul de sac, was found in 3·6%. With similar lesions placed below this level, the incidence of local recurrence was much higher, namely 23% (Gilchrist and David, 1948). These facts have resulted in renewed attempts, in selected cases, to preserve a portion of the rectum and anal canal and to restore continuity.

The proportion of growths suitable for such procedures is small when compared with those for which combined excision is essential. For this reason, in order to present a true picture of the place of restorative methods, it is desirable to record personal experience in the treatment of all carcinomas of the rectum, more especially in recent years. The role of restoration will thus be seen against the broad background of the most radical of all operations for rectal carcinoma, namely combined excision. Since many cancers situated in the rectosigmoid region have, in the past, often been removed by combined excision, growths at this site are included in the present series of carcinoma of the rectum. The level of the lower border of the sacral promontory has been arbitrarily used to mark this site.

Operability (resectability) rate.—Of the total number of carcinomas of the rectum seen, 94·8% were removed.

Operative mortality rate.—After exclusion of 54 major operations performed by my colleagues on my behalf and 19 local excisions performed for tiny growths and malignant polyps, some 523 major operations remain. Non-restorative operations numbered 381 of which 361 were combined excisions and the remaining 142 (27%) restorative procedures. The operative mortality rate for synchronous combined excision and restorative resection is the same, namely 4·2%. These figures cover the period 1948–1956.

Criteria for Restorative Operations

At St. Mark's Hospital we have formulated certain criteria for the selection of cases suitable for restoration of continuity.

(*a*) *Type of operation.*—The operative procedure must allow of normal defæcation. Thus the anal canal with its musculature and linings should be left undamaged together with a portion of the rectum above the ano-rectal ring. The rectum and a portion of the sigmoid colon together with the meso-sigmoid and meso-rectum must be excised *en bloc* for a distance of at least 5 cm. by measurement, below the lowest border of the growth. The same upward lymphatic field as that required for radical combined excision should be removed.

Both anterior resection and abdomino-anal resection (Maunsell-Weir) satisfy these requirements but the latter operation does not always give a perfect functional result. Further, in order to restore continuity, a long sigmoid loop or mobilization of the transverse colon is necessary. Of the 142 restorative operations the large majority, 138, were anterior resections.

(*b*) *Site.*—The lesion should not be less than 10 cm. from the anus by sigmoidoscopic measurement and in addition should not lie below the level of the peritoneal reflection. The peritoneal reflection is variable, but the sigmoidoscopic measurement *together with* the relation of the growth to the peritoneal reflection form a useful yardstick for assessing the site of a growth.

(*c*) *Extent and grade.*—When the primary growth is advanced with evidence of marked extra-rectal or peritoneal spread, or is of a high grade of malignancy, the chance of local recurrence is great. Under these circumstances a restorative operation should not be undertaken. However, when there are a few secondary deposits in the liver, if complete removal of the primary growth is possible, then restorative operation is desirable. In fact, apart from cases in which the primary growth is extensive and liver secondaries are judged not to occupy more than half the liver substance, restorative resection is the best palliative operation. Of the 138 anterior resections in this series 28, or 20%, were palliative in nature.

(*d*) *Build of the patient.*—Owing to operative difficulties and inability to define the mesenteric vascular pattern, a short obese subject with a small pelvis and fat-laden mesentery is generally unsuited to restorative operation.

Implantation of Malignant Cells

Recurrence in the suture line or in the vicinity of the anastomosis following anterior resection was noted in a restorative resection I performed in 1936. This necessitated combined excision about six months later. The risk of implantation of growth at operation was then clearly demonstrated and in 1950, Lloyd-Davies and I recorded the gravity of this hazard. Goligher *et al.* (1951) reported that transplantation of growth accounted for about 50% of recurrences at or near the suture line.

That malignant cells can be implanted into the colonic suture in rabbits was shown by Vink (1954) especially after "sterilization" of the bowel by locally acting sulphonamides and streptomycin. McGrew *et al.* (1954) reported the presence of free malignant cells in the colon in 42% of proximal ends and 65% of distal ends of resected large intestine.

At St. Mark's Hospital, since 1948, we have attempted to destroy malignant cells in the lumen of the bowel by exclusion of the bowel 5 cm. below the growth followed by thorough lavage of the rectum with 1 : 500 mercury perchloride. The rectum is then divided below the clamp. The proximal divided end of the colon is swabbed with the same solution and particular attention is given to the cut ends of the bowel to be anastomosed.

Since using this technique the local recurrence rate in the region of the anastomosis has fallen from 21% to 1·5% in the last 136 operations. It is admitted that the two series are not strictly comparable since as yet enough time has not elapsed—but these figures are strongly suggestive.

In one of the two cases with local recurrence, the exclusion clamp slipped during removal of the specimen and the other was an advanced growth with glands extending high on the aorta.

Anterior Resection—Results of Treatment

The number of abdomino-anal resections performed was only 4 and for this reason only the 138 anterior resections will be considered. The operative mortality rate for anterior resections performed at St. Mark's Hospital was 2·5% and at other hospitals was 7%.

Likewise the mortality rate for synchronous combined excisions was 3·3% but was 5·2% in cases treated elsewhere. The influence of sex on the operative mortality is noteworthy. In the male undergoing anterior resection, it was 6·6% whilst in the female only 1·6%. The mortality rate following synchronous combined excision in males was 4·2% and in females 3·3%.

Survival rate.—Dr. Cuthbert Dukes has already discussed the fallacies of comparison of results without taking into account the age and sex of the patient, and the site, extent and histological grading of the growth.

To illustrate this point the crude five-year survival rate following 138 anterior resections between 1948 and 1956 was 54%, whilst that of 361 synchronous combined excision was 46%. This is to be expected since the less advanced growths have, in the main, been subjected to anterior resection. In fact, the number of early or A cases treated by anterior resection was over twice as many as those undergoing combined excision. The survival rate in the female is also better than in the male (males 54·6%, females 79·9%), but these are figures for "radical cases" only.

A reasonable comparison of the results of operations can only be obtained by considering the radical treatment of growths at similar sites, in this instance in the intraperitoneal rectum and rectosigmoid after correction for age, sex and extent of the growth.

The crude five-year survival rate for 110 *radical* anterior resections has been shown to be 66%. When this figure has been corrected, the survival rate is 81%. A similar corrected survival rate for a comparable group of growths removed by combined excision is 78·5%.

The slight difference is not of statistical significance but it does support the view that anterior restorative resection has a place in the treatment of suitable growths of the upper rectum and rectosigmoid and that patients so treated have as good a prognosis, without a colostomy, as those subjected to combined excision.

We have all been anxious about the wisdom of performing restorative operations. It is now felt that it has been proved beyond all doubt that anterior resection has a place in the treatment of carcinoma of the rectum and the results compare favourably with those of combined excision. This is shown in the happiness and gratitude of patients alive and well without colostomies.

Section of Obstetrics and Gynæcology

President—R. A. BREWS, M.D., M.S., F.R.C.S., F.R.C.O.G.

[*June* 28, 1957]

Medico-legal Adventures and Misadventures in Gynæcology and Obstetrics [*Abridged*]

By F. E. CAMPS, M.D., D.T.M.&H.

THOSE who practise forensic pathology must encounter other important aspects of gynæcology and obstetrics than those associated with crime. In fact, the most common criminal aspect of the subject—criminal abortion—is almost always due to a "lay" operator.

Thus, apart from deaths from violence or criminal abortion, the Coroner investigates those associated with surgical operations, therapeutic procedures, and, for this may not be generally appreciated, deaths in which the public interest is involved such as food poisoning. Into such a category will fall, when associated with mortality, outbreaks of puerperal infection and of infections of babies both newborn and in the neonatal period.

Before the introduction of chemotherapy and antibiotics, streptococcal infections were of considerable interest to the epidemiologist, and following the judgment in the case of Lindsay County Council *v.* Marshall (1937) there was an added medico-legal flavour in respect of the liability of maternity units when puerperal infection occurred. It is of interest to notice that twenty years later this case has apparently been forgotten, whether due to a more modern outlook or as a result of the National Health Service.

Clearly the investigation of multiple or recurrent cases of infection in any community, whether it be small or large, is an epidemiological matter, but the investigation must be undertaken with the full co-operation of everybody whether it be a trainee or a consultant, a technician or a pathologist or even a police officer. Apart from ethical considerations, there is always the overwhelming opinion in this country that it is better to deal with such matters in public.

In addition, all unexpected or sudden deaths following midwifery or gynæcological procedures should be within the range of the Coroner's investigation.

Examples of the scope of his investigations can be given under the following headings:

1. *Deaths During or Following Operation or Delivery*

Into this category fall such things as hæmorrhage following operation and post-operative shock. In many of such cases, death appeared to be inevitable but operation essential to give any chance of life. Clearly it is against public policy for surgeons to be prevented from embarking upon forlorn hopes. At the same time, it is advisable when risks deliberately taken do not succeed that the public's mind should be relieved of any suspicion that *death was, in fact, inevitable*. For this reason the Coroner may decide to employ a pathologist, not associated with the hospital or surgeon, to carry out the autopsy. Indeed the hospital pathologist frequently desires to be relieved of the responsibility of having to criticize a colleague. In any event, there should be no reason to expect the standard of autopsy to be inferior to that done in hospital or that all necessary material for investigation should not be collected.

It is of interest in connexion with delivery, that whereas prior to 1939 deaths from obstetric shock associated with the premature administration of preparations of pituitary extracts were relatively common, I have seen none for the last three years. This may be because I no longer work in rural areas. Among other causes of death during or after delivery are those due to cardiac inhibition of which the following is an illustrative case:

"A young woman (primipara) had her baby in hospital and it was necessary to do an episiotomy. In order to make her as comfortable as possible—she was a doctor's wife—

the obstetrician suggested an immediate repair. This was performed under light anæsthesia in the form of trilene, gas and oxygen. When the needle entered the perineum her heart stopped and nothing restored it."

Such a case fulfils all the criteria demanded:

(1) *a state of sensitivity*—light anæsthesia.
(2) *a stimulus* —needle prick.

Such a case is similar to those believed to occur during criminal abortion, when the woman is very frightened. It may be, however, that some of those described by pathologists were, in fact, due to other causes.

From time to time, cases are seen which have died at home or shortly after arrival in hospital from concealed accidental hæmorrhage, while others still die, but not commonly, of post-partum hæmorrhage. Such deaths may be complicated by blood transfusion and it may be difficult to assess how much the death was due to hæmorrhage or to some miscarriage of the transfusion. It is also clear that women who die during labour (other than from some obvious vascular disease) require a most careful and critical autopsy: during the last year I have seen a fatal embolism due to liquor amnii.

II. *Deaths During Gynæcological Procedures*

Deaths occurring during therapeutic procedures are rare although the hazards of blood transfusion should always be borne in mind. Only one case of air embolus has been encountered following insufflation of the fallopian tubes for investigation of sterility. In this case the air entered because of rupture of adhesions at the distal end of the right fallopian tube due to an old ectopic gestation.

III. *Injuries to the Genital Tract Due to Other Procedures*

Occasionally, gynæcological complications arise from other procedures and in 1956 there was a somewhat unusual case:

"A married woman of 56 without children was admitted to hospital on account of an anæmia. Examination of the fæces showed persistent occult blood and as the source could not be discovered a barium enema was requested to exclude malignant disease. The technique employed was the insertion of a catheter with an inflatable balloon and the subsequent introduction of barium under gravity pressure. The examination which was carried out in semi-darkness appeared to proceed properly although the woman showed signs of discomfort which were regarded as normal. Radiological examination showed what appeared to be an obstruction and she was allowed to follow the usual routine of emptying the bowel in a bedpan and removal of the catheter. This was accompanied by passage of a little blood which did not give cause for alarm and she returned to the ward apparently a little shocked. On the following morning she complained of abdominal pain and a further radiological examination showed free barium in the peritoneal cavity. A laparotomy confirmed this and a colostomy was performed as it was believed that she had perforated a large bowel growth. As there was bleeding from the vagina, an apparently intact hymen was incised which revealed a tear in the vaginal wall about 1½ in. long. In spite of active treatment including blood transfusion she died eight hours after the operation.

"Autopsy revealed an extravasation of blood extra-peritoneally in the loose pelvic tissues which had arisen from vertical tears in the lateral walls of the vagina, typical of overstretching; barium was present in the tissues beneath. It was also present in the peritoneal cavity and the route of entry could be traced through the uterine cavity and fallopian tubes. It was therefore quite clear that the barium had, in fact, been introduced with the catheter and balloon in the vagina, the vaginal tears being due to distension by the balloon and the barium to gravity pressure with the introitus blocked by the balloon."

IV. *Coincidental Findings at Autopsy*

From time to time, coincidental gynæcological and obstetric findings are revealed during routine medico-legal autopsies and perhaps the most interesting was a three months' pregnancy with a butterfly pessary still in situ in a woman who had taken her life by coal gas poisoning.

V *Deaths Due to Abortion or Attempted Abortion*

Abortions are the most common cause of investigation and most of these are suspected if not proved to be due to interference. Apart from death from shock, air embolism, hæmorrhage or cardiac inhibition, the commonest cause of death is infection. The infecting organism has changed during the last twenty years, mostly due to the introduction of antibiotics. Although anaerobics, streptococci and staphylococci are occasionally

encountered with broad ligament infection and pyæmia, the commonest organism is *Cl. welchii*. Death may occur in two ways, either rapidly from septicæmia, in which case the external appearance of the body is usually leaden in colour with slight jaundice and autopsy reveals a gross blood-stream infection, or later from renal failure with the incorrectly-called "lower nephron nephrosis". Those due to an obvious clostridial infection present no difficulty but it is not uncommon to find renal failure with a similar picture with or without gangrene or necrosis of the uterine wall without isolation of a specific organism. It seems probable that in some of the cases the renal condition is consequent upon antiseptic fluid entering the blood stream through the placental sinuses during its introduction into the cavity with intent to cause abortion.

VI. *Other Criminal Acts*

Recently a prosecution was carried out under the Infant Life (Preservation) Act 1929. This Act provides that any person who *with intent to destroy the life* of a child *capable of being born alive, by any wilful act* causes a child to die *before it has an existence independent of its* mother shall be guilty . . .

In this case, the child believed at ante-natal examination to be of 26 weeks' gestation, was delivered on the day following an assault during which the mother was struck or kicked on the abdomen. The fœtal heart was heard on admission to hospital but not the following morning. On delivery the child was dead and subsequent autopsy showed fractured ribs and injuries to the lung and liver. All measurements and other evidence of maturity indicated the child to be of at least 28 weeks' gestation and there was, in fact, nothing to indicate that it could not have lived. A retro-placental blood clot was demonstrated. The accused man was acquitted of the charge although neither maturity nor cause of death *in utero* was seriously challenged.

[*May* 3, 1957]

DISCUSSION ON TUBERCULOUS CERVICAL ADENITIS

Mr. T. J. Wilmot:

Tuberculous cervical adenitis is now an uncommon condition in many parts of Great Britain, but it is still by no means uncommon in Northern Ireland where I have treated over 80 patients during the past five years.

This condition was discussed by the Section of Pædiatrics of this Society exactly a year ago (*Proceedings*, **49**, 969); many opinions expressed at that meeting will be in agreement with those put forward now.

When I was a student I was taught that one of the indications for tonsillectomy was tuberculous adenitis of the cervical lymph nodes; but I seldom saw tonsillectomy performed for this reason and I never saw the results of histological examination of tonsils removed on this account. Treatment of these cases was left largely in the hands of the general surgeons and the tonsils were often left undisturbed. An ear, nose and throat surgeon, trained in the detailed anatomy of the neck, trained to examine the throat and the pharynx with its extensions, and trained in the art of tonsillectomy, is the best fitted to deal with this condition. All my cases have been seen and treated in conjunction with Dr. Edwin James, the chest physician for this area.

Clinical Material

This paper is based on 78 patients seen between November 1951 and July 1956. The vast majority of these (73%) have shown involvement of the upper deep cervical lymph nodes, either alone or in conjunction with other lymphatic groups (Table I). In the 57 with involvement of this group of nodes, the infection has been unilateral in all but two, i.e. in 96·5%.

Age Incidence

Tuberculous cervical adenitis is regarded as being a disease of children and the maximum incidence occurs in childhood, but 44·8% of our patients were over the age of 15 when first seen and 34·5% were over the age of 25 (Table II).

TABLE II.—AGE INCIDENCE WHEN FIRST SEEN

No. of cases	3	26	14	8	11	10	5	1

Clinical Appearances

The characteristic feature of most of these patients is the complete lack of constitutional signs. As Dr. F. J. W. Miller has pointed out (1956), these do occasionally occur in the form of a febrile reaction with early softening, but this has been a very rare phenomenon in this series. The patient usually presents with a lump in the neck which may be quite recent or may have been present for months or years (Table III).

TABLE III.—LENGTH OF TIME SWELLING PRESENT WHEN FIRST SEEN

Less than one month	8
One to three months	22

Total	76

In only 4 (5·1%) did active pulmonary tuberculosis accompany the cervical adenitis. 1 patients (20·5%) gave a history of previous tuberculosis and in 2 of these the previous lesio had been a cervical adenitis. In 94·9%, however, the cervical lesion was the only evidenc of active tuberculosis during the time they were under our care.

The Role of the Tonsils

It has been part of this investigation to attempt to clarify the role played by the tonsils i this infection. Tonsillectomy has been performed in 44 patients; in 27 of these all tissu removed, including any adenoid tissue, has been examined histologically by Dr. J. Edga Morison of the Central Laboratory, Belfast. Of these, 12 (44·4%) showed evidence o tuberculosis in the tonsils and 1 case showed tuberculous infection in a small adenoi remnant. The appearances of the tonsils on clinical examination are of little or no significance and are no guide to the presence or absence of tuberculous infection. We believe tha with such a high tuberculous incidence, the tonsils should be removed in all cases where the deep cervical chain is involved unless there are strong contra-indications. Moreover, like Dr. Miller, we believe that intercurrent infection plays an important part in causing softening of previously quiescent but enlarged nodes. We think that non-specific tonsillitis is especially important in this respect and is another good reason why the tonsils and any other infected foci in the mouth, nose and throat, should be removed. Mr. Denis Browne has advocated this policy for many years but it does not appear to have been widely practised. I feel that the main clinical responsibility should be in the hands of ear, nose and throat surgeons. The general surgeon often feels that tonsillectomy is of little or no value: he does not, however, see the full clinical picture of this condition.

Management

Once active tuberculous infection of the cervical nodes is suspected, active steps should be taken to confirm the diagnosis and institute treatment. Our policy is to admit all patients to hospital within a few days. A thorough general examination is then made, an X-ray of the chest and, if necessary, of the neck carried out and tuberculin sensitivity tests done. The latter are of considerable diagnostic significance; in 50 recorded and proved cases 31 were positive in a dilution of 1/10,000, 13 in a dilution of 1/1,000 and only one was negative. Once the diagnosis has been confirmed, or is strongly suspected, chemotherapy is commenced and continues throughout surgical treatment and for a total period of not less than three months.

Where the disease is bilateral and extends well down the neck, extension from the mediastinum should be suspected. Chemotherapy, prolonged if necessary for many months, is then the treatment of choice and surgery should be limited to aspiration or curettage of cold abscesses, although limited surgical excisions may be possible at a later date. In 73 of our 78 cases (94%), however, the infection was unilateral, being localized to one or more of the upper groups. In 57 patients (73%), the upper deep cervical group only was affected and our treatment of these was basically excision if uncomplicated, or not responding rapidly to simpler measures. Calcified nodes are not excised but a partially calcified node, guilty of frequent flare-ups, is better excised in a young patient. Once surgical treatment has been completed, the patient is sent home and continues his chemotherapy under the direction of his general practitioner.

All specimens of tuberculous material have been examined bacteriologically by Dr. Violet Reilly who was able to demonstrate tubercle bacilli in 39 out of 51 patients but has only been able to culture these organisms on four occasions. Of these, three have been human and one bovine. This is in agreement with her general finding, published in 1950, that extrapulmonary tuberculosis in Northern Ireland is commonly human in origin.

Surgical Principles and Technique

Surgery is directed first towards the glands if there is softening or frank abscess formation because delay makes excision more difficult and is likely to lead to greater skin involvement with consequent scarring. If no evidence of softening is present, surgery is directed first towards the tonsils and adenoid tissue or towards eliminating dental sepsis. Whether any of these structures is infected with tubercle bacilli or pyogenic cocci is immaterial, infection is better eliminated. These simple procedures alone will be sufficient to allow many glands, at first thought to be tuberculous, to resolve without further treatment. In such cases, the tuberculin skin reactions are usually negative and the X-rays of chest normal. If the gland does not reduce rapidly in size after tonsillectomy, the patient can be sent home on chemotherapy. If the affected gland increases in size or shows any tendency to break down, excision is then performed without delay. In our series, in 40 cases where the clinical diagnosis of tuberculous adenitis was not in doubt, 33 did not resolve on chemotherapy and had a later surgical excision carried out (82·5%). There is much to be said, therefore, when everything indicates an isolated gland infection, for following up the tonsillectomy by a routine dissection of the gland. This I have done increasingly often as the series has continued.

All surgical treatment, once the diagnosis has been confirmed, has been carried out under isoniazid 5 mg. per kg. with PAS in doses of one cachet (1·5 grams) for each 50 mg. tablet of isoniazid. In very young children isoniazid syrup was given instead of tablets and the PAS was omitted. Chemotherapy has not, in our view, however, proved effective in clearing up the infection unaided and this is in keeping with the mechanical difficulty in getting the agents into the avascular tissue affected.

It is often possible to excise a cold abscess and underlying node in one mass. If the overlying skin is involved, but not extensively, it should be sacrificed: it should not be allowed to delay surgical excision, but on the contrary, should spur the surgeon on to early action. If skin involvement is extensive, preliminary aspiration or curettage with more prolonged chemotherapy may be necessary to reduce the lesion to satisfactory surgical dimensions. Here, experience is the best guide. When dissecting the skin over a cold abscess, the use of fine plastic surgery skin hooks is helpful. Careful, gentle, anatomical, sharp dissection of the whole lesion should be carried out, and suction should be available to remove any tuberculous pus. The key to most of these dissections is the sternomastoid muscle; once this has been carefully defined from the surrounding, and often dense, fibrous tissue, other landmarks become plain. Gentle retraction and the use of fine plain catgut rather than diathermy, facilitate healing which is usually very rapid. Incisions, of course, are placed in the line of the skin creases and only the minimum of skin is excised when it is inevitable. All obviously tuberculous glands should be excised, but normal glands should be left *in situ*.

When a diffuse tuberculous mass is present, prolonged chemotherapy is often successful in reducing this to a more localized lesion which can be excised. Sometimes, however, a cold abscess is so extensive, or in such a position, as to preclude excision. Under these conditions, the method I have found most successful is to open the area widely, using a skin-crease incision, and curette both abscess and the gland responsible for it under direct vision. The incision is then stitched carefully allowing room for a small drain and a polythene irrigation tube through which the cavity may be irrigated with PAS solution.

Any residual gland tissue can, if necessary, be excised later. In the few patients where I have used this method there has been no secondary infection.

All wound cavities, before suture, have been irrigated with PAS solution. In spite of the spilling of tuberculous pus and tedious, lengthy dissections, all our wounds have healed by first intention. There is little or no post-operative pain and children have the minimum of painful ward dressings. There is no doubt in the minds of most of the patients that they suffer more after tonsillectomy than after the neck dissection.

Results

Of those patients deemed suitable for surgery, 52 had an excision of glands carried out and of these, 3 developed recurrence deep to the cervical scar. These were treated by further excision and have not, to date, recurred again (Table IV).

TABLE IV.—RESULTS

Excision	52	3 Recurred. Treated by re-excision
		\+
		49
Subsided after: Tonsillectomy		7 No recurrence 1–5 years
Adenoidectomy		1
Minor surgery (aspiration, &c.)		5
Unsuitable for surgery because of long-standing, widespread, recurrent adenitis		6 Subsided with chemotherapy
Not considered for surgery because of coincident pulmonary disease		3
Subsided with chemotherapy alone, surgery not necessary		2
Refused operation		1
Died (coincident Hodgkin's disease)		1
Total		78

Simpler methods such as aspiration, incision and curettage were employed in only 11 patients; in 6 of these excision was later carried out. No skin grafts have been necessary.

Of the excised glands 49 were upper deep cervical, 8 were submandibular, 1 was submental, 1 was facial.

The results of excision have been good both clinically and cosmetically. In all but 3 of the patients operated on, the cervical lesion appears to have completely cleared up. In those whose glands recurred, a further simple excision and continuation of chemotherapy has resulted in apparent cure. We have not found it necessary to deal with these patients

as is so often advocated, by prolonged rest and other general measures; once the cervical lesion has been excised, convalescence need not be long and it has been our practice to return children to school within two or three weeks of the operation. Stay in hospital has been short following gland dissection, many patients have been home on the fifth day and the average has been between seven and eight days. Because of poor rural communications many patients have had to stay longer than was strictly necessary.

Operative Complications

(1) *Nerve injuries.*—The spinal accessory nerve was divided in one case where a large mass of glands had been present for two years and did not respond to chemotherapy. The nerve was traced into and out of the mass but could not be freed. It was divided. In this case, full function has returned to the affected muscles.

In 3 patients the cervical branch of the facial nerve has been cut; in only 1 of these is any weakness of the angle of the mouth now visible.

(2) *Keloid formation.*—Only in 2 patients has this occurred and then only to a minor degree. Both have received suitable radiation therapy with benefit.

Conclusion.—I believe that the E.N.T. surgeon is, or should be, the surgeon best equipped to deal with tuberculous cervical adenitis—a problem which is so closely integrated with oral and pharyngeal sepsis. Co-operation with the chest physician for the area is, however, highly desirable.

Mr. J. J. Mason Brown:

Incidence of the Disease

Admissions to the general surgical wards of a children's hospital give some indication of the incidence of cervical glandular tuberculosis.

In 1924 to 1925, 221 children were admitted with this diagnosis (110 patients per year). At this time also large numbers of children with cold abscesses were treated as out-patients but there is no means now of assessing their numbers. In the period 1947 to 1951 there were 78 admissions (16 per year) and from 1952 to 1956 there were only 43 admissions (9 per year). In the past ten years outpatient treatment has not been practised so that there has been a marked fall in the numbers coming for surgical treatment and probably also in the incidence of the disease.

The age incidence for 121 patients below the age of 12 is shown in Table I. The numbers

TABLE I.—TUBERCULOUS CERVICAL ADENITIS 1947–1956

Age Incidence

Year of life	Patients
1st	1
2nd	6
3rd	4
4th	11
5th	7
6th	10
7th	12
8th	13
9th	16
10th	16
11th	17
12th	8
All under 12	121

are too small to draw definite conclusions but the maximum incidence appears to be from the 7th to the 11th year although it is found at all ages and its frequency in the second year of life is not always appreciated. Of the 121 patients 58 were boys and 63 girls so that the sex incidence is practically equal.

Incidence in Town and Country

91, or 75%, came from the country and only 25% from the town. This is of interest because tuberculous cervical adenitis is still a common condition in the regions with a preponderance of rural population (Davidson, 1957). During the same period there were 18 children with other than cervical peripheral glandular tuberculosis and 13 of them, i.e.

72%, came from the towns. It seems that the country child is likely to develop cervical glandular tubercle whereas the town child is more likely to develop peripheral adenitis in other sites. The greatly improved social conditions, the rigid control of foodstuffs, the development of tuberculin-tested herds and the universal sterilization (in the towns at least) of all other grades of milk are responsible for the falling incidence of tuberculous cervical adenitis. The greater proportion of these cases results from bovine infection and it is not surprising that the greatest incidence is in country children. Indeed, there is good evidence that 2 of the children included under town cases acquired the infection as the result of a "nice country holiday". In the extra-cervical cases of peripheral glandular tuberculosis the organism gains entry through some breech in the skin surface and most of these cases have been in town children living in poor surroundings and in overcrowded conditions, and the source has been contact with a case of tuberculosis either directly or indirectly.

Pathology

Rational treatment must be founded on an understanding of the pathology. If tuberculous cervical adenitis is the glandular component of a primary tuberculous infection or complex, e.g. with the primary focus in the tonsil and spread to the jugulo-digastric glands or a primary infection in a tooth socket with spread to the submandibular nodes, bovine infection would be most likely and an attempt to remove the primary focus and the glandular component of the primary complex would be justified. If, on the other hand, the disease is a secondary spread from a primary complex elsewhere surgical treatment would be of no value except in the treatment of complications. Most children with tuberculous cervical adenitis show no evidence of another primary complex and section of the tonsils confirms that they are infected so that there seems little doubt in most cases that the lesion is the glandular part of a primary complex.

The behaviour of the cervical nodes resembles closely that of the nodes in peripheral adenitis following infection at the site of injury or injection (Miller, 1953). In the neck the nodes most often affected are the tonsillar glands and the submandibular node which between them drain a large part of the mouth and pharynx which are not readily examined and in which it is difficult to demonstrate a primary lesion. The tonsils may look normal and yet be the site of tuberculous infection. Primary tuberculous infection does occur in the mouth but its true nature may not be appreciated. Boyes *et al.* (1956) report 7 cases aged from 2 to 17 years, only 1 being over the age of 10. The lesion presents as a painless ulcer which usually follows trauma, such as tooth extraction, and there is early involvement of the regional nodes. In any tuberculous adenitis there is always one node in the gland mass which overshadows the rest, it is bigger, it appears first, it is the first to show periadenitis and the first to soften and the primary focus is in its catchment area.

The Aims of Treatment

As cervical glandular tuberculosis is usually the glandular component of a primary complex the aims of treatment must be to eliminate the infection in the shortest possible time with the least possible disturbance of the child, to secure healing without scarring and to prevent dissemination of the infection. Antibiotic therapy might be expected to fulfil these aims.

The results of antibiotic therapy.—If the glands are firm and of recent origin when therapy is begun the gland mass shrinks but one main gland remains large and may flare up and soften despite long-term use of isoniazid and PAS. There is no doubt that a four-weeks' course of streptomycin and PAS will shrivel the glands and make them less matted to each other but it is not long after the cessation of treatment before the glands soften. In addition the exhibition of isoniazid may cause the rapid breakdown of tuberculous cervical nodes and so precipitate abscess formation (Lincoln, 1956). It seems, therefore, that with the antibiotics at present available we can fulfil the aims of treatment only when treatment is begun at a very early stage. When a new and potent drug becomes available the usual tendency is to expect too much from its use, e.g. penicillin in acute osteomyelitis and Eumydrin in pyloric stenosis. The indications for surgical treatment previously worked out from a wealth of clinical experience tend to be forgotten and have to be re-learned if the drug does not come up to expectations.

The Possibilities of Surgical Treatment

Having accepted that the antibiotics cannot fulfil the requirements of treatment and believing that cervical adenitis is a primary complex, what has surgery to offer in its treatment? Logically both the primary focus and the nodes should be removed as soon as possible to prevent the further spread of infection. Which should be dealt with first? Swenson and Small (1952) advise removal of the primary focus, i.e. usually the tonsil. They advise that if a child presents with unilateral, matted, non-tender, cervical nodes of six weeks' duration or more, and the tuberculin reaction is positive, the tonsils and adenoids should be removed

immediately. If after two weeks the nodes are still enlarged they are excised. This seems to be an over-simplification because subacute non-specific cervical adenitis may last for more than six weeks and may take much more than two weeks to subside following tonsillectomy and in England and Wales 45% of children aged 14 have positive tuberculin reactions (Brigg *et al.*, 1955). If the tuberculin reaction becomes positive during the course of the adenopathy there is little doubt about the diagnosis. The problem is more difficult than Swenson makes out, for patients present in very different ways. There may be gradual insidious enlargement of a node. There may be a history of recent illness or the onset may be acute with systemic upset, well-marked fever and rapid enlargement of the node which is fairly acutely tender. Abscess formation occurs rapidly even if antibiotic therapy is given. The lesion may well be confused with acute adenitis and its true nature is realized only when the bacteriological report on the pus is received.

Other cases present with features between these two extremes, while yet again in other cases the general reaction of the child appears to have dealt with the infection and the glands calcify. Many of these calcified glands are only quiescent and await their opportunity when the child's resistance is lowered to flare up and form abscesses which may discharge on the surface leaving a sinus. X-ray evidence of calcification must not be taken as proof of healing. Tuberculous adenitis is seen in the following stages: (*a*) glands enlarged, firm and discrete; (*b*) the glands are firm for the most part but the largest one shows periadenitis and may show early softening in the centre; (*c*) there is cold abscess formation without skin involvement; (*d*) there is skin involvement shown by adherence and redness; and (*e*) the case is one of some standing which has been treated unsuccessfully and there are sinuses, recurrent abscesses or abscesses in calcified nodes.

In cases similar to those described by Swenson and Small (1952) the treatment should be by the immediate administration of antibiotics and by tonsillectomy. The tonsils are submitted to thorough histological examination. The decision regarding the nodes depends on the tonsillar biopsy; if tubercle is found the glands are removed by a limited excision but if the biopsy does not show tuberculosis the nodes are kept under observation. If the main gland remains enlarged there is good reason to suspect it and the cessation of antibiotic therapy is likely to be followed by softening and abscess formation and skin involvement will occur sooner or later. It might be argued that to remove the tonsils first runs the risk of precipitating secondary infection in the nodes while removal of the nodes first opens up the tissues of the neck to the spread of infection from the primary focus. It seems logical to remove the primary focus at the earliest possible opportunity.

Limited excision of the nodes implies the removal of the main gland and those immediately related to it, and not a radical block dissection. Objections to radical excision are that it causes deformity because of the extensive removal of the subcutaneous tissues. This is certainly a valid criticism of radical excision done for late cases in which other methods have failed but is then not a criticism of the method but of the delay which rendered it necessary. The slight deformity which follows limited excision should be compared with that due to abscess formation which may be prevented by timely excision.

Results of Surgical Treatment

In this series of 121 cases (Table II) excision was carried out in 45 as the first form of

TABLE II.—SURGICAL TREATMENT 121 PATIENTS

148 *Operations*

Aspiration	7	Failure	6	(86%)
Incision and expression	10	Failure	4	(40%)
Incision and curettage	62	Failure	21	(34%)
Primary excision (no abscess)	31	Failure	1	(3%)
Primary excision (small abscess)	14	Failure	2	(14%)
Secondary excision, i.e. after failure of other methods	24	Failure	0	
All excisions	69	Failure	3	(4%)

surgical treatment (other than tonsillectomy) they received. In 31 there was no clinical evidence of spread beyond the nodes and there was one failure, i.e. further treatment was required. In 14 children there was evidence of softening and periadenitis but no evidence of involvement of the skin and there were 2 failures. Excision was used also as a secondary treatment when all other methods had failed and when abscess formation arose late in the apparently quiescent case with calcified nodes. Such secondary excision was done in 24 patients and was successful in all. In all, therefore, excision was carried out on 69 occasions and only 3 required further surgical treatment.

In 121 children there were 148 operative procedures including aspirations, but excluding procedures carried out at other hospitals. The 69 excisions have been considered already.

The remaining 79 operations (Table II) were, incision and curettage 62 with failure in one-third of cases; incision and expression 10 with 40% failure; and aspiration 7 with success in only 1 case.

It is a fundamental mistake in treatment to allow abscess formation to occur except in cases which present acutely when it cannot be avoided. Limited excision under antibiotic cover at an early stage is a most valuable method of avoiding abscess formation and its complications and of cutting short the otherwise long period of treatment. The prolonged period of antibiotic treatment of this glandular part of a primary complex is not justified at this age although it would be if it could eradicate the disease or prevent its recurrence. In the present state of our knowledge and with the antibiotics at present available surgery is indicated (*a*) to remove the primary focus be it tonsil or tooth, (*b*) to remove the nodes if the tonsils are tuberculous and if they do not subside, (*c*) for the treatment of complications arising during and following the stopping of antibiotic therapy, and (*d*) for late abscess and sinus formation in previously treated cases. Lastly, the unsightly adherent scars following incision and curettage, aspiration or incision and expression may be greatly improved by surgical means when it is certain that the disease is quiescent.

These are not many cases on which to base conclusions but I recall the very large numbers of children treated surgically so effectively by my predecessors Miss G. Herzfeld, Sir John Fraser and Sir Harold Stiles, without the aid of antibiotics. Surgery should not be abandoned or relegated to the treatment of cold abscesses. At present the optimum form of treatment is a combination of antibiotics and surgery. The surgeon should have the opportunity of assessing the patient before there is skin involvement. The place of surgery is not solely to retrieve the failures resulting from other methods of treatment.

Dr. E. F. James:

My particular concern is the diagnosis and treatment of chest diseases, but the most prominent of these is tuberculosis, and as there are certain basic similarities between tuberculous lesions wherever they occur in the body, it is not possible to deal with pulmonary tuberculosis without being interested in the disease as a whole. I have concentrated, therefore, on the more general implications of this study of cervical adenitis, in the hope of gaining information about the mysterious behaviour of tuberculosis.

The infectiousness of tuberculosis cannot be doubted, yet out of 78 cases of cervical adenitis an obvious source of infection was found in only one, although 164 family contacts were X-rayed. We believe that the human tubercle bacillus was responsible for the majority of our cases, and a family history of pulmonary tuberculosis was found in 10 cases, but, apart from the one mentioned above, the history was remote and no active disease was present in the family at the time the cervical adenitis presented itself. If it had not been for our previous knowledge of the tubercle bacillus, therefore, there was little to suggest that we were dealing with an infectious disease.

The first outstanding feature of our patients was that the lesions almost always were sharply localized; only 4 patients had active tuberculous lesions elsewhere. It is true, of course, that tuberculosis can be generalized in the shape of miliary disease and meningitis, but these are now rare and have always been relatively uncommon. It is also true that a patient can have multiple tuberculous lesions, but in my experience it is most unusual to see more than one active lesion in a person at the same time.

The second outstanding feature was the absence of constitutional symptoms. An excellent general condition was the rule, and we found no clinical evidence to suggest a lowering of general resistance to tuberculosis, of which the adenitis was a local manifestation. Consequently when the local lesion was efficiently treated, recovery was rapid and complete. Rest and treatment to improve the general condition were quite unnecessary. The revolutionary benefits which have followed the discovery of specific anti-tuberculous drugs have focused attention on the importance of treating the tuberculous lesion, and a logical outcome has been the widespread use of surgery in dealing with obstinate lesions. The new drugs when they do not offer definitive treatment, and they rarely provide it in cervical adenitis, at

least permit the surgeon to operate without the risk of precipitating generalized tuberculosis. Although in theory tuberculosis is a general disease, in practice it is astonishingly localized, and the application of specific anti-tuberculous treatment has shown that if we treat the lesion, the patient can be left to take care of himself. Our study of these patients gave us a picture of a disease in which evidence of recent infection was difficult to find. Indeed, in one case there was an interval of forty-two years between what we took to be the time of infection and the appearance of the adenitis. We formed the impression of tuberculous infection rather as something which sets the stage for later events than as a cause of immediate disease. This does not diminish the importance of infection, indeed it increases it, because it means that anyone who has been infected with tubercle bacilli, however little disturbance they have caused on entering his body, is liable to develop a destructive tuberculous lesion, if suitable conditions arise.

What are these suitable conditions? It seemed to us that the disease arose because of a local and not a general breakdown in resistance, and here it might be helpful to remember the phenomenon of tuberculin hypersensitivity. When a person is infected for the first time with tubercle bacilli, his tissues become hypersensitive to the protein portion of the bacillus, broadly described as tuberculin. After that, a test dose of tuberculin injected into the skin will produce a reaction, varying according to the dose and the degree of hypersensitivity, from inflammation to necrosis and sloughing. The same inflammatory effect may be produced on any dormant tuberculous lesion which the person may be harbouring and tuberculin can change an inert caseous mass into an active tuberculous abscess. The result of injecting tuberculin, therefore, can be the same as that which follows the multiplication of tubercle bacilli in a lesion, or a fresh infection.

We believe that non-specific pyogenic or virus infection can behave like an injection of tuberculin in activating old tuberculous foci and that this mechanism is often responsible for determining the onset of tuberculous cervical adenitis. Jones (1951), in an excellent paper on tuberculous lymphadenitis in the Nigerian African, stated quite positively that non-specific pyogenic infection of the tonsils and teeth was the important ætiological factor in cervical adenitis in the African, because of its sensitizing effect on pre-existing tuberculous foci. The evidence incriminating non-specific infection is circumstantial as far as the glands are concerned but I have seen some cases which would seem to demonstrate its operation in the lungs. It seems reasonable, therefore, to offer the conception of the origin of tuberculous lesions at the site of old infection from the action of an excess of hypersensitivity, generated by accidental extraneous factors.

It would be dogmatic to suggest that all lesions arise in this way, and progressive tuberculosis following immediately on primary infection is well known. Nevertheless, I believe that this theory accounts for the majority of cases of tuberculosis. If it is accepted it becomes obvious why the link between infection and disease is so difficult to establish, and why a tuberculous lesion can suddenly arise in a person who appears to be in perfect health. It would also explain why the modern treatment, which is directed mainly against the lesion, is so strikingly effective and why, although tuberculosis mortality is now negligible in the United Kingdom, morbidity is falling much more slowly. The most rational approach to tuberculosis would seem to be to seek it diligently and to treat it vigorously until eventually there is an uninfected community in which tuberculous disease is unknown.

BOOK REVIEWS

The Voice and Its Disorders. By Margaret C. L. Greene, L.C.S.T. (Pp. ix + 224; illustrated. 45s.) London: Pitman Medical Publishing Co. 1957.

This book of 224 pages contains a considerable amount of useful information. It describes first the normal mechanisms of voice production and this takes about a quarter of the book. The rest of the book is devoted to disorders of the voice and the methods of correction. Illustrative case histories are given in this section and they are of considerable help in demonstrating the scope of speech therapy. It is important that a speech therapist should know something of the pathology of the voice disorders that are referred for treatment, but this limit has been exceeded in this book and the medical sections have become a rather bad and inaccurate textbook of laryngology. It is in this way that this book goes wrong even if the facts were right. For example, much unnecessary information is given, the diagnosis of syphilis, the symptoms of hyperthyroidism, clinical details of cancer, the place of irradiation in the treatment of cancer, the use of drainage after laryngectomy and many other slightly misleading snippets of clinical information. Surely a textbook on speech therapy is no place to discuss the relative merits of and indications for the various possible treatments of cancer of the throat, as is done on page 185.

The physiology of respiration is described in a manner which suggests a scientific accuracy which is not present. If the breath is held till the subject swoons he will become unconscious because of cerebral anoxia and not carbon dioxide poisoning as stated on page 14. Furthermore forced respiration of air, 20% oxygen, will not cause swooning from excess of oxygen. After forced respiration the respiratory centre does not "comfortably take charge of the situation". There is a period of apnœa due to carbon dioxide tension having been reduced by the forced respiration and it is some time before normal respiration is re-established.

When the author discusses speech therapy she is on much surer ground and she writes with authority. She realizes that the main function of the speech therapist is to encourage the patient, to improve his morale and to show him how to improve his voice. She emphasizes the need for auditory training so that the patient can hear his own faults and she points out the value of recording the patient's voice and playing it back to him and thus demonstrating his faults and also demonstrating improvement as the therapy progresses. Her methods of teaching œsophageal speech are good and once again she realizes that the therapist gives encouragement and one of her main functions is to arrange for other laryngectomized patients with good speech to see the patient and show him what can be done.

There is an extensive bibliography at the end of the book, but the quotations from these papers are not always digested before being quoted. For example these contradictory statements occur on consecutive pages: Unilateral abductor paralysis. This is the most common of the post-thyroidectomy complications. Complete unilateral recurrent paralysis. This is the most common type of paralysis and accounts for 90% of all vocal cord palsies. Functional aphonia following thyroidectomy. It must be stressed that by far the most common voice disorder following thyroidectomy is an hysterical one.

It is interesting to speculate on the conclusion a student would reach after reading and comparing these three statements.

The impression given by reading this book is that the author knows speech therapy and teaches it well. The sections dealing with speech therapy are clear and authoritative and easy to read. There are, however, errors and half-truths in the physiology and pathology and discussions on the choice of surgical treatment are out of place in a book like this. If these sections are to be included in a book of this sort there should have been closer collaboration with laryngologists so that the obvious errors could have been excluded. In the opinion of the reviewer the scope of this book is too great to have been undertaken by a speech therapist without a medical co-author.

Gastro-duodenal Ulcer. Physio-pathology, Pathogenesis and Treatment. By J.-Jacques Spira. (Pp. xvi+549; illustrated. 73s. 6d.) London: Butterworth & Co. (Publishers) Ltd. 1956.

The author of this handsomely produced book has spent much of his professional life in studying the problems of the ætiology of peptic ulceration and of its management. He has read widely on the subject whilst developing his theses, and has collected a bibliography which is so large that it occupies over 150 of the total of some 550 pages that make up the book. This is possibly the most valuable part of this book, but its usefulness might have been greater if the bibliography had been broken up and classified so that the relevant references came at the end of the individual chapters and sections.

The book begins with a review of the physiological and pathological considerations, and

leads on to a discussion of the ætiology of gastro-duodenal ulceration and the elaboration of the author's own theories on the subject.

These centre round his belief that fats are of major importance in the production of peptic ulceration. It may not be felt that this adds anything of fundamental importance to the elucidation of the subject or that his method of treatment is particularly revolutionary. There will, however, be none who will deny the truth of the widely appreciated advice to avoid stooping after a meal and the unwisdom of taking articles of food which are known to lead to discomfort.

An Introduction to Electrocardiography. By L. Schamroth, M.B., B.Ch.Rand., M.R.C.P.E., F.R.F.P.S. (Pp. xi + 60; illustrated. 12s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

There is no dearth of textbooks on electrocardiography, but many of them deal with the subject at such length as prove cumbersome to the physician who needs a convenient guide to the interpretation of occasional tracings. This small manual is meant to supply this need. In many places, however, a description of the clinical state is introduced, but its brevity makes it unhelpful. Moreover, the bipolar chest leads (CR) receive no mention in spite of their undoubted superiority over Wilson's so-called unipolar leads, in the diagnosis of cardiac pain.

No natural electrocardiograms are shown, and the tracings are portrayed as line drawings, admittedly well executed in many respects, but giving them an artificial appearance, and a false impression of the design of the QRS complex, and particularly of the S–T segment.

The purpose which this manual best fulfils, and fulfils well, is the graphic illustration of the basic principles of electrocardiography. As an introduction to the subject it is well worth possessing, and the absence of natural electrocardiograms has allowed its publication at a low cost.

The Principles and Art of Plastic Surgery. 2 Vols. By Sir Harold Gillies, C.B.E., F.R.C.S., and D. Ralph Millard, Jr., M.D. (Pp. xxi + 652; illustrated. £12 10s.) London: Butterworth & Co. (Publishers) Ltd. 1957.

It was expected that a book by Sir Harold would be an exceptional one. His unrivalled experience in plastic surgery, and his unorthodox and provocative approach demand attention, while his co-option of a younger co-author at least promised that the narrative would be readable.

Simple handling of the volumes shows that they are impressive, and the publishers are to be congratulated on a very fine production. The number of illustrations is prodigious, and this alone must have given great difficulty in production. The provision of photos and drawings at the side of the text on nearly every page is something that publishers shrink from, and Messrs. Butterworth have set a standard that it is hoped will be followed. The reader will appreciate the pleasure of finding the text and appropriate illustrations on the same page.

As to the style and composition, it is clear that this work is not a textbook comparable to any other. It is a history of the development and progress of plastic surgery, closely woven with an autobiography and biography of the senior author and his colleagues.

The chapter of acknowledgments is graceful, but suffers from too many superlatives. All Sir Harold's geese have got to be swans! The use of slang and of colloquial terms is frequent throughout the book, and will be irritating to many who may find them as puzzling as the sudden appearance of P.A.W.G. (postauricular Wolfe Graft)! On the other hand, these terms and the humorous reminiscences that go with them will bring pleasure to those who have been associated with Sir Harold.

A commentary on each chapter is impossible, but as one reads one realizes that the story of plastic surgery and that of Sir Harold are one and the same. His restless energy and enthusiasm, his ingenuity in meeting surgical problems, are all portrayed, and noteworthy is his ability to apply the techniques of others to solve his own puzzles. The use of Esser's inlay for the correction of ectropion is an example of his questing brain, and the use of the epithelial inlay behind the syphilitic nose was brilliant in conception. The recognition of the first tubed flap in 1917, and the implications and application were probably realized in a flash, and formed the basis of all tubed flap work ever since. At the same time, Sir Harold has had the provocative faculty of stirring his colleagues from self-satisfaction into a state of indignant thought.

Every chapter shows how the early problems were met and treated, and the same problems are therefore the easier to manage to-day—inlay grafting, flaps, cross leg flaps, lymphœdema. Some of the results are astounding, and one wonders how some of the large scale flaps ever survived.

This is a magnificent publication, full of humour and helpful advice on all the plastic problems.

DISCUSSION ON POLIOMYELITIS VACCINATION IN 1956

Professor C. H. Stuart-Harris (Department of Medicine, University of Sheffield):

Our story begins in 1955 when the first supplies of poliomyelitis virus vaccine became available in this country. The vaccine, made according to the original formula as described by Salk (Salk *et al.*, 1953) had been prepared by Dr. W. Wood of Glaxo Laboratories. The original M.R.C. Working Party on polio planned to use this first limited supply by inoculating it into groups of adults and then into children. Antibodies to the three polio viruses were to be measured before and after inoculation and the serological response was to have been compared with results obtained in experimental animals. Beyond these serological trials no one could tell where the story might lead when, in April 1955, the report of the Vaccine Evaluation Centre of the University of Michigan was released (Francis *et al.*, 1955). This American trial, which was probably the most careful large-scale study of any prophylactic ever undertaken, appeared to establish the effectiveness of 3 doses of the Salk vaccine in school-age children. The impact of this report, which was released with an unprecedented display of publicity, had hardly died away when we learnt of the occurrence of cases of poliomyelitis in groups of American children inoculated with vaccine in 1955. As the full story of what will always be known as the Cutter disaster became known (Langmuir *et al.*, 1956) it was obvious that our own plans would have to be abandoned until the cause of the setback had been ascertained. In the meantime a group of 15 adults had in fact received Dr. Wood's first vaccine and measurement of the antibody response in this group showed that the vaccine was fully antigenic (Tyrrell *et al.*, 1956).

By the autumn of 1955 it became clear that the trouble with the Cutter vaccine was due to residual live virus in the vaccine as issued. Although all three types of virus had in fact been recovered from the final vaccine, almost all the cases of poliomyelitis resulting from its use were found to have been infected by type I virus. Use of the Mahoney strain of type I virus which had been and still is incorporated in all American-made vaccine had already been criticized on the grounds of its high virulence, and it was decided that this virus should not be used in any vaccine made in Britain. While our manufacturers were seeking an alternative type I virus with a lesser power of inducing paralysis in monkeys, the Medical Research Council appointed three committees to deal with the several problems concerned in the further exploration of the use of polio vaccine. The most important of these is undoubtedly that headed by Sir Sam Bedson which, under the title of the Safety Tests Committee, has had under constant review all matters connected with the preparation of vaccine and its test under the Therapeutic Substances Act by the Biological Standards Division of the Laboratories at the National Institute for Medical Research. We shall hear something of the work of this division from Dr. Tobin who will also deal with the tests of the antigenicity of the vaccine in children. The second committee whose chairman is Professor E. T. C. Spooner was appointed to deal with all matters connected with laboratory investigations which might be required in any further studies on the vaccine. The third committee, on whose behalf I am speaking, was appointed to make observations on the clinical effects of poliomyelitis vaccine which might guide the Medical Research Council in any advice which it was required to give to other authorities.

Nothing further could be done in Britain until it was known that an alternative type I strain which was less virulent than the Mahoney virus but yet was also antigenic in animals, had been found. Fortunately Danish work (von Magnus *et al.*, 1955) with the strain of Brunhilde virus as modified by Enders in tissue culture gave us a hint and this same strain, now known as Brunenders virus, became the basis of vaccine production by Dr. Wood. When it became reasonably clear that some vaccine made from the new strain would become available in the spring of 1956, discussions began concerning its use. I shall not deal with all the arguments which occurred but merely with the conclusions. As the British vaccine contained a different strain of type I virus from that used in the Francis trial in the U.S.A., it was felt that we could not assume, without trial, that our own material would give results

comparable with the Salk vaccine. Secondly, the American vaccine left the problem of the pre-school-age child unanswered. Actually the youngest children in the American trial, who were aged 6, appeared to have received less protection from the vaccine than those aged 8 or 9. As the attack-rate and hence susceptibility of the pre-school child are higher than those of school children, it seemed to us that the vaccine ought to be tested in young as well as in older children. These two arguments led us to recommend to the Medical Research Council that a field trial of the British vaccine should be undertaken before the latter came into general use. I shall leave the further story of what ultimately transpired to Dr. Knowelden, who is the secretary of our committee and a member of the Statistical Research Unit of the Medical Research Council.

Dr. W. Wood:

The Production of Poliomyelitis Vaccine in 1956[1]

The poliomyelitis vaccine production unit at Glaxo Laboratories was created in the summer of 1954. At this time the United States field trial of the vaccine developed by Dr. Jonas E. Salk was in progress but several months were to elapse before any assessment of its clinical efficacy was possible. At this stage then, in the latter months of 1954, work was begun at Sefton Park in Buckinghamshire on the propagation of virus strains Mahoney, MEF–1, and Saukett which were, and still are, those representative of the three antigenic types of poliomyelitis virus used for vaccine manufacture in the United States.

By the spring of 1955, three small batches of vaccine had been prepared and tested. Although it was not possible to carry through the field trial as proposed by the M.R.C., one of the batches was used to immunize a small number of staff and students at Sheffield University and the results published by Tyrrell (1956) were the first demonstration that batches of satisfactory potency were being prepared in this country.

It was at this stage that a very significant step was taken by the Medical Research Council in recommending that vaccine manufactured in the United Kingdom should be prepared from a less virulent strain than Mahoney as the type 1 component. For it had become clear during the summer of 1955 that incompletely inactivated Mahoney virus in certain vaccine batches in the U.S.A. had induced some cases of paralytic poliomyelitis. During the ensuing months many dozens of type 1 strains from both sides of the Atlantic were tested in monkeys for virulence and antigenicity. Eventually both the Wellcome Research Laboratories and ourselves, in collaboration with the M.R.C., selected a partially attenuated line of the Brunhilde strain which we called "Brunden" as the most suitable strain. This strain had been modified originally by Enders by repeated tissue culture passage in human embryonic tissue and subsequently fed to chimpanzees by Sabin, and is probably very similar to the strain which Gear (1956) has called "Brunenders". Following intramuscular inoculation in rhesus monkeys, Brunden virus produced significantly less paralysis than did Mahoney and the antigenicity of inactivated preparations of both viruses appeared comparable. Strain Brunden was therefore used as the type 1 component in the preparation of all subsequent vaccine batches. The methods employed at the main stages of the production process are outlined in Fig. 1.

Virus production.—One of the facts emerging from the U.S.A. field trial was the necessity to prepare virus fluids with at least one million infectious particles per millilitre in order to have the inactivated virus provide an adequate antigenic stimulus. Two main methods of "bulk" propagation of virus have been evolved which yield fluids of requisite titre. The most widely adopted method is an elaboration of the Dulbecco and Youngner techniques by which monkey kidney tissue is treated with trypsin and the cell aggregates so produced are grown out in stationary cultures to give a sheet of new epithelium, for the most part one cell thick. For bulk production, it is usual to use 5-litre bottles and, after a confluent monolayer of new epithelium has developed, the spent nutrient is removed and fresh medium is added

together with the virus inoculum. In a few days the virus has invaded and destroyed the kidney cells and the virus progeny is released into the fluid phase of the culture which is then "harvested".

The other method of bulk preparation of poliomyelitis viruses is the one introduced by the Connaught Laboratories in 1952 and is essentially a large-scale version of the Maitland technique whereby the tissue is chopped into pieces about 1 to 2 mm. in diameter which are allowed to float free in the nutrient medium. This method was the one employed for the preparation of the virus in 1953 which was later processed into vaccine in the U.S.A. for the Field Trial in 1954 (Farrell *et al.*, 1955) and is the one we employ at Sefton Park. Superficially, it is a much less elegant technique than the trypsinized cell method and the titres of the virus pools produced are slightly lower. However, in practice, it is a most trouble-free operation to manage, and as the procedures carried out are independent of any demonstration of cell growth—which indeed may not occur—considerable latitude is available in the timing of the inoculation and harvest stages.

Virus inactivation.—Salk's method of inactivation using a 1 :4,000 formalin concentration at a temperature of 37° C. is employed (Salk, 1953). Each type of virus is inactivated independently in lots of 50 or 100 litres. The two significant changes which were introduced in the United States in the light of the early 1955 experiences, viz. the necessity to test large samples for active virus not only at the end of the inactivation period but also three days earlier; and the requirement that filtration should be carried out after formalin addition in order to break down aggregates of virus, are perhaps in themselves largely responsible for the impressive record of safety built up in the United States over the last two years.

However, in addition to compliance with formal regulations, the attention paid to the simple mechanics of the operation itself and the general lay-out of the working areas is also important. For example, the basic assumption—implicit in the performance of the required tests of safety—that the sample tested is truly representative of the bulk fluid, has involved the adoption of lengthy and repeated periods of mixing, and the frequent transfer of the bulk fluid to freshly sterilized containers. The final "trivalent" vaccine is prepared by blending one or more single strain pools of each type in roughly equivalent proportions.

Safety testing.—The principles and practice of the various safety tests which are required will be dealt with in detail in the paper by Dr. Tobin. It is noteworthy, however, that the performance of these tests on the scale required, is associated in our experience with one pressing problem which often results in delays occurring in the completion of a particular test. This is the frequency with which the kidney tissue of apparently healthy monkeys is minimally contaminated with a member of a large group of viruses, loosely designated simian or "wild" viruses (Hull *et al.*, 1957). The emergence of these viruses, sometimes after prolonged cultivation in safety test bottles requires much additional work in order definitely to associate the virus with a particular lot of monkey tissue rather than with the vaccine sample being tested.

Potency testing.—For the 1956 programme it was not possible to test for antigenic potency the individual single strain pools which were to be combined together to form the trivalent vaccine. These tests, which were performed in monkeys, were carried out only on the final triple preparation but now, to avoid the possibility of using poorly antigenic monovalent pools, potency tests are carried out at the monovalent as well as the trivalent stage.

In conclusion, I would like to record the appreciation felt by those concerned with the manufacture of this particular vaccine for the practice of duplicate safety testing of vaccine batches adopted for an initial period by the M.R.C. Control Laboratories, thus providing an assurance of safety that cannot always be guaranteed within the confines of a single testing unit.

Dr. J. O'H. Tobin (Biological Standards Control Laboratory, Medical Research Council Laboratories, Hampstead):

Safety and Potency Testing of Poliomyelitis Vaccine

The regulations governing poliomyelitis vaccine production and testing have been laid down in a general way in the Therapeutic Substances Amendment Regulations (1956) and are based on those used in the United States. Dr. Wood has already described how vaccine is made; it is my task to describe how it is tested in the Biological Standards Control

Laboratory. After the manufacturers have tested inactivated single strain pools of each virus type for safety by cell culture methods, and for antigenicity, pools of each type are blended to form the final vaccine. 3½ litres of this, neutralized with sodium metabisulphite—but before the addition of preservatives—are sent to us for cell culture tests. 100 ml. from each filling lot, after distribution into final containers, are also sent to us for inoculation into monkeys and for potency tests. This sample is the same as that which will be used for immunization in the field. The tests we do are similar to those done by the manufacturers on the final vaccine and, at the moment, are done concurrently with them.

Vaccine testing can be divided up into three parts: (*a*) cell culture safety tests; (*b*) monkey safety tests; and (*c*) potency tests.

(*a*) *Cell culture safety tests.*—Usually 2,000 ml. of vaccine are inoculated on to monkey kidney cell cultures in Pyrex feeding bottles. These are prepared in the usual way, the cultures being grown in Parker 199 solution containing 5% horse serum free from polio virus inhibitors. After rinsing the cultures with Hanks solution, neat vaccine, freshly dialysed against Hanks and 199 solution, is added and incubated at 37° C. After three to four days, 10 ml. of 199 medium is also added to the cultures to keep the cells in good condition during the remainder of the first week of incubation. The bottles are examined twice weekly for three weeks. The culture medium is changed and samples for subculture taken after seven, fourteen and twenty-one days. These subcultures are inoculated in pools of 3 or 4 on to other bottles, which are observed for a fortnight. At the end of twenty-one days the original cultures are divided into groups and challenged with a minimal amount of stock strains of the three types of polio virus to confirm their sensitivity to these agents. We have preferred to add only 10 ml. of dialysed vaccine at first as in three experiments we have found that we get more virus "takes" with a thin layer of fluid over the cell sheet than with deeper ones.

The only real trouble we have had with our cultures is "foamy agent" (Rustigian *et al.*, 1955). This seems to be seasonal, occurring mostly in the early and late months of the year. During this time we have always tested 2½ litres of vaccine to compensate for the loss of cell sheets during the third week of incubation.

(*b*) *The monkey safety test.*—Owing to the substitution in the British vaccine of the Mahoney strain of type I polio virus by Brunenders, some modification of those methods used in the United States has been made. Brunenders (Gear, 1956) is an attenuated variant of the Brunhilde strain, isolated by Enders and further studied by Sabin (1955). As attenuated strains have been shown to be more easily isolated in cynomolgus than in rhesus monkeys, fifteen of each species are used in the monkey test. They are treated concurrently with cortisone as this drug increases the sensitivity of monkeys to the Brunenders strain and as it was in cortisone-treated monkeys that live virus was regularly isolated from American vaccine suspected of containing live virus (Eklund *et al.*, 1956; Syverton *et al.*, 1956).

The following schedule is used for the monkey test at present: 125 mg. cortisone is given two days before, and on the day of, injection of vaccine, and at least 50 mg. every other day for the following twenty-two to twenty-six days. Both rhesus and cynomolgus monkeys are injected intracerebrally, intraspinally and intramuscularly as it is thought that this is better than using any one of these routes separately (U.S. Report, 1956). Both species are observed for twenty-four to twenty-eight days and then sacrificed for histological examination of the brains and spinal cords. In addition, the cynomolgus monkeys have blood taken twice weekly for virus isolation as viræmia is a feature of polio virus infection in these animals.

We use rhesus, and not exclusively cynomolgus monkeys, as three viruses and not only type I, are used in vaccine production. MEF-1, the type II strain, is as virulent in rhesus as in cynomolgus monkeys and both species appear to be similar in their sensitivity to the type III strain.

(*c*) *Potency tests.*—Twelve rhesus monkeys are given 1 ml. of vaccine at weekly intervals and bled seven days after the third dose. The sera are titrated at doubling dilutions against 50–100 $TCID_{50}$, using two tubes per dilution. The virus/serum mixtures are held for three hours at 37° C. before inoculating them on to cell cultures. If less time of contact or a lower temperature is used, results become more irregular. We have compared the three Glaxo vaccines used last year with a vaccine kindly supplied by Eli Lilly & Co. and find they compare favourably with the American one, which we use at the moment as our unofficial standard. These vaccines have also been compared with each other using guinea-pigs and cotton rats (Perkins, 1957).

The antigenic response in children to the three batches of Glaxo vaccine has also been determined in co-operation with the Medical Research Council committee on the laboratory investigations of poliomyelitis, and is quite satisfactory (Medical Research Council, 1957). These vaccines were of the same potency whether tested in children, in monkeys, in guinea-pigs or in cotton rats. They were equally potent in children under and over 5 years of age.

Most of these children produced antibody, only 2 failing to produce some to all three types. However, some titres were lower than one would have liked. Whether all these children will respond to a booster dose of vaccine in one to two years' time is not yet known, but they are being followed-up to determine this point.

Dr. J. Knowelden:

When the Minister of Health and Secretary of State for Scotland announced in January 1956 a poliomyelitis vaccination programme for children in England, Wales and Scotland born in the years 1947 to 1954, the Medical Research Council's Statistical Research Unit, acting on behalf of the Poliomyelitis Vaccines Committee, was invited to plan for an assessment of the protective effect of the vaccine that was to be issued later in the year. It was expected that the demand for vaccine would greatly exceed the supply, and in these circumstances of shortage it was planned to compare the incidence of poliomyelitis in vaccinated children with that in children whose parents had registered them for vaccination but for whom none was available. The selection of which children were to be vaccinated amongst those registered had to be made uniformly throughout the country and without bias to make such comparisons between incidence rates valid. It was decided to make this selection according to the month of birth.

From January to March 1956 the parents of just over 1,900,000 children, i.e. 30% of the available children in the age group approximately 1–9 years, registered them with local health authorities. Registration was about twice as frequent in school age children, born 1947–50, as in pre-school children, born 1951–54. On the basis of an estimated supply of vaccine sufficient to give two doses of 1 c.c. each to 200,000 children, it was announced towards the end of April that those selected for vaccination were the 95,723 registered children born in November of the years 1947–50, and the 98,687 registered children born in March and November of the years 1951–54. August was selected as a reserve month for any excess vaccine available after the requirements of these groups had been satisfied.

Vaccination was carried out by local health authorities from early May to the end of June; 178,161 children received two injections with at least three weeks' interval between them, and 32,379 received one only. From special studies undertaken in Buckinghamshire, London, Manchester and Sheffield it appeared that local reactions to these injections were mild. No albuminuria, or obvious excess of cells or casts was detected in an examination of specimens of urine from a small sample of children subsequent to vaccination. In the whole country illnesses possibly related to vaccination were reported in 6 children; although none was believed to be caused by the injections, the absence of comparable information from unvaccinated children makes it impossible to determine whether there was an excess of such illness in vaccinated children. 3 children developed paralytic poliomyelitis within thirty days of an injection, but none developed paralysis in the inoculated limb. 3 children developed aseptic meningitis without isolation of polio virus within the same period.

From early May 1956 local health authorities supplied case reports to the Statistical Research Unit for every notification of poliomyelitis in a child under 10 years of age. Of these reports, 512 related to registered children, vaccinated or unvaccinated. Clinical reports on these children were requested from the hospital clinicians or general practitioners, while specimens of blood and stools were examined in the University laboratories at Aberdeen, Edinburgh, Glasgow and Manchester and by the Public Health Laboratory Service. From these data the cases were classified by clinical and laboratory findings. 10 "abortive" cases were excluded as they exhibited no signs of central nervous system involvement, while 37 were not poliomyelitis at all in the clinicians' opinion.

The protective effect of the vaccine was estimated by a comparison of the incidence of poliomyelitis in vaccinated children from July 1, 1956, to January 31, 1957, with that in registered, unvaccinated, children during the same period. Prior to July 1, vaccination was still in progress and the populations at risk were unknown. All children born in August, the reserve month, were excluded from the comparison as the method of selection by which 20% of them were vaccinated was left to the individual choice of the Medical Officers of

Health and it is impossible to say what factors determined this choice in the 200 separate authorities. For various reasons 33,064 children born in March or November and eligible for vaccination received no injections. Among these defaulters those born in November 1951–54, had a higher attack rate of paralytic poliomyelitis than unvaccinated children born in other months and not eligible for vaccination. It was considered that this excess, limited to the one age group, was not evidence of a bias in those defaulting, i.e. that the vaccinated children were an unbiased sample of registered children born in March and November.

In the 74,660 vaccinated children born in 1947–50 who received two injections of vaccine, one case of paralytic poliomyelitis occurred, giving an attack rate of 1·3 per 100,000. This was only 16% of the attack rate in the corresponding unvaccinated children, 8·2 per 100,000 (Table I). 3 cases of paralytic poliomyelitis occurred in the 74,024 children born in 1951–54

TABLE I.—ATTACK RATES OF POLIOMYELITIS IN VACCINATED AND UNVACCINATED CHILDREN

	No. of children	Paralytic		Non-paralytic with virus isolation	
		Cases	Rate per 100,000	Cases	Rate per 100,000
		1947–50 *Births*			
Vaccinated	74,660	1	1·3	1	1·3
Not vaccinated ..	1,116,359	91	8·2	25	2·2
		1951–54 *Births*			
Vaccinated	74,024	3	4·1	0	—
Not vaccinated ..	446,857	90	20·1	15	3·4

who received two injections, giving a rate of 4·1 per 100,000, only 20% of the attack rate in the corresponding unvaccinated children, 20·1 per 100,000. There was a significant reduction in incidence in vaccinated children but the rates were based on too small an experience to measure the degree of protection with any precision. Although the incidence of non-paralytic illnesses with isolation of virus was lower in vaccinated than in unvaccinated, the reduction was not significant. There was insufficient evidence on which to judge the effect of one injection only.

Owing to the shortage of vaccine and the relatively mild epidemic of poliomyelitis in the summer and autumn of 1956, the assessment of poliomyelitis vaccine has had to be based on a small experience. Nevertheless, the results show that there was some protection in both pre-school and school children, and that the Brunenders strain, used in the British vaccine as a substitute for the virulent Mahoney strain incorporated in American vaccines, conferred protection against type I infections.

for refreshing sleep and a fresh awakening

Effective against all types of insomnia not due to pain, CARBRITRAL* provides a combination of pentobarbitone sodium, a rapid-acting barbiturate, with carbromal, a mild sedative. This combination ensures the speedy onset of sleep and gently sustains it throughout the night, with little or no depression the following day.

CARBRITAL

* Trade Mark

In bottles of 25 and 250 capsules each containing pentobarbitone sodium (1½ grs.) and carbromal (4 grs.) Also as Carbrital Elixir.

The G.B.I. believes that old people need a holiday or a change of environment as much as do those who are still at work. It has an assisted holiday scheme by means of which any of its dependants can make her own holiday booking at a place of her own choice and receive from the G.B.I. a proportion of the cost at the end of the holiday. Working Governesses and Private Teachers who cannot afford a holiday are also assisted. In this way over £500 is spent every year and it is money well spent. One 97 year old takes the waters at Bath every summer. She makes her own arrangements and packs her own bag!

For home massage and relief of local tissue pain

Algesal is unique in containing *no counter-irritant*. It is suitable for repeated application by the patient at home, since it will not irritate or redden the skin.

The single, active ingredient is a non-irritating, skin-penetrating salicylate, carried in a soothing white vanishing cream with a pleasant smell of lavender.

INDICATIONS: Fibrositis or muscular rheumatism, osteoarthritis, backache due to lumbo-sacral strain, tenosynovitis, frozen shoulder and local tissue pain after injury or exercise.

Algesal balm gives rapid symptomatic relief in acute fibrositis and muscular rheumatism

Algesal

non-irritating, skin-penetrating anti-rheumatic salicylate balm

Samples and full descriptive literature will be sent on request to the manufacturers

A History of Medicine

by **DOUGLAS GUTHRIE**

It is the aim of this work to construct an outline of the progress of medicine from the days of Imhotep to those of Sir William Osler. The work of the leading scientists and practitioners, the fashions and sects in medicine throughout the ages, the geographical march of medicine from Greece to Salerno and Padua, and thence, by way of Leyden, to Britain and America, the epoch-making researches of Harvey and Claude Bernard, of Lister and many another—these are but a few of the topics which the historian must fit into his mosaic of medical history. *72 plates* *30s*

HISTORY OF THE ROYAL MEDICAL SOCIETY

1737—1937 *by* **JAMES GRAY MA FRSE**

This is the first detailed history of the oldest medical society in Great Britain from the time of its foundation until the bicentenary celebrations in 1937. *Illustrated* *Edinburgh University Press* *42s*

A Selection of Important Medical Books

TEXTBOOK OF MEDICAL TREATMENT

Edited by D. M. DUNLOP, M.D., F.R.C.P., SIR STANLEY DAVIDSON, M.D., P.R.C.P.Ed., and STANLEY ALSTEAD, M.D., F.R.C.P.

Seventh Edition. 944 *pages.* 33 *illustrations.* **55s.**

"Reviewers have spoken so highly in the past of one of the most popular of textbooks that there is really no more to add to the observation that it is living up to its reputation."—*Lancet.*

THE CLINICAL APPLICATION OF HORMONE ASSAY

By JOHN A. LORAINE, M.B., Ch.B., Ph.D., M.R.C.P.Ed.

378 *pages.* 66 *illustrations.* **30s.**

No clinical endocrinologist can afford to be without this clear and authoritative account of hormone assay methods, both in this country and in all parts of the world.

NON-VENEREAL SYPHILIS
A Sociological and Medical Study of Bejel.

By E. HERNDON HUDSON, M.D., D.T.M. & H., F.A.C.P.

212 *pages.* 106 *illustrations.* **30s.**

This new monograph by a doctor who has specialised in the study of bejel will be invaluable to the general physician and public health officer as well as to the specialist in syphilis and tropical medicine.

POLYMYOSITIS

By J. N. WALTON, M.D., M.R.C.P., and RAYMOND D. ADAMS, M.D.

280 *pages.* 72 *illustrations.* *Ready January.*

Dr. Walton, author of *Subarachnoid Haemorrhage*, and his American colleague present this new monograph in an attempt to clarify muscle disorders.

A HANDBOOK ON DISEASES OF CHILDREN Including Dietetics and the Common Fevers.

Eighth Edition. By BRUCE WILLIAMSON, M.D., F.R.C.P.

495 *pages.* 145 *illustrations.* **27s. 6d.**

"This book fills a definite need for a small but authoritative work on the diseases of children for the desk of the general practitioner. It is the best handbook on the subject on the market to-day."
—*Journal of the American Medical Association.*

AORTOGRAPHY: Its Application in Urological and some other Conditions.

By W. BARR STIRLING, Ch.M., F.R.C.S.Ed., F.R.F.P.S.G.

300 *pages.* 160 *illustrations.* **50s.**

"The text is lucid and stimulating and the reproductions are superb. This monograph is a valuable guide to radiologists and surgeons."—*Lancet.*

THE FOREQUARTER AMPUTATION

By H. F. MOSELEY, D.M., M.Ch., F.R.C.S., F.A.C.S.

88 *pages.* 100 *illustrations.* **42s.**

A new monograph, beautifully illustrated, covering every aspect of forequarter amputation, which will be of value to all orthopaedic surgeons.

BRITISH PHARMACEUTICAL CODEX 1954

SUPPLEMENT 1957

The number of new medicaments which have become important since the Codex was published in 1954 has made it necessary to revise several parts of the main book. This has been done in a Supplement which came into operation on November 4, 1957. The Supplement, which has the same status as the Codex, has been prepared with the assistance of nine committees and sub-committees representing all branches of medical and pharmaceutical knowledge.

The Supplement contains new monographs and formulæ, a large number of amendments to specifications in the main volume, and authoritative information on the action and uses of the new medicaments.

For the child with acidosis

. . . *to maintain the blood sugar*

When there is difficulty in digesting fats as the result of carbohydrate shortage, the effect of Lucozade, with its glucose content and its pleasant flavour, can be quite dramatic. In fact, wherever there is a poor appetite and little power to assimilate ordinary food, Lucozade will frequently prove irresistible and quickly strengthening.

Lucozade requires no preparation. It is a lightly carbonated glucose solution with an attractive golden colour and a pleasant citrous flavour. The liquid glucose content is 23.5% w/v or about 21 calories for each fluid ounce.

An evaluation of ROTER *tablets in* PEPTIC ULCER

Extracts from the
BRITISH MEDICAL JOURNAL
1955, 2, 827

PACKINGS: Tins of 40, 120, 640, and dispensing size 720
(P.T. exempt). Basic N.H.S. price: 1/- for 10 tablets.

Roter Tablets are not advertised to the public, and may be prescribed on E.C.10 forms.
Literature and samples on request.

F.A.I.R. LABORATORIES LTD., TWICKENHAM, MIDDLESEX

KOLANTYL

for more complete medical treatment of peptic ulcer

ANTISPASMODIC
To reduce ulcer pain and to delay stomach emptying, so assisting antacid action.

ANTACID
To neutralise excess acid. The antacid component of 'Kolantyl' is virtually ideal; rapid and prolonged in action, neither laxating or constipating.

ANTILYSOZYME
To inhibit excess lysozyme, which is believed to be a factor in the aetiology of peptic ulcer.

DEMULCENT
To ensure ingredients adhere to mucosal surfaces and to assist in protecting the ulcer crater.

". . . may be safely tried out under G.P. conditions with every prospect of a good result . . ."
Medical World (1955) 82: 379

Formula

Each tablet or 10 c.c. of Gel contains:

'Merbentyl' (diethylaminocarbethoxy-bicyclohexyl hydrochloride)..... 5 mg.
Dried Aluminium Hydroxide Gel 400 mg.
Heavy Magnesium Oxide ..... 200 mg.
Sodium Lauryl Sulphate ..... 25 mg.
Methylcellulose ..... 100 mg.

Gel
Bottles of 12 fl. oz.

Tablets
Cartons of 48 and 240 tablets in roll packs of 12.

Dosage
1 to 2 tablets (2 to 4 teaspoonfuls of Gel) 3 or 4 times a day.

Merrell Research

'Kolantyl' and 'Merbentyl' are registered trade marks of the Wm. S. Merrell Co.

Distributed in Great Britain and Republic of Ireland by
RIKER LABORATORIES LTD.
LOUGHBOROUGH, LEICS.

"Aspirin is a serious gastric irritant, particularly in peptic ulcer patients"*

"Calcium aspirin... can be used with impunity"*

**Extracts from B.M.J., 2-7-55*

SOLPRIN is accordingly often prescribed

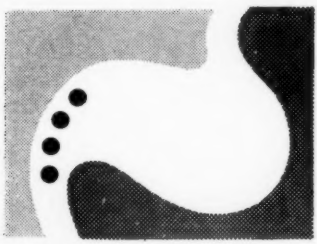
Solprin contains aspirin in soluble form. It is a highly efficient analgesic—the more quickly and easily absorbed by reason of its solubility. Dissolved in water, the tablets produce a solution of calcium acetylsalicylate. Solprin is extremely well tolerated, even by sufferers from peptic ulcer.

Solprin will be found particularly valuable when heavy or prolonged dosage is called for. Patients find Solprin easy to take and palatable.

SOLPRIN REGD.

Soluble and substantially neutral

Not advertised to the public



Solprin is available only on prescription and only in Great Britain and Northern Ireland. Clinical samples and literature will be supplied on request.

N.H.S. BASIC PRICE 12/6 for 500 tablets in foil

RECKITT & COLMAN LTD., HULL & LONDON (PHARMACEUTICAL DEPT., HULL)

Tral

A NEW PRODUCT FOR PEPTIC ULCER

In Tral, Abbott introduces a convenient new anticholinergic that is:
Potent enough to block hypersecretion and hypermotility in peptic ulcer.
Selective enough to avoid the side effects resulting from unwanted anticholinergic action outside the gastro-intestinal tract.
Safe enough to permit the broad range of dosage so necessary if therapy is to be truly individualized.

filmtab **Tral**

(*Hexocyclium, Abbott*)

More than 1,000 clinical trials have shown that Tral is not only adequate in its antisecretory-antimotility effects, but has perhaps the most highly specific post-ganglionic cholinergic blocking effect of any drug yet developed — at least to the degree that side effects have been strikingly fewer and milder than normally expected from anticholinergics.
It is supplied as Filmtab Tral (25 mg.) in bottles of 100 tablets.

Abbott **LABORATORIES LTD · LONDON**

. . . and though there are many—perhaps too many—analgesics available to the practitioner, the balanced properties of Hypon make it a tablet far more effective than most. Extensive tests show that Hypon has the power not only to relieve pain but to do so very rapidly. Constipation, so often encountered following the administration of codeine is effectively counteracted by the addition of phenolphthalein. Caffeine offsets the depressing effects of aspirin and phenacetin. Hypon is invaluable where prolonged administration is called for (chronic rheumatic conditions for instance). Furthermore, the antipyretic properties of Hypon tablets are of particular value in the treatment of the febrile states of influenza, tonsillitis . . .

HYPON

rapidly relieves pain

Turning

Medical history has already reserved a special place for ACHROMYCIN tetracycline because of its impressive therapeutic potency and remarkably broad spectrum. Now, with the advent of ACHROMYCIN V, the therapeutic merits of tetracycline are turned to still greater advantage. Presenting tetracycline in company with sodium metaphosphate, ACHROMYCIN V achieves swifter, more efficient, more complete absorption. As a result, the therapy becomes still more secure, without any increase in daily dosage or cost. Customary adult dosage is a single capsule (250 mg.) four times daily—though this may safely be increased in unusually severe conditions.

Achromycin*

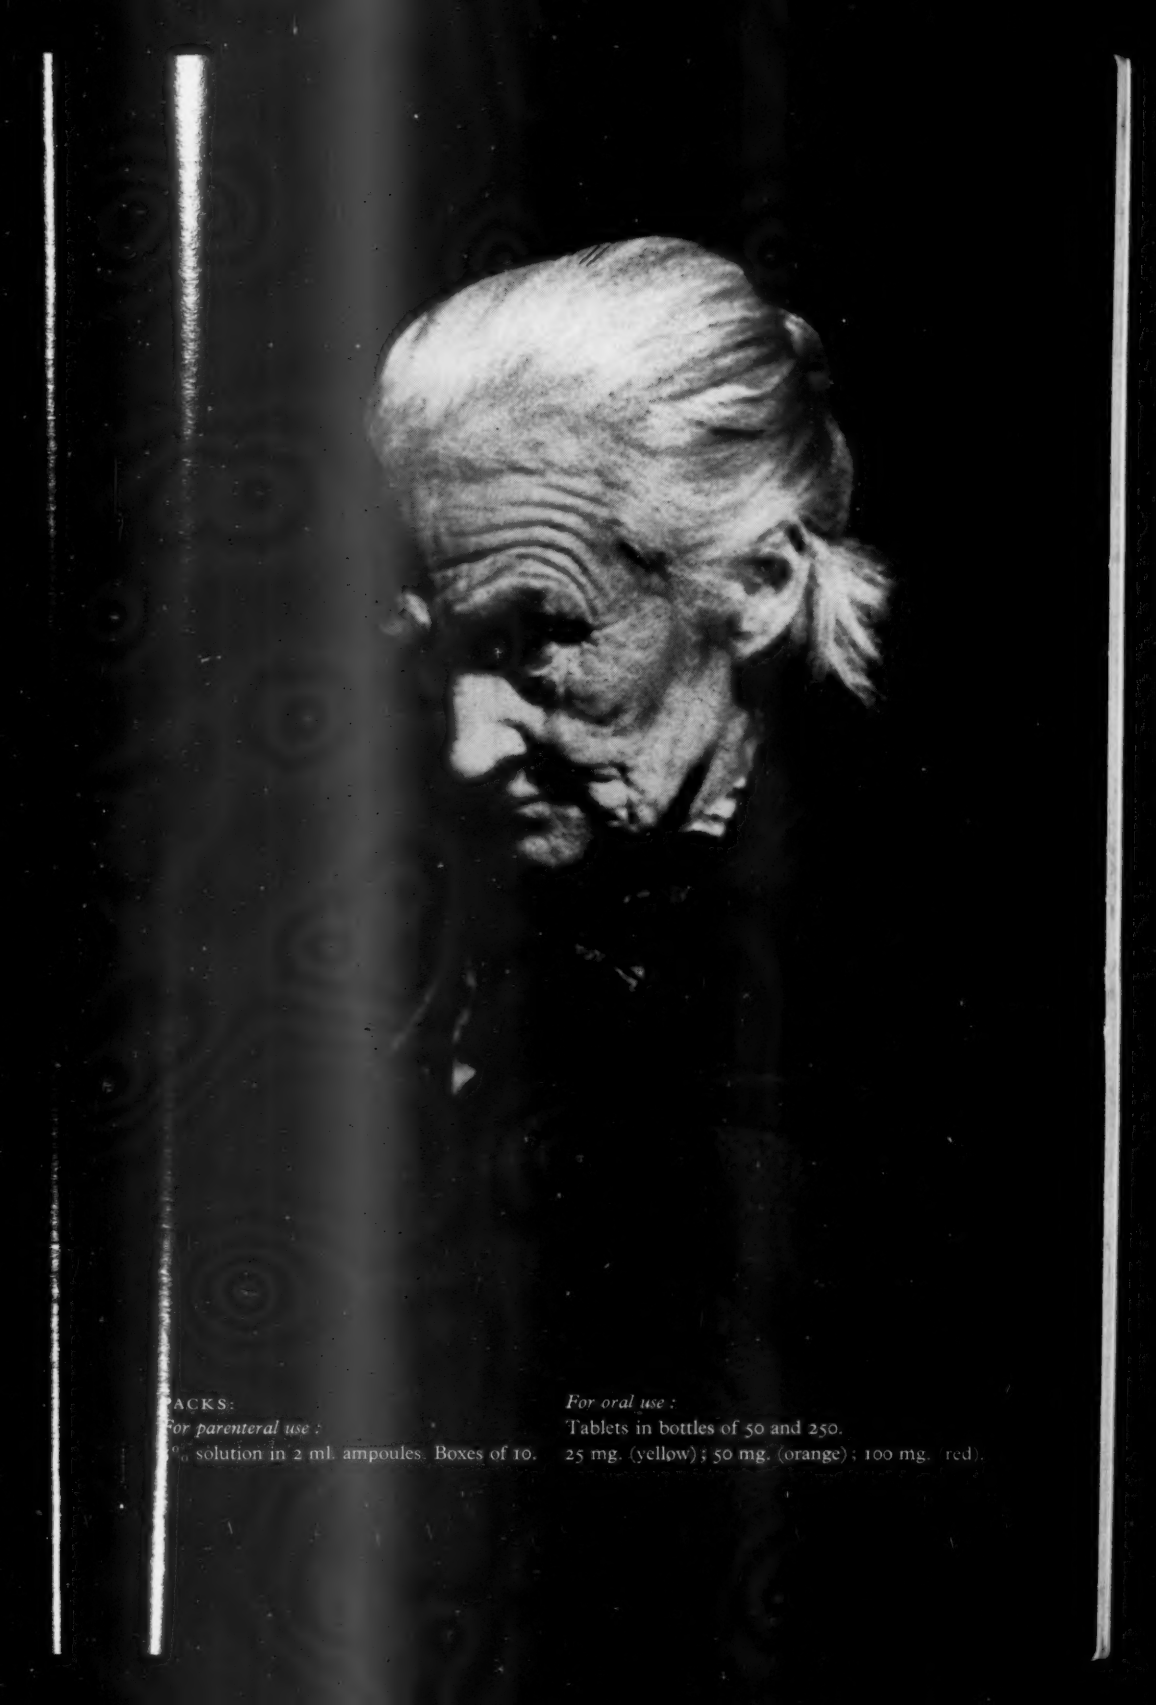
TETRACYCLINE WITH SODIUM METAPHOSPHATE

*REGD. TRADE MARK

Each oral capsule contains ACHROMYCIN tetracycline 250 mg.; Sodium Metaphosphate, 380 mg. Bottles of 16, 100 and 1,000. ACHROMYCIN V is also available as an orange-flavoured syrup containing in each 5 c.c. 125 mg. of tetracycline activity. Bottles of 2 and 16 fl. oz.

LEDERLE LABORATORIES DIVISION

Cyanamid OF GREAT BRITAIN LTD., London, W.C.2



The routine management of elderly sick or infirm patients must certainly pose a real problem to doctor and family alike, particularly when the emotional problems of the aged are complicated by advanced malignant disease. Often the chronic patient is unwilling or unable to be admitted to hospital and the burden falls to a great extent on the general practitioner.

It is in the treatment of these patients that Sparine plays a most important role for it quickly calms the patients' agitation by inducing a state of emotional detachment without sedation, and paves the way for better reception of analgesia. Moreover, not only does it actively enhance the pain-killing effects of such drugs as morphine, allowing them to be given in smaller, safer doses, but by its anti-emetic action Sparine limits the risk of the vomiting which so often arises either as a symptom of the disease or as a reaction to drug or radiation treatment.

Better relief for Arthritics — minimum side effects

In salicylate therapy BUFFERIN (Antacid Analgesic) has these two special advantages. It is *faster-acting* — twice as fast as ordinary aspirin. It is *better-tolerated* — even in large doses, as for arthritis.

According to a British survey, as many as 42% of arthritics are intolerant to aspirin. And in a blind trial among arthritics with a *proved* intolerance to aspirin, 70% had no gastric symptoms after taking large doses of BUFFERIN over periods of 4 to 16 months. (1).

In clinical tests, it was shown that BUFFERIN raises the salicylate blood level of humans more than 20% higher in *ten* minutes than ordinary aspirin does in *twenty* minutes. Hence the importance of BUFFERIN in all salicylate therapy.

Only BUFFERIN contains the antacid agents which :—

* reduce gastric upset to a negligible minimum (2), (3);
* actually speed the pain-relieving ingredient into the bloodstream (4), (5).

It acts faster. It is better tolerated. It contains no sodium.

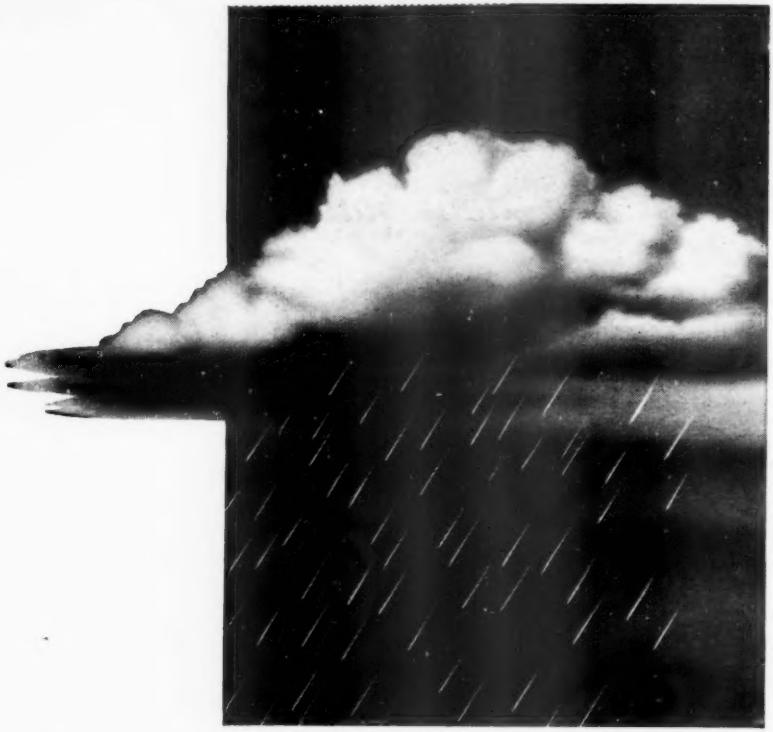
Announcing a new journal

Diseases of the COLON & RECTUM

to start publication January 1958



* * *

DISEASES OF THE COLON AND RECTUM will be the official journal of the American Proctologic Society. It is to be handled in the British market by Pitman Medical Publishing Company. Under the editorship of Dr. Louis A. Buie and with distinguished editorial and advisory boards among whose members are numbered eminent British surgeons, the journal will aim to provide for the first time a centralized source of authoritative information covering current advances in the medical and surgical treatment of diseases of the colon, rectum and anal canal. Contributions will be international and each issue will include comprehensive abstracts of world literature. The journal will be Crown 4to size, will be superbly produced and there will be lavish use of illustrations. Publication will be bi-monthly. Subscription per year will be £5 including postage, and orders may be placed now with the publishers in London or with any medical bookseller.

Published every 2 months ***Subscription £5 per annum*** *(including postage)*

RELEASING the surplus

In cardiac oedema and other conditions where excess fluid accumulates in the tissues, DIAMOX acetazolamide can be relied upon to release the surplus promptly and safely. DIAMOX induces diuresis in a novel and highly efficient manner —by inhibiting the enzyme carbonic anhydrase. A single dose will induce a powerful diuretic response, persisting for six to twelve hours—and in many cases of congestive heart failure DIAMOX *alone* is capable of maintaining the patient oedema-free. As clinical experience of DIAMOX grows, more and more applications are revealed—including glaucoma, toxaemias and oedema of pregnancy, epilepsy and premenstrual tension. DIAMOX has also been used in emphysema, drug-induced oedema, renal oedema and obesity.

Front-line weapon

Since its introduction, 'Ilotycin' brand erythromycin has established itself as a safe and potent oral antibiotic. Clinical experience has shown that it can play a vital part as a front-line weapon against a wide range of infections. 'Ilotycin' has a penicillin-like antibacterial spectrum, is powerfully bactericidal, has negligible effect on the normal intestinal flora, and is fully effective by mouth. It has accordingly become the logical first choice after penicillin in the treatment of common infections.

The average daily dose is 1 Gm., increased in severe infections.

'Ilotycin' is available as Tablets of 100 mg. and 250 mg.; also as 'Ilotycin' Paediatric and as 'Ilotycin Glucoheptonate' Intravenous.

BUFFERED THEOPHYLLINE FOR THE PROPHYLAXIS & TREATMENT OF ASTHMA

'ENGLATE' combines theophylline sodium with glycine, which acts as a powerful buffer against gastric hydrochloric acid and thus reduces the precipitation of theophylline. Theophylline sodium glycinate causes less gastro-intestinal disturbances than other xanthine compounds and can therefore be prescribed in larger doses to obtain maximum theophylline activity.

'ENGLATE' syrup is specially recommended for children up to 12 years in preference to tablets.

Influenza and the stomach

It is suggested* that gastric complications of "Asian 'flu" are aggravated by the use of aspirin. Even if this has not been proved, it is wise to avoid any risk of stomach irritation when treating febrile patients.

Paynocil contains chemically unmodified aspirin, but this is blended with glycine to give instant dispersal and prevent gastric irritation.

Paynocil tablets are pleasant to take. They disperse instantly on the tongue and need no water, no chewing, no swallowing whole, and no disguising.

The new complete treatment for migraine

ORGRAINE

Composition (per tablet)		Action
Ergotamine Tartrate B.P.	1.0 mg.	→ constricts dilated cerebral arteries
Caffeine B.P.	100.0 mg.	→ potentiates ergotamine
Hyoscyamine Sulphate B.P.C. (1949)	0.0875 mg.	→ alleviates nausea and vomiting
Atropine Sulphate B.P.	0.0125 mg.	
Phenacetin B.P.	130.0 mg.	→ relieves residual occipital pain

In a recent clinical article (J.A.M.A., 1957, 163, 1115) it was stated that in a series of 2,511 cases in which 28 agents were tested in the symptomatic treatment of migraine, ergotamine tartrate was proved to be the most useful drug—and 81% of the patients showed improvement when ergotamine tartrate and caffeine were compounded with belladonna alkaloids.

Orgraine applies the same successful principles of treatment.

Availability of Vitamins in Yeast

Deficiencies of single factors of the Vitamin B Group do not occur. Accordingly, even if a deficiency condition appears to result from the lack of an individual factor of the group and it is considered necessary to give intensive treatment with this factor *the entire Vitamin B Complex should always be administered concurrently.*

It is, however, extremely important, in view of suggestions in recent publications, that the vehicle selected as a source of the entire B Complex does not withhold its vitamin content from the patient.

Human experiments show that the rich, natural vitamin potency of Aluzyme is totally available to the human system.

A Surgeon's Saga

Arthur Augustus William Heald
A surgeon's knife was keen to wield,
He worked and laboured, read and learned
Till high degrees he quickly earned.
Although considered quite a 'blood',
His practice never was much good,
Because his hand so badly shook
When knife or scalpel up he took.
This soon was seen by surgeons older
(Whom time and knighthoods had
made bolder),
And with one voice they all did say,
"Drink Guinness, Arthur, every day."
Since Arthur followed their prescription
The change has beggared all description,
With hand so steady in operation,
He cuts the highest in the Nation.

ST. ANDREW'S HOSPITAL

FOR NERVOUS AND MENTAL DISORDERS

NORTHAMPTON

President—THE EARL SPENCER

Medical Superintendent—THOMAS TENNENT, M.D., F.R.C.P., D.P.H., D.P.M.

THIS Registered Hospital is situated in 130 acres of park and pleasure grounds. Voluntary patients, who are suffering from incipient mental disorders or who wish to prevent recurrent attacks of mental trouble, temporary patients and certified patients of both sexes are received for treatment. Careful clinical, biochemical, bacteriological and pathological examinations. Private rooms with special nurses, male or female, in the Hospital or in one of the numerous villas in the grounds of the various branches, can be provided.

WANTAGE HOUSE

This is a Reception Hospital in detached grounds with a separate entrance, to which patients can be admitted. It is equipped with all the apparatus for the complete investigation and treatment of Mental and Nervous Disorders by the most modern methods: insulin treatment is available for suitable cases. There is an Operating Theatre, a Dental Surgery, an X-ray Room, an Ultra-Violet Apparatus, and a Department for Diathermy and High-Frequency treatment. It also contains Laboratories for Biochemical, Bacteriological and Pathological Research. Psychotherapeutic treatment is employed when indicated.

MOULTON PARK

Two miles from the main Hospital there are several branch establishments and villas situated in a park and farm of 650 acres. Milk, meat, fruit and vegetables are supplied to the Hospital from the farm, gardens and orchards of Moulton Park. Occupational Therapy is a feature of this Branch, and patients are given every facility for occupying themselves in farming, gardening and fruit growing.

BRYN-Y-NEUADD HALL

The seaside house of St. Andrew's Hospital is beautifully situated in a park of 330 acres, at Llanfairfechan, amidst the finest scenery in North Wales. On the north-west side of the Estate a mile of sea-coast forms the boundary. Patients may visit this branch for a short seaside change or for longer periods. The Hospital has its own private bathing house on the seashore. There is trout-fishing in the park.

At all the branches of the Hospital there are cricket grounds, football and hockey grounds, lawn tennis courts (grass and hard courts), croquet grounds, golf courses, and bowling greens. Ladies and gentlemen have their own gardens, and facilities are provided for handicrafts, such as carpentry, etc.

For terms and further particulars apply to the Medical Superintendent: TELEPHONE No. 4354 Northampton (three lines) who can be seen in London by appointment.

VIMALTOL

A QUALITY PRODUCT OF MODERN NUTRITIONAL SCIENCE

'VIMALTOL' is a concentrated vitamin food, formulated by and prepared under the control of the 'Ovaltine' Research Laboratories—which are actively investigating problems in nutrition and dietetics. They bring to its manufacture a high degree of scientific knowledge and a meticulous standard of hygiene.

'Vimaltol' contains malt extract, yeast, halibut liver oil and iron. Every ingredient used is rigidly tested for purity and quality, the final product being accurately standardized for vitamin content.

In addition to its vitamins, 'Vimaltol' provides valuable nutrients of undoubted assistance to infants, fast-growing children, nursing mothers and to those whose diet is inadequate or unbalanced. It helps to build up strength, weight and the natural powers of resistance. 'Vimaltol' is highly palatable—a decided advantage when recommending it for children.
